Example 5.3.1 (Valuation of a coefficient)**.** For $v(\pi) = \lambda > 0$, the tropical polynomial of $1 + x + \pi y$ is $\min(0, w_1, \lambda + w_2)$. Its repeated-minimum locus is the standard tropical line translated by $(0, -\lambda)$. Its vertex is $(0, -\lambda)$, and the outgoing primitive directions remain $(1, 0), (0, 1), (-1, -1)$, all with weight one. The coefficient valuation affects position, not the tangent lattices.

5.4 Corners and stable intersections

5.4.1 Corner divisors

On a weighted tropical curve, a continuous piecewise affine function φ has a divisor at its vertices:

$$\operatorname{div}_C(\varphi) = \sum_p \left(\sum_{e \ni p} m_e \, \partial_e \varphi(p) \right) [p]. \tag{5.4.1}$$

Here ∂_e is differentiation in the primitive lattice coordinate pointing away from p, and subdivision inserts vertices at all breakpoints. This is the outgoing-slope convention used throughout the series. On the line,

$$\operatorname{div}_{\mathbb{R}}(\max(0, t)) = [0], \qquad \operatorname{div}_{\mathbb{R}}(\min(0, t)) = -[0].$$

The coefficient is the right derivative minus the left derivative. These are the previously studied atomic-curvature calculations in a tropical divisor notation.

In higher dimension, a normal vector is defined only modulo a tangent vector. A formula must compensate for this ambiguity.

Definition 5.4.1 (The corner divisor)**.** Let C be a constant-weight tropical cycle and let φ be continuous and affine on every cell of a subdivision. Denote the linear part of its restriction to σ by ℓ_σ. The weight of $\mathrm{div}_C(\varphi) = \varphi \cdot C$ on a facet τ is

$$m_\tau(\varphi \cdot C) = \sum_{\sigma \supset \tau} m_\sigma \ell_\sigma(n_{\sigma,\tau}) - \ell_\tau \left(\sum_{\sigma \supset \tau} m_\sigma n_{\sigma,\tau} \right). \tag{5.4.2}$$

Integral slopes give integral divisor weights when the weights of C are integral. Real slopes are also allowed, with real divisor weights.

Balancing puts the vector in the second term in L_τ, where ℓ_τ is defined. Replacing a lift $n_{\sigma,\tau}$ by $n_{\sigma,\tau} + a$, with $a \in N_\tau$, changes the first term by $m_\sigma \ell_\sigma(a)$ and the second by $m_\sigma \ell_\tau(a)$. These agree because φ is continuous along τ. Hence the formula is independent of the lifts. If φ is the restriction of one ambient affine function, the two terms cancel completely.

The resulting divisor is again balanced and is independent of subdivision. This is a substantive compatibility theorem; it makes it possible to iterate corner operations. The same construction in GK17 applies to piecewise smooth functions and smooth weights, using derivatives at each point of the face.

References. [GK17, Definition 1.10, Remark 1.11 and Propositions 1.12–1.14]; Section 10.3.

There is a useful analytic dictionary. For constant-weight C,

$$\mathrm{d}'\mathrm{d}''[\varphi] = \delta_{\varphi \cdot C} \tag{5.4.3}$$

when φ is piecewise affine and the currents are taken on C. For a piecewise smooth function there is also the facewise Hessian:

$$\mathrm{d}'\mathrm{d}''[\varphi] = [\mathrm{d}'_P \mathrm{d}''_P \varphi] + \delta_{\varphi \cdot C}.$$

Thus differentiating each affine piece and obtaining zero does not compute the derivative of the whole current. The missing terms live on the interfaces.

References. [GK17, Corollaries 3.19–3.20].

Example 5.4.2 (The sign of a tropical polynomial)**.** The tropical polynomial F_f in (5.1.1) is concave. Consequently the effective tropical hypersurface is the corner divisor of $-F_f$, not of F_f. Near a general facet where two exponents differ by dq_0, with q_0 primitive, the slope jump of $-F_f$ in a transverse integral coordinate is $d > 0$. This recovers the binomial multiplicity.

In particular, for the tropical line,

$$u(w) = \max(0, -w_1, -w_2) = -F_f(w), \qquad \operatorname{div}_{\mathbb{R}^2}(u) = L, \qquad \mathrm{d}'\mathrm{d}''[u] = \delta_L.$$

This statement is on the real tropical chart. It does not replace the analytic function $-\log|f|$ by $F_f \circ \mathrm{trop}$ at points where cancellation occurs.

Example 5.4.3 (The correction term in the corner formula)**.** Subdivide $\mathbb{R}^2$ along $x = 0$, with both weights one, and use normal lifts $n_+ = (1, a)$ and $n_- = (-1, b)$. For $\varphi = 2x + 3y$, formula (5.4.2) gives

$$(2 + 3a) + (-2 + 3b) - 3(a + b) = 0.$$

For $\psi = \max(0, x) + 3y$, it gives

$$(1 + 3a) + 3b - 3(a + b) = 1.$$

Thus the affine function has no corner, whereas the second function has divisor $[x = 0]$. The correction along the common tangent space is exactly what removes the dependence on the chosen lifts.

Example 5.4.4 (Slopes on the tropical line)**.** Give the three rays outgoing slopes a, b, c, using their primitive parameters. The coefficient of the corner at the central vertex is $a + b + c$. For the restriction of an ambient affine function $\ell(w) = Aw_1 + Bw_2 + C$, these slopes are $B, A, -A - B$, so the sum is zero. For a general piecewise affine function they need not sum to zero. In particular, slopes $0, 0, -1$ give negative curvature at the vertex although the function is affine, hence convex, on every ray.

This calculation is the simplest reason the continuous facewise-convexity criterion in CLD12 requires correction. A condition on each maximal cell does not control the terms on their interfaces. Appendix A gives the exact source locator and the corrected interpretation.

5.4.2 Stable intersection of tropical cycles

Two coincident lines have a one-dimensional set-theoretic intersection, whereas the intersection of two codimension-one cycles in a plane should have dimension zero. Tropical geometry resolves this discrepancy by a displacement procedure.

For cycles $C, D \subset N_{\mathbb{R}}$, translate D by εv, with v generic and $\varepsilon > 0$ small, intersect transverse faces, and take the limiting cycle as $\varepsilon \to 0$. When cells σ, τ meet transversely in complementary dimensions, their contribution has multiplicity

$$m_\sigma m_\tau \, [N : N_\sigma + N_\tau]. \tag{5.4.4}$$

The index counts how far the two integral tangent lattices are from generating the ambient lattice. It is finite under the stated transversality condition. For two primitive lines in $\mathbb{Z}^2$, it is the absolute determinant of their direction vectors.

Theorem 5.4.5 (Stable intersection)**.** *For constant-weight integral $\mathbb{R}$-affine tropical cycles in $N_{\mathbb{R}}$, the displacement construction defines a cycle $C \cdot D$, independent of the sufficiently small generic displacement and of subdivision. It is bilinear, associative and commutative, its codimension is the sum of the codimensions, and its support is contained in $|C| \cap |D|$. The construction extends to real weights and to the smooth weights used by GK17.*

Independence of displacement uses balancing. It is not a general fact about arbitrary weighted polyhedral sets. The combinatorial intersection is defined before any attempt to multiply singular currents.

References. [GK17, Sections 1.3–1.4, especially formula (1.4.1)].

Example 5.4.6 (A transverse intersection of multiplicity two)**.** In $\mathbb{R}^2$, give each of the lines

$$H = \{x = 0\}, \qquad Q = \{x + 2y = 0\}$$

weight one. Their primitive tangent vectors are $(0, 1)$ and $(2, -1)$. They generate the sublattice of vectors with even first coordinate, of index two. Hence

$$H \cdot Q = 2[0].$$

The corresponding algebraic example is

$$z_1 = 1, \qquad z_1 z_2^2 = 1.$$

Its coordinate algebra is $K[z_2^{\pm 1}]/(z_2^2 - 1)$, of length two. In characteristic two the two roots merge into a nonreduced point; the intersection length and tropical index remain two. Both individual tropical lines have weight one because their defining exponent vectors $(1, 0)$ and $(1, 2)$ are primitive.

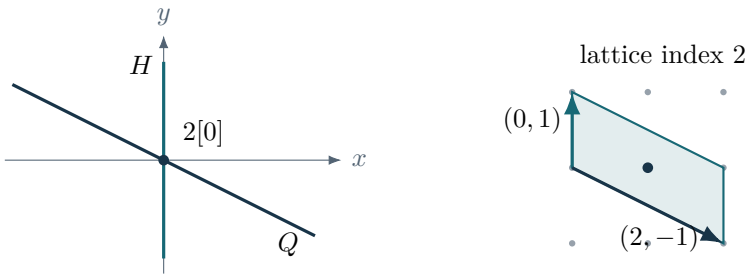

Figure 5.2: Transversality does not force multiplicity one. The two primitive tangent vectors span a fundamental parallelogram of lattice area two; the quotient lattice has two elements.

The same index will appear in products of curvature currents. With $u = \max(0, x)$ and $v = \max(0, x + 2y)$, the corner cycles are H and Q. Their product in the delta-calculus is therefore $2\delta_0$. This formula is justified by that calculus; it is not a definition of the product of two arbitrary distributions.

Example 5.4.7 (Two different self-intersections)**.** A straight line translated in a nonparallel direction becomes disjoint from itself, so its stable self-intersection is zero. The tropical line L behaves differently. Translate its vertex by $(\varepsilon, 2\varepsilon)$. There is one transverse intersection, at $(0, \varepsilon)$, between the original vertical ray and the translated southwest ray. Their primitive directions have determinant of absolute value one. Letting $\varepsilon \to 0$ gives

$$L \cdot L = [0].$$

Although both set-theoretic self-intersections contain the entire original curve, the stable answers differ.

Example 5.4.8 (Determinants and intersection multiplicities)**.** Let $p = (a, b)$ and $q = (c, d)$ be primitive integral covectors with $ad - bc \neq 0$. The weight-one lines $\langle p, w\rangle = 0$ and $\langle q, w\rangle = 0$ have primitive tangent vectors $(-b, a)$ and $(-d, c)$. Their stable intersection is the origin with weight

$$[\mathbb{Z}^2 : \mathbb{Z}(-b, a) + \mathbb{Z}(-d, c)] = |ad - bc|.$$

The torus homomorphism $(z_1, z_2) \mapsto (z_1^a z_2^b, z_1^c z_2^d)$ has the same degree. Indeed, its character-lattice map has cokernel of order $|ad - bc|$, so its finite kernel has that scheme-theoretic length. The formula remains valid in inseparable characteristic, where the kernel need not be reduced.

Example 5.4.9 (A nontrivial lattice index)**.** Let two weighted rational lines in $\mathbb{R}^2$ have primitive directions $u = (1, 0)$ and $v = (1, 2)$, with weights a and b. A generic small translate meets transversely, and the stable intersection multiplicity is

$$ab[\mathbb{Z}^2 : \mathbb{Z}u + \mathbb{Z}v] = ab|\det(u, v)| = 2ab.$$

The factor two is an index of integral tangent lattices. It is not the angle between the lines. If the two lines coincide, their set-theoretic intersection is one-dimensional, whereas the stable intersection is defined by a displacement construction and the expected codimension. This is why ordinary intersection of supports cannot be substituted for tropical intersection of cycles.

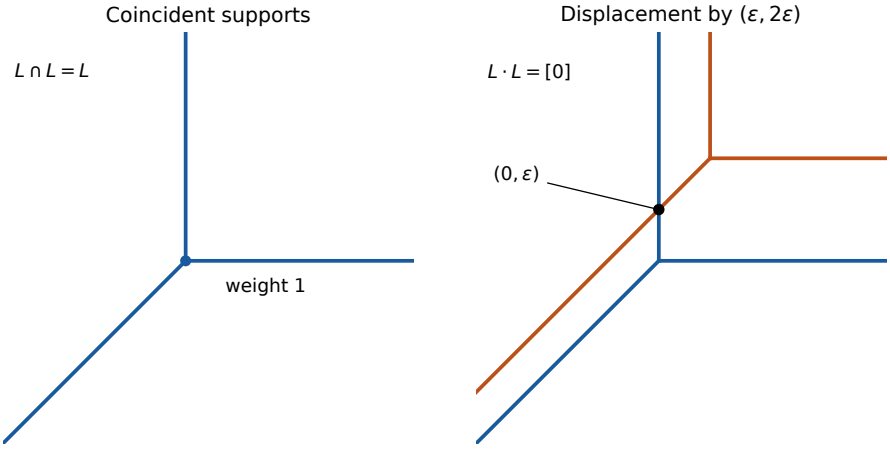

Figure 5.3: The set-theoretic self-intersection of a tropical line is the whole line. A generic displacement gives one transverse point of lattice multiplicity one, which tends to the vertex. The stable self-intersection is that weighted vertex.

5.5 Weighted Gauss points and the role of cancellation

The tropical image contains real vectors which need not be valuations of K-rational points. Weighted Gauss seminorms explain this already for a torus, without changing the ground field.

Proposition 5.5.1. *Let K be a complete non-Archimedean field, $M \simeq \mathbb{Z}^r$, and $w \in N_{\mathbb{R}}$. The rule*

$$|f|_w = \max_m |a_m| e^{-\langle m, w\rangle}, \qquad f = \sum_m a_m \chi^m \in K[M],$$

is a multiplicative norm extending that of K. It determines a point $s(w)$ of the analytified torus, and $\operatorname{trop}(s(w)) = w$. The map s is continuous.

Proof. Choose a basis of M and put $r_i = e^{-w_i}$. The Laurent-polynomial case of Proposition 1.2.2 gives multiplicativity with these radii.

The norm is nonzero on every nonzero polynomial and has the specified values on characters. These facts give the analytic point and its tropicalization. Continuity follows from the topology of analytification: evaluation of each Laurent polynomial along s is the maximum of finitely many continuous functions. □

At these points one has $-\log|f(s(w))| = F_f(w)$. At a general analytic point with the same tropicalization only the inequality $-\log|f(x)| \geq F_f(w)$ holds. Thus s is a section on the torus, but it is not a section on every subvariety: if f vanishes on a subvariety, the Gauss norm of a nonzero f remains nonzero. A point of the subvariety over w must carry cancellation information absent from the torus Gauss point.

5.6 Primitive lattices and the index in a pushforward

Lemma 5.6.1. *If $L \subset N_{\mathbb{R}}$ is a rational linear subspace, then $N_L = N \cap L$ is saturated in N. If $L_\tau \subset L_\sigma$ are rational subspaces with dimension difference one, N_σ / N_τ is free of rank one.*

Proof. If $kn \in N_L$ for a nonzero integer k and $n \in N$, then $n = k^{-1}(kn) \in L$, so $n \in N_L$. Thus the quotient has no torsion. The same argument inside N_σ proves that N_σ / N_τ is torsion free. Its rank is the dimension difference, since both subspaces are rational. A finitely generated torsion-free abelian group of rank one is infinite cyclic. □

Proposition 5.6.2. *Let $F : N \to N'$ be integral linear and injective on the span of a d-dimensional rational polyhedron σ. Let $\sigma' = F(\sigma)$ and*

$$e = [N'_{\sigma'} : F(N_\sigma)].$$

For a compactly supported (d, d)-superform α on the relative interior of σ' one has

$$\int_\sigma F^* \alpha = e \int_{\sigma'} \alpha.$$

Proof. Choose bases of the two tangent lattices. The resulting square integral matrix A has nonzero determinant and $|\det A| = e$. Pullback acts on both exterior factors, so the top-form coefficient is multiplied by $(\det A)^2$. The ordinary change of variables in the scalar integral contributes $|\det A|^{-1}$. Their product is e. The sign convention for top superforms is the same on both sides and does not introduce an orientation sign. □

For finitely many maximal cells mapping onto one image cell, summing this formula produces the weight $\sum_\sigma m_\sigma [N'_{\sigma'} : F(N_\sigma)]$. This explains the lattice factor in tropical pushforward and integration. Identifying that weighted pushforward with the tropicalization of an algebraic image, divided by the generic algebraic degree when appropriate, requires the Sturmfels–Tevelev multiplicity theorem. The change-of-variables calculation does not prove that algebraic theorem.

Example 5.6.3. For a nonzero integer d and $F(t) = dt$ on the tropical line, $F^*(a(y)d'y \wedge d''y) = d^2 a(dt)d't \wedge d''t$. Integration gives $|d| \int a(y)dy$. The same factor is the degree of the torus isogeny $z \mapsto z^d$. If the characteristic of the fibre field divides d, distinct geometric points need not count that degree; scheme lengths do. For an initial fibre this is the residue characteristic. An isogeny over a characteristic-zero ground field remains separable even when its degree is divisible by the residue characteristic.

5.7 Monomial maps and scheme-theoretic degree

The lattice indices in tropical intersection are algebraic degrees. The following calculation proves this for a general isogeny of split tori, including inseparable characteristic. It also distinguishes the multiplicity of an initial degeneration from the number of geometric points in a generic fibre.

Let M and M' be free abelian groups of rank r, and let $A : M' \hookrightarrow M$ be injective with finite cokernel. Over any field k, the inclusion of group algebras gives a morphism

$$f : T_M = \operatorname{Spec} k[M] \longrightarrow T_{M'} = \operatorname{Spec} k[M'], \qquad f^*\chi^{m'} = \chi^{Am'}.$$

Proposition 5.7.1. *The map f is finite faithfully flat of degree $d = [M : A(M')]$. Every fibre algebra has vector-space dimension d over the residue field of the target point.*

Proof. Choose one representative b from each coset in $M/A(M')$. Every monomial has a unique expression $\chi^b\chi^{Am'}$, so

$$k[M] = \bigoplus_{b \in M/A(M')} k[M']\chi^b$$

as a module over $k[M']$. Independence follows because distinct monomials form a k-basis of the group algebra. Hence this algebra is finite free of positive rank d, and thus faithfully flat. Tensoring with the residue field of a point of $T_{M'}$ produces a d-dimensional algebra over that field. It is finite, hence zero-dimensional, and its dimension is its scheme length with residue degrees counted. □

Proposition 5.7.2 (Smith normal form and inseparability)**.** *After integral changes of bases, f is the map*

$$(z_1, \dots, z_r) \longmapsto (z_1^{d_1}, \dots, z_r^{d_r}), \quad d_i > 0, \quad d_1 \mid d_2 \mid \cdots \mid d_r,$$

and $d = \prod_i d_i = |\det A|$. Over an algebraically closed field of characteristic $p > 0$, write $d_i = p^{a_i}e_i$ with $p \nmid e_i$. Each geometric fibre has $\prod_i e_i$ distinct points, each of length $p^{\sum_i a_i}$. In characteristic zero every geometric fibre is reduced with d points.

Proof. Smith normal form is the integer row-and-column reduction of a full-rank integral matrix to the displayed diagonal matrix. The basis changes are torus automorphisms, so they preserve the fibre schemes and degree. In one coordinate, after choosing a p^{a_i}th root b_i of the nonzero target coordinate,

$$z_i^{d_i} - b_i^{p^{a_i}} = (z_i^{e_i} - b_i)^{p^{a_i}}.$$

The polynomial $z_i^{e_i} - b_i$ has e_i distinct nonzero roots, since its derivative does not vanish at any root. The local quotient at each root is isomorphic to $k[t]/(t^{p^{a_i}})$ and has length p^{a_i}. Tensoring these one-coordinate algebras proves the count and the length in r coordinates. The same derivative argument with $a_i = 0$ applies in characteristic zero. □

This statement uses the characteristic of the field over which the fibre is formed. If K has characteristic zero and residue characteristic p, the isogeny $z \mapsto z^p$ has reduced geometric fibres over K, while its reduction can have a nonreduced fibre of length p. The total degree is p in both calculations; the source of multiplicity differs. Tropical multiplicity uses the appropriate initial degeneration over a residue field.

5.8 Binomial complete intersections and tropical weights

Return to a complete non-Archimedean field K. Let $m_1, \dots, m_r$ be linearly independent elements of $M \simeq \mathbb{Z}^r$, let $a_i \in K^\times$, and set

$$Z = V(\chi^{m_1} - a_1, \dots, \chi^{m_r} - a_r) \subset T_M.$$

Theorem 5.8.1. *The scheme Z is finite of length $d = [M : \sum_i \mathbb{Z}m_i]$. Its tropicalization is one point w_0, uniquely determined by*

$$\langle m_i, w_0 \rangle = v(a_i) \quad (1 \le i \le r).$$

This point has tropical multiplicity d. The conclusion includes nonreduced schemes and weights outside the original value group.

Proof. The equations define the fibre of the isogeny associated with the sublattice generated by the m_i, over the point $(a_1, \dots, a_r)$. Proposition 5.7.1 proves the length and nonemptiness. Every analytic point of Z satisfies the

displayed valuation equations. They have a unique real solution because the m_i form a real basis. A finite nonzero K-algebra has a maximal ideal with finite residue extension of K; the extended absolute value gives an analytic point. Thus the tropicalization is exactly $\{w_0\}$.

Choose a valued extension containing a solution t of the binomial system. Translation $z = ty$ changes the equations to $\chi^{m_i}(y) = 1$. The closure of this kernel in the torus over the valuation ring is finite free of rank d: the same coset-basis proof works over a ring, and imposing the target coordinates equal to one preserves that free basis. Its generic fibre is the translated Z, and it has no valuation-ring torsion. Hence it is the schematic closure. Its special fibre has dimension d as a vector space over the residue field. After algebraic closure of that residue field, the sum of local lengths is still d. This is exactly the tropical multiplicity in dimension zero. □

Corollary 5.8.2 (Transverse hypersurfaces)**.** *The stable product of the r tropical binomial hypersurfaces is $d[w_0]$, equal to the tropical cycle of Z.*

Proof. Write $m_i = b_i \bar{m}_i$ with $\bar{m}_i$ primitive. The ith hypersurface has weight b_i. The primitive normal covectors $\bar{m}_i$ are real-linearly independent. The transverse lattice-index rule gives multiplicity $|\det(\bar{m}_1, \dots, \bar{m}_r)|$ for the weight-one hyperplanes; multiplying their weights gives $|\det(m_1, \dots, m_r)| = d$. The support is their unique intersection point w_0. This uses the transverse part of the tropical intersection construction, not a general lifting theorem for intersections. □

Example 5.8.3. Consider in a three-dimensional torus the equations

$$x^2 = a, \qquad xy^3 = b, \qquad yz^5 = c.$$

The exponent matrix has determinant 30, so the intersection has length 30. Its tropical point satisfies

$$w_x = \frac{v(a)}{2}, \qquad w_y = \frac{v(b) - w_x}{3}, \qquad w_z = \frac{v(c) - w_y}{5}.$$

The first hypersurface has weight two. The other two exponent vectors are primitive and give weight-one hypersurfaces. Their three primitive normal vectors have determinant 15; multiplying by the weight two recovers 30. Thus neither the individual weights nor the primitive intersection index alone gives the answer. The computation remains valid in characteristics two, three and five.

For non-binomial equations, a transverse intersection of tropical supports need not by itself identify an algebraic scheme intersection without the relevant lifting and proper-intersection hypotheses. The binomial proof succeeds because one finite free algebra controls both the generic fibre and the initial fibre. In the general theory, flatness, initial degenerations and multiplicity comparison replace that explicit algebra. This is the point at which the geometric results used by Gubler and collaborators enter the calculus.

References. [Gub13, Sections 5 and 13]; [GK17, Section 1]. The finite-free and initial-fibre calculations are proved here; the general tropical multiplicity and intersection conventions are those of the cited sources.

5.9 Real weights and valued extensions

A tropical point is a real vector; it is not required to be the valuation vector of a point over the original ground field. There is a direct construction of a complete valued extension realizing any prescribed vector. It explains why the definition by initial degenerations remains meaningful for arbitrary real weights.

Proposition 5.9.1. *For every $w = (w_1, \dots, w_r) \in \mathbb{R}^r$, there is a complete valued extension L/K and elements $t_i \in L^\times$ with $v(t_i) = w_i$. The absolute value on L restricts to the given one on K.*

Proof. On the Laurent polynomial ring $K[T_1^{\pm 1}, \dots, T_r^{\pm 1}]$ take the weighted Gauss norm

$$\left| \sum_m a_m T^m \right|_w = \max_m |a_m| e^{-\langle m, w \rangle}.$$

It is multiplicative. One proof uses the associated graded ring: the initial homogeneous part of a nonzero polynomial is nonzero, and the graded Laurent polynomial ring over the graded residue field is a domain, so initial parts of a product cannot multiply to zero. Equivalently, refine the real weight order by a monomial order to select a leading exponent; the leading coefficients multiply without cancellation. Extend the norm to the fraction field by $|f/g|_w = |f|_w / |g|_w$, then complete. The images t_i of T_i have the prescribed norms, while constants keep their original norms. □

This is a valued extension construction, not a finite-extension assertion. A finite extension cannot introduce an arbitrary real value over a discretely

valued field: its value group remains a finite-index enlargement. Thus strictification by a general analytic extension and descent through a finite field extension are different operations.

5.10 The closure algebra and all initial relations

Fix L, t as above and put $R = L^\circ$, $\mathfrak{m} = L^{\circ\circ}$ and $k = R/\mathfrak{m}$. Translate the given subscheme $X \subset T$ by t^{-1}, so its ideal becomes $I_t \subset L[z_1^{\pm 1}, \dots, z_r^{\pm 1}]$. The closure algebra in the torus over R is

$$A = R[z_1^{\pm 1}, \dots, z_r^{\pm 1}]/J, \qquad J = I_t \cap R[z_1^{\pm 1}, \dots, z_r^{\pm 1}].$$

Proposition 5.10.1. *The algebra A is torsion-free over R and hence flat over this valuation ring. Its special-fibre ideal is generated by the reductions of all normalized polynomials in I_t: divide each nonzero polynomial by one of its coefficients of maximal absolute value and then reduce.*

Proof. The map $A \to L[z^{\pm 1}]/I_t$ is injective by the definition of J. Its target has no R-torsion, because every nonzero element of R is invertible in L. Thus A is torsion-free. We use the standard valuation-ring criterion that every torsion-free module is flat.

A normalized polynomial has coefficients in R, with at least one unit coefficient, so it belongs to J and reduces to a nonzero initial polynomial. Conversely, take $g \in J$. If all its coefficients belong to $\mathfrak{m}$, its reduction is zero. Otherwise a coefficient of maximal absolute value is a unit of R; dividing by that coefficient changes its reduction by a nonzero scalar in k and gives one of the stated normalized relations. These two observations identify the ideals in $k[z^{\pm 1}]$. □

The proof shows why dividing by a small scalar is necessary even if it is not a unit in R. The relation belongs to the generic-fibre ideal, where that scalar is invertible; taking the saturated closure then retains its normalized reduction. Reducing only an arbitrary list of original equations computes a potentially larger scheme. The explicit example with $f_2 - f_1 = \pi(y - 1)$ earlier in this chapter is exactly this saturation phenomenon.

If t' is another choice with the same valuation vector, the coordinate ratios t'_i/t_i have absolute value one after passage to a common valued extension.

Their reductions are units. They induce a torus translation of the special fibre, so geometric component lengths and the resulting tropical multiplicities are unchanged. This is the elementary part of independence from the translating point. General valued-base-change invariance of tropical multiplicities remains the comparison theorem used in their definition.

5.10.1 Where the lifting theorem enters

Suppose an analytic point of X has tropicalization w. Evaluation in its completed residue field sends each normalized relation to zero, so its reductions cannot generate the unit ideal in the appropriate residue torus. This gives the elementary implication from an analytic point to nonempty initial degeneration. The reverse implication requires lifting from a nonempty reduction to an analytic point of the prescribed tropical fibre. It is the geometric content of the fundamental theorem, not a consequence of the termwise minimum rule alone.

Likewise, flatness of a closure does not by itself identify the initial scheme obtained from any unsaturated presentation. The closure, its relevant analytic domain, and the reduction map must refer to the same normalized ideal. Keeping these objects aligned prevents a common circular argument in informal explanations of tropicalization.

5.11 Hypersurface weights from Newton edges

At a generic point of a maximal face of a tropical hypersurface, the active exponents form a segment in the Newton subdivision. Let its endpoints be m_0 and $m_0 + dq$, where $q \in M$ is primitive and $d > 0$. The initial polynomial has the form

$$\chi^{m_0} P(\chi^q), \qquad P(z) = c_0 + c_1 z + \cdots + c_d z^d, \quad c_0 c_d \neq 0.$$

Proposition 5.11.1. *The tropical multiplicity of this maximal face is d, the lattice length of the dual Newton edge. This remains valid in inseparable residue characteristic.*

Proof. Extend q to a basis of M. Since χ^{m_0} is a unit, the initial scheme becomes

$$\operatorname{Spec} k[z^{\pm 1}]/(P(z)) \ \times \ (\mathbb{G}_m)^{r-1}.$$

The first algebra has dimension d over k. Indeed P has degree d and nonzero constant term, so z is already invertible in $k[z]/(P)$ and localization does not change that quotient. After algebraic closure it decomposes into local Artinian algebras at its roots, whose lengths sum to d. The product with the torus preserves these generic component lengths. No separability assumption is used. □

In a two-dimensional transverse slice at a codimension-two face, the dual Newton cell is a polygon. List its oriented edge vectors as $d_i q_i$ around the boundary. Their sum is zero. After choosing dual oriented lattice bases, rotating each primitive q_i to the corresponding primitive outgoing normal u_i gives

$$\sum_i d_i u_i = 0.$$

By Proposition 5.11.1, the d_i are exactly the hypersurface weights. This proves balancing for the hypersurface in that local slice, and hence modulo the tangent lattice of the original face. The Newton-subdivision correspondence supplies the duality of the slice and polygon; the actual balancing equation is the closed-polygon identity. Higher-codimension ideals need the more general multiplicity theorem.

5.11.1 The sign of the tropical divisor

The tropical polynomial $F(w) = \min_m(v(a_m) + \langle m, w\rangle)$ is concave. With the positive Hessian convention of this book, its effective hypersurface current is therefore

$$\delta_{\mathrm{Trop}(V(f))} = \mathrm{d}'\mathrm{d}''[-F].$$

The corner coefficient across a maximal face is the jump between the two active slopes, and the primitive normal calculation gives the lattice length d. This proves the formula from the corner identity. It is a formula on the real tropical space. It must not be replaced by an equality $\log|f| = -F \circ \mathrm{trop}$ on every analytic point: cancellation makes that equality fail away from the Gauss section, as seen at the beginning of the chapter.

5.12 Why the weight is locally constant on the regular locus

Proposition 5.12.1. *Let C be a balanced pure d-dimensional tropical cycle with constant weights on a polyhedral complex. If an open part of its support is an open subset of a single d-dimensional affine space, its weight is locally constant there.*

Proof. At a facet introduced by the subdivision inside this affine space, precisely two local maximal sides occur. Their tangent lattices agree, and their outgoing primitive classes in the rank-one quotient are opposite. Balancing says $m_+n - m_-n = 0$, so $m_+ = m_-$. In a sufficiently small affine ball, two generic interior points can be joined by a polygonal path avoiding the codimension-two skeleton and crossing only facets. Repeated application of this equality identifies the weights along the path. Points on lower-dimensional subdivision faces inherit this common local weight. □

This is an alternative explanation of local constancy once the balancing theorem has been established. It does not say that the initial schemes are all isomorphic, nor that one weight can be extended unchanged across a singular tropical vertex. In computations, choose a point inside each maximal cell to obtain its multiplicity, and then use the separate weights in the balancing equation at their common face.

References. Initial degenerations and the lifting theorem are treated in [Gub13, Sections 5–6 and 13]; the closure and hypersurface calculations above make the normalization and multiplicities explicit. For the valuation-ring flatness criterion, see `https://stacks.math.columbia.edu/tag/0539`.

5.13 Initial ideals and analytic tropical fibres

Let K be a complete non-Archimedean field, put $v = -\log|\cdot|$, and write $M = \mathbf{Z}^n$. For $w \in \mathbf{R}^n$ and $f = \sum_m a_m \chi^m \in K[M]$, put

$$\|f\|_w = \max_m |a_m| e^{-\langle m,w\rangle}, \qquad \mu_w(f) = \min_{a_m \neq 0} \big(v(a_m) + \langle m, w\rangle\big).$$

A term is active if it attains this maximum, or equivalently this minimum. Denote by $\mathcal{T}_w$ the completion of $K[M]$ for $\|\cdot\|_w$. The multilaurent presentation of Theorem 1.17.2 identifies it, as a normed algebra, with

$$K\{r_1^{-1}T_1, r_1S_1, \dots, r_n^{-1}T_n, r_nS_n\}/(T_iS_i - 1)_i, \qquad r_i = e^{-w_i}.$$

Lemma 5.13.1 (Coordinate bases for weighted subspaces)**.** *Let $E = K^q$ have the norm $\|(a_i)\| = \max_i |a_i| r_i$, where every $r_i > 0$. For every s-dimensional subspace $W \subset E$ there are distinct indices $b_1, \dots, b_s$ and a basis $g_1, \dots, g_s$ of W such that*

$$(g_i)_{b_j} = \delta_{ij}, \qquad \|g_i\| = r_{b_i}, \qquad \Big\|\sum_i c_i g_i\Big\| = \max_i |c_i| r_{b_i}.$$

The same assertions hold after every isometric field extension, with the same basis and weights. If all $r_i = 1$, reduction of the unit ball of W has dimension s over $\widetilde{K}$, and its reduction commutes with residue-field extension.

Proof. Choose a nonzero vector in W, choose a coordinate at which its weighted norm is attained, and divide by that coordinate. This gives g_1 with pivot b_1, pivot coefficient one, and norm r_{b_1}. Apply induction to the kernel in W of the b_1-coordinate. Its basis vectors have zero b_1-coordinate. Subtract their pivot multiples from g_1 to make all other pivot coordinates of g_1 zero. Each subtraction has norm at most r_{b_1}: its scalar coefficient c occurs in a pivot coordinate of weight r_b and satisfies $|c| r_b \le r_{b_1}$. The b_1-coordinate stays one, so the norm stays r_{b_1}. This completes the construction.

The ultrametric inequality gives the upper bound for a linear combination. Its pivot coordinates are exactly the c_i, giving the reverse bound. These calculations remain valid over an isometric extension. For unit weights the unit ball is therefore $\bigoplus_i K^\circ g_i$, its reduction has basis $\overline{g}_i$, and the identical description over the extension proves the last assertion. □

Proposition 5.13.2 (The tropical fibre algebra)**.** *Let $I \subset K[M]$ be an ideal and $X = \operatorname{Spec}(K[M]/I)$. For every real weight w, the fibre $X_w = \{x \in X^{\mathrm{an}} : -\log|\chi^{e_i}(x)| = w_i\}$ is the affinoid space*

$$X_w = \mathcal{M}(\mathcal{T}_w / I\mathcal{T}_w).$$

The ideal $I\mathcal{T}_w$ is closed and is the norm closure of I in $\mathcal{T}_w$.

Proof. Theorem 1.18.3 makes every ideal of $\mathcal{T}_w$ closed. Write an element of $I\mathcal{T}_w$ as a finite sum $\sum_j h_j f_j$ with $f_j \in I$ and $h_j \in \mathcal{T}_w$. Approximating the finitely many h_j by Laurent polynomials approximates this sum by elements of I. Thus its closure is precisely $I\mathcal{T}_w$.

An analytic point in the indicated fibre bounds every Laurent polynomial by $\|\cdot\|_w$, so its seminorm extends to $\mathcal{T}_w$ and kills $I\mathcal{T}_w$. Conversely, the bounds

on T_i, S_i and the identities $T_i S_i = 1$ force $|T_i| = r_i$ at every point of the displayed quotient. Restriction to $K[M]/I$ gives the corresponding point of X^{an}, by Proposition 2.10.1. The two constructions are inverse, continuous in the evaluation topologies, and identify the analytic structures by the rational-domain universal property of Theorem 2.31.2, applied to the finitely many coordinate and inverse-coordinate inequalities. □

Theorem 5.13.3 (The tropical fundamental theorem over the original field)**.** *With the preceding notation, the following conditions on $w \in \mathbf{R}^n$ are equivalent:*

1. $w \in \mathrm{Trop}(X) := \mathrm{trop}(X^{\mathrm{an}})$*;*
2. $\mathcal{T}_w / I\mathcal{T}_w \neq 0$*;*
3. *every nonzero $f \in I$ has at least two active terms at w.*

This holds with trivial valuation, arbitrary real radii, and nonreduced X.

Proof. The equivalence of the first two conditions follows from Proposition 5.13.2 and Theorem 1.20.1. If f has a unique active term $a_m \chi^m$, then

$$f = a_m \chi^m (1 + h), \qquad \|h\|_w < 1.$$

Lemma 1.1.4 makes f invertible in $\mathcal{T}_w$, so the quotient is zero. Conversely, if that quotient is zero, then $1 \in I\mathcal{T}_w$. By the closure assertion in Proposition 5.13.2, there is $g \in I$ with $\|1 - g\|_w < 1$. Its constant coefficient has absolute value one and every other term has weighted size less than one. Thus g has a unique active term, contradicting the third condition. □

Proposition 5.13.4 (Initial ideals and scalar extension)**.** *Put $R = K^\circ$ and $k = \widetilde{K}$. Let $J = I \cap R[M]$ and let $\overline{J}$ be its image in $k[M]$. For any complete isometric extension L/K, with residue field l, one has*

$$\overline{IL[M] \cap L^\circ[M]} = \overline{J}\, l[M].$$

Moreover, $R[M]/J$ is flat over R, its special fibre is $k[M]/\overline{J}$, and this special fibre is nonempty exactly when $0 \in \mathrm{Trop}(X)$.

Proof. For a finite set $F \subset M$, let V_F be its coordinate span and $W_F = I \cap V_F$. Every vector space over K is torsion-free and therefore flat by [StacksAlg, Tag

0539], applied to the valuation ring K itself. Tensoring the kernel sequence $W_F \to V_F \to K[M]/I$ thus gives

$$(IL[M]) \cap (V_F \otimes_K L) = W_F \otimes_K L.$$

Apply Lemma 5.13.1 with unit weights. The reductions of the unit balls on the two sides therefore differ exactly by scalar extension from k to l. Taking the union over finite supports proves the ideal identity.

The closure algebra injects into $K[M]/I$, hence has no R-torsion. It is flat by the valuation-ring criterion, [StacksAlg, Tag 0539]. Its special fibre has the stated presentation. If $\overline{J}$ contains a monomial, lifting the equality expressing this monomial as a finite sum of reduced relations gives an element of I whose reduction is that monomial. It has a unique active term. Conversely, normalize an element of I having a unique active term by its largest coefficient; its reduction is a unit monomial in $\overline{J}$. Thus $\overline{J}$ is proper exactly when every relation has at least two active terms. Theorem 5.13.3 finishes the proof. □

Proposition 5.13.5 (Completion retains the initial relations)**.** *Let $\widehat{I} = I\mathcal{T}_0$, let $\mathcal{T}_0^{\leq 1}$ denote the Gauss unit ball, and reduce this unit ball coefficientwise to $k[M]$. Then*

$$\operatorname{red}(\widehat{I} \cap \mathcal{T}_0^{\leq 1}) = \overline{J}.$$

Proof. One inclusion follows from $I \subset \widehat{I}$. Given $h \in \widehat{I}$ with $\|h\|_0 \leq 1$, approximate it by $g \in I$ with $\|g - h\|_0 < 1$, using Proposition 5.13.2. Then $\|g\|_0 \leq 1$ and g, h have identical reductions. This proves the reverse inclusion. Coefficientwise reduction is a Laurent polynomial because only finitely many coefficients of a convergent Laurent series can have absolute value one. □

Theorem 5.13.6 (Initial degenerations at arbitrary real weights)**.** *Choose a complete isometric extension L/K and $t \in (L^\times)^n$ with $v(t) = w$. Such a choice exists for every real w. Write I_t for the image of $IL[M]$ under $\chi^m \mapsto t^m \chi^m$, and set*

$$\operatorname{in}_{w,t,L}(X) = \operatorname{Spec}\left(\widetilde{L}[M]/\overline{I_t \cap L^\circ[M]}\right).$$

After residue-field extension and translation by a point of the residue torus, this scheme is independent of L, t. It is nonempty exactly when $w \in \operatorname{Trop}(X)$. For every complete isometric extension E/K,

$$\operatorname{Trop}(X_E) = \operatorname{Trop}(X).$$

Proof. Extend the multiplicative weighted Gauss norm on $K[M]$ to its fraction field and complete. The coordinate monomials give the required t, with the original absolute value on K. Multiplicativity is the Gauss calculation of Proposition 1.2.2. Theorem 2.35.5 places any two choices in a common complete valued extension. Proposition 5.13.4 compares the resulting initial ideals under that extension. For two translating points in the common field, the ratios t'_i/t_i have absolute value one; their residues induce a torus translation between the two special fibres.

Theorem 2.33.13, applied to the fibre algebra of Proposition 5.13.2, shows that every tropical fibre is nonempty before a complete extension exactly when it is nonempty afterwards. This proves tropical base-change invariance. Translation by t identifies the fibre at w with the unit-radius fibre. Proposition 5.13.4 and Theorem 5.13.3 now give the assertion about nonemptiness. □

Proposition 5.13.7 (Properness of toric tropicalization)**.** *The map* trop : $X^{\mathrm{an}} \to \mathbf{R}^n$ *is continuous and topologically proper. Its image is closed.*

Proof. Continuity follows from evaluation on the invertible characters. The inverse image of a closed box is the closed analytic subspace defined by I in the corresponding affinoid polyannulus; Proposition 2.24.1 gives its compactness. For a compact subset of $\mathbf{R}^n$, choose a box containing it; its inverse image is closed in that compact polyannulus, hence compact. Closedness of the image also follows directly from Theorem 5.13.3: its complement is the union, over $f \in I$, of the open loci where one term of f is uniquely active. □

References. These arguments reconstruct the initial-degeneration and lifting mechanisms of [Gub13, Sections 3–5]. The analytic lifting step here is the closed-ideal approximation in the actual tropical-fibre algebra; the proof uses the previously established affinoid spectrum and base-change results.

5.14 A combinatorial calculus of corners

Let N be a lattice and put $V = N \otimes_{\mathbf{Z}} \mathbf{R}$. A rational polyhedron may have arbitrary real translation constants; its direction space is rational. All complexes in this section are finite. Write $N_\sigma = N \cap \operatorname{span}_{\mathbf{R}}(\sigma - \sigma)$. A real

weighted d-cycle is a pure d-dimensional rational polyhedral complex with constant real weights w_σ on its facets, satisfying

$$\sum_{\sigma \supset \tau} w_\sigma u_{\sigma/\tau} = 0 \quad \text{in } V/N_{\tau,\mathbf{R}}.$$

Here $u_{\sigma/\tau}$ is the primitive outward generator of the rank-one lattice N_σ/N_τ. Subdivision preserves a weight on each subdivided facet; cells of weight zero may be discarded. We identify cycles after a common weighted subdivision. A piecewise affine function on a cycle is continuous and affine on the cells of some finite rational subdivision. Its slopes may be real.

Lemma 5.14.1 (Primitive vectors and saturated lattices)**.** *A primitive vector of $\mathbf{Z}^n$ extends to a lattice basis. A saturated subgroup $A \subset \mathbf{Z}^n$ is generated by part of a basis and has a free quotient. The group $\mathrm{GL}_n(\mathbf{Z})$ is generated by row interchanges, sign changes, and adding an integer multiple of one row to another.*

Proof. The Euclidean algorithm, applied successively to coordinate pairs, uses these invertible row operations to send a vector to $(d, 0, \dots, 0)$, where d is the greatest common divisor of its coordinates. For a primitive vector $d = 1$; applying the inverse row-operation matrix to the standard basis proves the first assertion. If $A \neq 0$ is saturated, divide a nonzero element by the greatest common divisor of its coordinates. Saturation puts the resulting primitive vector a in A. The image of A in $\mathbf{Z}^n/\mathbf{Z}a \simeq \mathbf{Z}^{n-1}$ is saturated: if a nonzero integer multiple of a class lies in that image, a representative has that multiple in A, since $\mathbf{Z}a \subset A$, and hence belongs to A. Induction and lifting a quotient basis now give a basis whose first members generate A.

For an invertible integral matrix, the greatest common divisor of its first column is one, since any common divisor would divide its determinant ± 1. Row operations reduce that column to the first standard vector. The lower-right block is again invertible over $\mathbf{Z}$; reduce it by induction, and then clear the remaining entries of the first row using the lower identity rows. This reduces the entire matrix to the identity and proves the generation assertion. □

Lemma 5.14.2 (Refinement and products of balanced complexes)**.** *Finite rational polyhedral complexes admit common rational refinements. Balancing is invariant under refinement, and the Cartesian product of two balanced cycles, with product weights, is balanced. The star at a face and the quotient of that star by the direction space of the face are balanced.*

Proof. Take all affine supporting hyperplanes of the finitely many faces, and cut every polyhedron by them. The resulting sign cells and their faces form a common refinement. At a new codimension-one face lying inside an old facet, there are two incident pieces with the same weight and opposite primitive normals. At a subdivision of an old codimension-one face, the old normal equation is unchanged. All other new faces have smaller dimension. These observations prove refinement invariance in both directions.

A codimension-one face of a product is either $\tau \times \rho$ or $\sigma \times \nu$, where exactly one factor has codimension one. Its normal equation is the normal equation in that factor multiplied by the weight of the other factor. For a star, the normals and weights are the original ones at the faces containing the chosen face. Its direction lattice is saturated, so passage to the quotient preserves the primitive normal quotient lattices and the balancing equations. □

Definition 5.14.3 (The corner operator)**.** Let C be a balanced d-cycle and φ a piecewise affine function on it. On a subdivision on which φ is affine, let φ_σ denote its linear part. At a codimension-one face τ choose any real linear extension $\ell_\tau : V \to \mathbf{R}$ of φ_τ, and choose a lattice lift $n_{\sigma/\tau}$ of each primitive normal. The corner $D_\varphi C$ has weight

$$w_{D_\varphi C}(\tau) = \sum_{\sigma \supset \tau} w_\sigma (\varphi_\sigma - \ell_\tau)(n_{\sigma/\tau}). \tag{C}$$

For $d = 0$ the corner is zero.

Proposition 5.14.4 (Well-defined corner weights)**.** *Formula* (C) *is independent of all normal lifts, linear extensions, and adapted subdivisions. It is linear in C and in φ, and $D_\ell C = 0$ for every globally affine function ℓ. It commutes with integral affine lattice isomorphisms.*

Proof. Changing a lift adds a vector in $N_{\tau,\mathbf{R}}$, on which $\varphi_\sigma - \ell_\tau$ vanishes by continuity. Changing ℓ_τ by a linear form h vanishing on that space changes the sum by $-h(\sum_\sigma w_\sigma n_{\sigma/\tau}) = 0$, by balancing. At a new face inside an old

affine piece, the two contributions cancel; in fact the same linear extension can be used on both sides. At a subdivided old face, the formula has the old value. Lemma 5.14.2 now compares any two adapted subdivisions. The formula gives both linearities. For a globally affine function choose its common linear part as every ℓ_τ; all summands vanish. A lattice isomorphism transports the saturated lattices, their primitive generators, and this same formula, proving the last assertion. □

Theorem 5.14.5 (Balancing and commutation of corners)**.** *For every balanced real cycle C and continuous piecewise affine functions φ, ψ on it, $D_\varphi C$ is balanced and*

$$D_\psi D_\varphi C = D_\varphi D_\psi C.$$

Proof. Both assertions are local at an original face of codimension two. Take its star and quotient by its direction space. Subtract linear extensions of the two functions along that face. By Proposition 5.14.4, this changes neither corner. We have reduced to a two-dimensional balanced rational fan, with both functions homogeneous and linear on its cones. Cut cones with lineality by rational hyperplanes if necessary, so that the cones are pointed; their two-dimensional cones then have two extreme rays. Let the distinct primitive ray vectors be $v_1, \dots, v_s$. For a cone with extreme rays v_i, v_j put

$$d_{ij} = [N_{\langle v_i, v_j \rangle} : \mathbf{Z}v_i + \mathbf{Z}v_j], \qquad a_{ij} = a_{ji} = w_{ij}/d_{ij};$$

put $a_{ij} = 0$ if there is no such cone. Modulo $\mathbf{R}v_i$, its primitive normal is the class of v_j/d_{ij}. Indeed v_i is primitive in the rank-two saturated lattice; Lemma 5.14.1 completes it to a basis, in which $v_j = bv_i + d_{ij}e$ with the appropriate sign of e. Balancing at v_i therefore says

$$\sum_j a_{ij} v_j = \lambda_i v_i \quad \text{for some } \lambda_i \in \mathbf{R}.$$

The weight of the first corner on the ray i is consequently

$$b_i(\varphi) = \sum_j a_{ij}\varphi(v_j) - \lambda_i \varphi(v_i). \tag{R}$$

One may use v_j/d_{ij} instead of a lattice lift in (C), since their difference is tangential. Symmetry of a_{ij} and the displayed balancing equations give

$$\sum_i b_i(\varphi) v_i = \sum_j \varphi(v_j) \sum_i a_{ij} v_i - \sum_i \lambda_i \varphi(v_i) v_i = 0.$$

This is balancing for the corner at the origin. The coefficient of the second corner at that origin is

$$\sum_i b_i(\varphi)\psi(v_i) = \sum_{i,j} a_{ij}\varphi(v_j)\psi(v_i) - \sum_i \lambda_i \varphi(v_i)\psi(v_i),$$

which is symmetric in φ, ψ. Hence the two orders agree. For a cycle of dimension one, its corner is a zero-cycle, whose further corner is zero; in dimension zero both assertions are immediate. The local calculation and refinement invariance prove the theorem in every dimension. □

Lemma 5.14.6 (Restriction, products, and quotient directions)**.** *The corner depends only on the restricted function on the support of its cycle. If p is projection from a product, then*

$$D_{\varphi \circ p}(C \times E) = (D_\varphi C) \times E.$$

Taking a star commutes with the corner after replacing the function by its local piecewise linear part. If a fan has a rational lineality space L, and the function is pulled back from its quotient by L, the corner is the pullback of the corner on that quotient, with the same weights.

Proof. All terms of (C) are determined by the restricted affine functions. A codimension-one face of $C \times E$ belonging to the E factor has zero weight for this corner, since the function has a common affine extension there. At a face belonging to the C factor, the formula is the corner weight in C multiplied by the weight in E. Stars leave the normal quotient lattices unchanged. For the last assertion, $N \cap L$ is saturated; Lemma 5.14.1 gives a lattice splitting of N over $N/(N \cap L)$. The fan is then a product of L with its quotient, so the product calculation applies. □

References. The corner construction follows Allermann–Rau, *First steps in tropical intersection theory*, Section 3. The proof above gives the full rank-two calculation, including its tangential correction, before using any differential forms or toric Chow theory.

5.15 The standard-chart homotopy

Let K be complete and nontrivially valued, with its original absolute value. Fix $0 < |a| < 1$ and integers $r, q \geq 0$. Put

$$A = K\langle X_0, \dots, X_r, T_1, \dots, T_q \rangle / (X_0 \cdots X_r - a), \qquad V = \mathcal{M}(A).$$

Proposition 3.26.1 gives the continuous Gauss section $s : \Delta_a \to V$, where

$$\Delta_a = \{(w_0, \dots, w_r) \in \mathbb{R}^{r+1}_{\geq 0} : \sum_i w_i = v(a)\}.$$

After eliminating $X_0 = a/(X_1 \cdots X_r)$, $s(w)$ is the Gauss point of radii e^{-w_i} in X_i, $1 \leq i \leq r$, and radius 1 in every T_j. Let $\Sigma_a = s(\Delta_a)$ and write $\mathrm{val} : V \to \Delta_a$ for the values of $X_0, \dots, X_r$.

Lemma 5.15.1 (Mixed Gauss displacement)**.** *For $x \in V$, write $E = \mathcal{H}(x)$, $\xi_i = X_i(x) \in E^\times$ and $b_j = T_j(x) \in E$. For $0 < t \leq 1$, take the Gauss absolute value of radius t in all variables $S_1, \dots, S_r, Z_1, \dots, Z_q$ over E, and extend it to the completed rational function field E_t. The substitutions*

$$\begin{aligned} X_i &\longmapsto \xi_i(1 + S_i) && (1 \leq i \leq r), \\ X_0 &\longmapsto \xi_0 \prod_{i=1}^{r} (1 + S_i)^{-1}, \\ T_j &\longmapsto b_j + Z_j && (1 \leq j \leq q). \end{aligned}$$

define a bounded homomorphism $A \to E_t$ and hence a point $H(x,t) \in V$. Set $H(x,0) = x$. For every $t \in [0,1]$,

$$|X_i(H(x,t))| = |X_i(x)| \quad (0 \leq i \leq r), \qquad |T_j(H(x,t))| = \max\{|T_j(x)|, t\}.$$

Proof. The Gauss absolute value is multiplicative by Proposition 1.2.2. For $t > 0$ the polynomial $1 + S_i$ has norm 1, so it is nonzero and invertible in the rational function field, also when $t = 1$. All displayed coordinate images have norm at most one, and their product in the first $r + 1$ coordinates is a. Convergent restricted series can therefore be evaluated in the complete field E_t. This yields a homomorphism from the Tate algebra, contractive for its Gauss norm, which kills the defining relation. It descends contractively for the quotient norm on A. Multiplicativity and the exact Gauss norms of $1 + S_i$ and $b_j + Z_j$ give the stated coordinate values. At $t = 0$ they are the values at x, as required. □

Theorem 5.15.2 (A jointly continuous strong deformation retraction)**.** *The map $H : V \times [0,1] \to V$ of Lemma 5.15.1 is jointly continuous and is a strong deformation retraction onto Σ_a. More precisely,*

$$\begin{aligned} H(x,0) &= x, & H(x,1) &= s(\mathrm{val}(x)), \\ H(s(w),t) &= s(w), & \mathrm{val}(H(x,t)) &= \mathrm{val}(x). \end{aligned}$$

It commutes with complete isometric ground-field extension.

Proof. We first give a formula proving joint continuity, including at $t = 0, 1$. Let $P \in K[X_1^{\pm 1}, \dots, X_r^{\pm 1}, T]$ and choose $D \in \mathbb{N}^r$ so that $Q = X^D P$ is a polynomial. Expand the finite polynomial

$$Q\big(X_1(1+S_1), \dots, X_r(1+S_r), T+Z\big) = \sum_{\beta,\gamma} Q_{\beta\gamma}(X,T) S^\beta Z^\gamma.$$

Since the factors $1 + S_i$ have norm one, the exact formula is

$$|P(H(x,t))| = \frac{\max_{\beta,\gamma} |Q_{\beta\gamma}(x)|\, t^{|\beta|+|\gamma|}}{\prod_{i=1}^{r} |X_i(x)|^{D_i}}, \tag{H}$$

where the term of degree zero uses $0^0 = 1$. Its right side is continuous in (x, t): it is a finite maximum divided by a continuous positive function. Every X_i is invertible on V. The Laurent polynomial algebra is dense in A by Proposition 3.26.1. All evaluations $H(x, t)$ are contractive for one fixed quotient norm, so approximating an arbitrary $f \in A$ by Laurent polynomials gives uniform approximation of the real functions $|f(H(x, t))|$ on $V \times [0, 1]$. Thus all such evaluation functions are continuous, which is precisely continuity into the Berkovich spectrum.

At $t = 1$, translation of any variable of the unit Gauss norm by a scalar of norm at most one is isometric. Indeed, the ultrametric inequality makes substitution contractive on polynomials, and the inverse translation gives the reverse bound; the assertion then extends to fractions. Apply this to $S_i \mapsto 1 + S_i$ and $Z_j \mapsto b_j + Z_j$. For every Laurent polynomial $P = \sum c_{\alpha\mu} X^\alpha T^\mu$,

$$|P(H(x,1))| = \max_{\alpha,\mu} |c_{\alpha\mu}| \prod_{i=1}^{r} |X_i(x)|^{\alpha_i}.$$

This is the defining Gauss norm of $s(\mathrm{val}(x))$, including radius one for every free coordinate T_j. Density gives the same equality on A.

Let $x = s(w)$. The norm of every monomial after displacement is at most its original Gauss norm, so $|P(H(x, t))| \le |P(x)|$. In (H), the constant coefficient is $Q(x)$ and has norm equal to the Gauss norm of Q at $s(w)$. Consequently the same formula gives the reverse inequality. Thus H fixes every skeletal point. The identity at time zero is its definition, and preservation of val is the coordinate formula in the lemma. These are all strong deformation retraction identities.

For a complete isometric extension L/K and a point $x' \in V_L$ over x, the completed residue-field embedding $\mathcal{H}(x) \hookrightarrow \mathcal{H}(x')$ is isometric. Formula (H) therefore gives the same value on every original Laurent polynomial before and after projection. Density proves commutation on A. At the endpoint the standard Gauss section over L restricts to that over K, with unchanged real radii. □

Proposition 5.15.3 (The maximum-parameter composition law)**.** *For all $x \in V$ and $s, t \in [0, 1]$,*

$$H(H(x, s), t) = H(x, \max(s, t)).$$

Proof. When one parameter is zero the assertion is immediate. For positive parameters, realize the completed residue field of $H(x, s)$ inside the completed Gauss rational field used in its definition. The injection comes from its actual evaluation homomorphism, after quotienting its kernel, taking fractions, and completing. Gauss extension preserves the norm of every coefficient. Iterating the construction therefore uses independent variables (S, Z) of radius s and (S', Z') of radius t, and substitutes

$$X_i \mapsto \xi_i(1 + S_i)(1 + S'_i), \qquad T_j \mapsto b_j + Z_j + Z'_j.$$

The two sets of variables are symmetric, so assume $s \leq t$. Set

$$W_i = S_i + S'_i + S_i S'_i, \qquad V_j = Z_j + Z'_j.$$

The rational coordinate change from (S, Z, S', Z') to (S, Z, W, V) is an isometry of Gauss fields with radii (s, s, t, t). To see this directly, its inverse formulas are

$$S'_i = (W_i - S_i)/(1 + S_i), \qquad Z'_j = V_j - Z_j.$$

The displayed images have their assigned norm bounds, because $s \leq t$ and $|1 + S_i| = 1$, including when $s = t = 1$. Hence substitution of an old polynomial has norm at most its original Gauss norm. Its image is a new polynomial divided by a product of powers of $1 + S_i$, of norm one. Applying the reverse substitution to that numerator gives the reverse bound. This proves equality for polynomials and then for their fractions. The same argument for $V = Z + Z'$ is linear and has no denominator.

After this isometry the iterated substitution is simply $X_i \mapsto \xi_i(1 + W_i)$ and $T_j \mapsto b_j + V_j$. It does not involve (S, Z); its Gauss norm is the single displacement norm of radius t. This proves the identity on Laurent polynomials, and uniform approximation proves it on all of A. □

Proposition 5.15.4 (Monomial and bounded affine covariance)**.** *On a torus times a unit polydisc, the mixed displacement construction is unchanged by a torus coordinate change $Y_i = c_i X^{m_i}$ whose exponent matrix lies in $\mathrm{GL}_r(\mathbb{Z})$, together with a free-coordinate change $U = BT + b$ with B, B^{-1} having entries in K° and $b \in (K^\circ)^q$. Whenever such a change identifies two standard chart domains, it intertwines their entire homotopies. In particular the construction is independent of which monomial coordinate is eliminated from $X_0 \cdots X_r = a$.*

Proof. For $0 < t < 1$, the normalized relative displacement of Y_i is

$$W_i = \prod_j (1 + S_j)^{m_{ij}} - 1.$$

Integer binomial coefficients have norm at most one, including those for negative exponents. The binomial series therefore converge for radius t, and $|W_i| \le t$. The inverse integral matrix gives the inverse substitutions with the same bounds. The two maps of radius-t Tate algebras are contractive inverses, hence isometric. At $t = 1$ use instead the variables $R_i = 1 + S_i$. Their radius-one Gauss norm is unchanged by translation. A unimodular monomial change permutes the Laurent monomial basis, so preserves the Gauss norm and its extension to fractions. At time zero both constructions are evaluation at the original point.

For the free variables, the relative displacement of $BT + b$ is BZ. Both B and its inverse are contractive for the radius-t coordinate maximum norm, so their induced Gauss substitutions are isometric. The constant b merely changes the center. These isometries identify all polynomial evaluations defining the homotopies; density identifies the analytic evaluations. Finally, changing the eliminated coordinate expresses the new independent monomial variables in the old ones by an integral invertible exponent matrix and powers of a, precisely the torus changes just treated. □

References. The construction uses explicit Gauss displacement on the standard semistable chart. At the endpoint, evaluation in a rational Gauss field retains the norm-one denominators and their multiplicative inverses.

5.16 Finite polyhedral initial data

Write $S = K[x_0, \dots, x_n]$ with its usual grading, and let $H \subset S$ be homogeneous. For $\omega \in \mathbf{R}^{n+1}$, pass to a complete isometric extension realizing the coordinate weights, translate the variables, and reduce normalized homogeneous relations. This gives a homogeneous ideal $\mathrm{in}_\omega(H)$ in a polynomial ring over the residue field. The arguments of Proposition 5.13.4 apply degree by degree to polynomial rings as well. We compare ideals after residue-field extension and diagonal change of coordinates.

Lemma 5.16.1 (The Hilbert function of an initial ideal)**.** *For every degree d, the degree-d component of $\mathrm{in}_\omega(H)$ is the reduction of the unit ball of the translated subspace H_d. Consequently*

$$\dim_{\widetilde{L}}\big(\widetilde{L}[x]/\,\mathrm{in}_\omega(H)\big)_d = \dim_K (S/H)_d.$$

Proof. The reduction of the unit ball of H_d is a vector subspace. Multiplying a normalized homogeneous relation of degree $e \le d$ by a monomial of degree $d-e$ gives a normalized relation in H_d. Conversely, every reduced vector in H_d is one of the homogeneous initial relations defining the ideal. Thus its degree-d part is exactly this reduced subspace. After translating, Lemma 5.13.1 with unit weights gives its dimension $\dim_K H_d$. Subtract this from the number of degree-d monomials. □

Lemma 5.16.2 (Finitely many monomial ideals with a fixed Hilbert function)**.** *In a polynomial ring in finitely many variables, there are only finitely many monomial ideals with a prescribed Hilbert function. This finite set depends only on that function and the number of variables, not on the coefficient field.*

Proof. Suppose there were infinitely many distinct such ideals. Enumerate the monomials by nondecreasing degree. Successively retain an infinite subfamily on which membership of the next monomial is constant. The limiting membership choices define a monomial ideal Q: divisibility preserves membership because it does so in every ideal of every sufficiently late subfamily. In each degree its standard monomials have the prescribed cardinality. The polynomial ring is Noetherian by [StacksAlg, Tag 00FN], so Q has finitely many monomial generators, all of degree at most some D.

An infinite subfamily agrees with Q on all monomials of degree at most D. Each member therefore contains Q. Since its standard-monomial count equals that of Q in every degree, the containment is equality. This contradicts the distinctness of the infinite subfamily. All choices involved only sets of exponent vectors. □

Proposition 5.16.3 (A uniform degree bound for homogeneous initial ideals)**.** *There is an integer D depending only on the Hilbert function of S/H such that every $\mathrm{in}_\omega(H)$, over every residue extension, is generated in degrees at most D. The same D works for all further ordinary initial ideals of these ideals.*

Proof. Fix a degree-compatible monomial order. For a homogeneous ideal J over a field, let $\mathrm{LM}(J)$ be the monomial ideal generated by its leading monomials. Its standard monomials form a basis of the quotient in every degree. Indeed, finitely many leading monomials generate $\mathrm{LM}(J)$ by Noetherianity. Choose homogeneous elements of J having these leading monomials. Polynomial division by them terminates because the monomial order is well ordered and reduces every homogeneous polynomial to a linear combination of standard monomials. Such a combination cannot belong to J unless it is zero, since otherwise its leading monomial would belong to $\mathrm{LM}(J)$. The same division proves that the chosen elements generate J.

By Lemma 5.16.1, all ideals under consideration have the Hilbert function of H. Their monomial leading ideals therefore belong to the finite list of Lemma 5.16.2. Take D to be the largest degree among the minimal monomial generators in this list. Lifting these generators as in the preceding paragraph proves the bound. An ordinary weight initial ideal has the same Hilbert function, by the same degreewise argument over a trivially valued field, so the bound applies to it as well. □

Lemma 5.16.4 (Plücker coordinates and weighted row reduction)**.** *Let $W \subset K^F$ have dimension s, where F is a finite set of exponent vectors, and let C be a full-rank row matrix for W. For an s-element column set B with $\det C_B \neq 0$, put*

$$p_B(\omega) = v(\det C_B) + \sum_{b \in B} \langle b, \omega \rangle.$$

If B minimizes $p_B(\omega)$, the rows g_b of $C_B^{-1}C$, indexed by $b \in B$, satisfy

$$(g_b)_{b'} = \delta_{bb'}, \qquad v((g_b)_m) + \langle m, \omega \rangle \geq \langle b, \omega \rangle.$$

Their initial forms form a basis of the initial subspace. Which coefficients survive is determined by equalities among the finitely many functions p_B.

Proof. The pivot identity follows from the matrix inverse. Cramer's rule expresses $(g_b)_m$, up to sign, as the ratio of the minor obtained by replacing b by m to $\det C_B$. Minimality gives the displayed inequality. The resulting rows have distinct pivots and weighted norms $e^{-\langle b,\omega\rangle}$; the pivot-coordinate argument of Lemma 5.13.1 applies. After translating and dividing the b-th row by the b-th translating monomial, its pivot is one. Reduction therefore gives independent spanning rows. A nonpivot coefficient survives exactly when the corresponding minor has the same value of p as B. □

Theorem 5.16.5 (Finite polyhedral strata for initial degenerations)**.** *There is a finite polyhedral complex covering $\mathbf{R}^{n+1}$, defined by integer linear forms and constants in $v(K^\times)$, such that on the relative interior of each cell the schemes defined by $\mathrm{in}_\omega(H)$ are isomorphic after residue extension and diagonal torus translation. For an ideal $I \subset K[M]$, there is consequently a finite integral $v(K^\times)$-affine polyhedral complex on $\mathbf{R}^n$ for which $\mathrm{Trop}(\operatorname{Spec} K[M]/I)$ is the support of a subcomplex.*

Proof. Take D from Proposition 5.16.3. For each $d \le D$ apply Lemma 5.16.4 to H_d. Cut weight space by all equalities between the finitely many affine functions p_B occurring in these degrees. Their normals are integral and their constant differences belong to $v(K^\times)$. The resulting finite hyperplane arrangement is the required polyhedral complex.

Fix weights ω, ω' in the same relative interior. In each degree choose one common minimizing pivot set B; the same coefficients in its row basis survive at both weights. Realize both weights in a common valued extension, with translating points t, t'. For every surviving exponent difference $m-b$, the unit ratio $(t'/t)^{m-b}$ has norm one. On the subgroup $A \subset \mathbf{Z}^{n+1}$ generated by all these differences, their residues define a character $\rho : A \to \widetilde{L}^\times$. This character extends to the full exponent lattice after a finite algebraic residue extension. To see this directly, adjoin the standard basis vectors successively. When adjoining e_i, if no positive multiple of e_i belongs to the current subgroup, give e_i any nonzero value. Otherwise let $q > 0$ be least with qe_i in that subgroup, adjoin a root b of $T^q - \rho(qe_i)$, and set $\rho(a+me_i) = \rho(a)b^m$. This is well defined and extends ρ. A root is obtained by quotienting by an irreducible factor of that polynomial. After finitely many steps, translation by the resulting torus

point sends every surviving coefficient in every row at ω to its coefficient at ω'. The ideals are generated by these rows in degrees at most D, so the translation identifies the ideals.

For the Laurent ideal, take the homogeneous kernel

$$H = \ker\bigl(K[x_0,\dots,x_n] \longrightarrow (K[M]/I)[z,z^{-1}]\bigr), \qquad x_0 \mapsto z, \quad x_i \mapsto z\chi^{e_i}.$$

Localizing all the variables and putting $x_0 = 1$ recovers I. Initial relations commute with this operation: multiplication by a monomial shifts every term valuation by the same amount, and any Laurent relation can first be multiplied by a monomial and homogenized. Restrict the constructed complex to $\omega_0 = 0$. Nonemptiness of the resulting initial scheme is constant on every relative interior. By Theorem 5.13.6 this is exactly membership in $\mathrm{Trop}(X)$. That set is closed by Proposition 5.13.7; hence it contains the closure of every selected relative interior. It is therefore a union of closed cells, together with all their faces. □

Theorem 5.16.6 (Initial degenerations describe local stars)**.** *Let $X \subset \operatorname{Spec} K[M]$ be a closed subscheme and $w \in \mathrm{Trop}(X)$. Give the residue field of an initial degeneration $Y = \mathrm{in}_w(X)$ the trivial absolute value. Then*

$$\mathrm{Trop}(Y) = \mathrm{Star}_w \mathrm{Trop}(X).$$

Here the right side consists of those u for which $w + \varepsilon u \in \mathrm{Trop}(X)$ for all sufficiently small positive ε. More precisely, for every fixed u, the schemes $\mathrm{in}_{w+\varepsilon u}(X)$ and $\mathrm{in}_u(Y)$ are equivalent after residue extension and translation for all sufficiently small positive ε.

Proof. Homogenize as in Theorem 5.16.5, and write $\omega = (0,w)$ and $v = (0,u)$. Choose the common degree bound D of Proposition 5.16.3, also valid for the further initial ideals. In every degree at most D, minimize the pair

$$\left(p_B(\omega),\ \sum_{b\in B}\langle b, v\rangle\right).$$

There are finitely many pairs. Thus a lexicographically minimizing basis is minimizing for $p_B(\omega+\varepsilon v)$ whenever $\varepsilon > 0$ is sufficiently small. Cramer's rule then says that its surviving row entries are exactly those which first survive at ω and then have minimal v-weight. After the first reduction these rows

are a basis of the degree piece of $\mathrm{in}_\omega(H)$; their second reduction is therefore its degree piece at v, by Lemma 5.16.4.

We spell out the coefficient comparison. Fix a complete field L and t of value ω. Adjoin Gauss variables q_i of values εv_i to L and complete their fraction field, obtaining E. Use tq for the one-step translation. For a row entry c_{bm} put $a = m - b$. An entry survives both operations precisely when

$$v(c_{bm}) + \langle a, \omega \rangle = 0, \qquad \langle a, v \rangle = 0.$$

Its coefficient after the first reduction is $\overline{c_{bm} t^a} \in \widetilde{L}$. The ordinary weight initial form over the trivially valued field retains this coefficient. The one-step coefficient in $\widetilde{E}$ is $\overline{c_{bm} t^a}\, \overline{q^a}$. Thus the discrepancy is exactly the character $a \mapsto \overline{q^a}$ on the subgroup generated by the surviving exponent differences. Extend this character to the whole exponent lattice by the finite root-adjunction argument in the preceding theorem. A single torus translation then compares all the row generators.

For completeness, the ordinary initial ideal obtained by retaining the terms of least v-weight agrees, up to this same kind of translation, with the valued-extension definition of in_v over a trivially valued field. Indeed, introduce Gauss variables s_i of values v_i and divide each selected row by its pivot monomial. For a retained exponent difference a one has $\langle a, v \rangle = 0$, so the only new coefficient factor is the character $a \mapsto \overline{s^a}$. This also extends after algebraic residue extension. The common degree bound identifies the full homogeneous ideals from the compared rows. Localizing and dehomogenizing gives the claimed scheme equivalence. The nonemptiness criterion of Theorem 5.13.6, over both fields, gives the equality of supports. □

References. The classical finite Gröbner-complex and local-star theorems are discussed in [Gub13, Sections 10 and 12–13]. The proof here uses finite-dimensional weighted elimination, a Hilbert-function degree bound, and the analytic fundamental theorem already proved above.

5.17 Pushforwards and the projection formula

For an affine map, the same letter denotes its linear part when applied to direction vectors or direction lattices.

Lemma 5.17.1 (The index along a facet)**.** *Let $f : N \to N'$ be a lattice homomorphism, and let $\tau \prec \sigma$ be rational polyhedra of dimensions $d-1, d$. Suppose f is injective on $N_{\sigma,\mathbf{R}}$ and that $\tau' = f(\tau)$ is a facet of $\sigma' = f(\sigma)$. Put*

$$a_\sigma = [N'_{\sigma'} : f(N_\sigma)], \qquad a_\tau = [N'_{\tau'} : f(N_\tau)].$$

There is a positive integer $m_{\sigma/\tau}$ such that

$$f(u_{\sigma/\tau}) = m_{\sigma/\tau} u_{\sigma'/\tau'} \mod N'_{\tau'}, \qquad a_\sigma = a_\tau m_{\sigma/\tau}.$$

Proof. Injectivity and saturation give $f(N_\sigma) \cap N'_{\tau'} = f(N_\tau)$: the inverse image of $N'_{\tau',\mathbf{R}}$ inside $N_{\sigma,\mathbf{R}}$ is $N_{\tau,\mathbf{R}}$. The image of the primitive outward generator in the rank-one quotient is a positive integer $m_{\sigma/\tau}$ times the target generator. The finite groups fit into the exact sequence

$$0 \longrightarrow N'_{\tau'}/f(N_\tau) \longrightarrow N'_{\sigma'}/f(N_\sigma) \longrightarrow N'_{\sigma'}/(N'_{\tau'} + f(N_\sigma)) \longrightarrow 0.$$

The final group has order $m_{\sigma/\tau}$, so taking orders proves the equality. □

Theorem 5.17.2 (Balanced pushforward)**.** *Let C be a finite balanced real d-cycle in $N_{\mathbf{R}}$ and let $f : N_{\mathbf{R}} \to N'_{\mathbf{R}}$ be an integral affine map. There is a well-defined balanced d-cycle f_*C. After subdivision so that images are cells, its weight on a d-dimensional target cell σ' is*

$$w_{f_*C}(\sigma') = \sum_{\dim \sigma = d,\ f(\sigma) = \sigma'} w_C(\sigma)[N'_{\sigma'} : f(N_\sigma)]. \tag{P}$$

Facets on which the dimension drops contribute zero. Pushforward is linear and functorial under composition of integral affine maps.

Proof. Images of rational polyhedra are rational polyhedra: eliminate one coordinate at a time from their finite systems of affine inequalities, pairing a lower and an upper bound for that coordinate. Equalities are eliminated by substitution. This finite elimination also permits real constants. Choose a common target subdivision of all images and pull its defining hyperplanes back to the source. On every facet where f is injective, source cells correspond bijectively to the target cells lying in its image. Formula (P) therefore defines a finite weighted complex. Adding more hyperplanes merely subdivides it with the same generic weights; two choices are compared by their combined hyperplanes. This also proves invariance under a source subdivision.

Fix a target face τ' of dimension $d-1$ and sum over all source faces τ of dimension $d-1$ with $f(\tau)=\tau'$. Multiply the balancing equation at τ, after applying the linear part of f, by $a_\tau=[N'_{\tau'}:f(N_\tau)]$. For an incident full-rank facet σ, Lemma 5.17.1 replaces its term by $w_C(\sigma)a_\sigma u_{f(\sigma)/\tau'}$. If f has rank less than d on σ, its normal maps into $N'_{\tau',\mathbf{R}}$ and gives zero in the normal quotient. Each full-rank σ with $f(\sigma)\supset\tau'$ occurs exactly once: the inverse image of the target facet is its unique facet mapping to τ'. The sum is consequently the balancing equation for the weights (P). This proves balancedness, including faces bordering a zero-weight region.

Linearity follows from the sum. For a second map g, a facet contributing to $(g\circ f)_*C$ has full rank at both stages, while a dimension drop cannot be reversed. On a contributing facet the two finite indices multiply, since g is injective on the relevant direction space. After a common subdivision, summing these products proves $(g\circ f)_*=g_*f_*$. □

Theorem 5.17.3 (The corner projection formula)**.** *Let f and C be as in Theorem 5.17.2, and let φ be a continuous piecewise affine function on the target. Then*

$$f_*(D_{\varphi\circ f}C)=D_\varphi(f_*C).$$

Proof. Refine the complexes so that all images are cells and φ is affine on each image. For a target $(d-1)$-cell τ', extend the linear part of $\varphi|_{\tau'}$ to a linear form ℓ on the target. On any source face τ mapping onto τ', use $\ell\circ f$ in the corner formula. For an incident facet σ of full image dimension, the difference $\varphi_{f(\sigma)}-\ell$ vanishes tangentially to τ'. Lemma 5.17.1 therefore gives

$$a_\tau\big(\varphi_{f(\sigma)}-\ell\big)\big(f(n_{\sigma/\tau})\big)=a_\sigma\big(\varphi_{f(\sigma)}-\ell\big)(n_{f(\sigma)/\tau'}).$$

A facet collapsed to dimension $d-1$ has $f(N_{\sigma,\mathbf{R}})=N'_{\tau',\mathbf{R}}$, so its term vanishes. A lower-rank facet cannot contain such a τ. Multiply by $w_C(\sigma)$ and sum over τ and its incident facets. As in the pushforward proof, every full-rank facet over a target facet containing τ' occurs once. The resulting sum is exactly the corner weight of f_*C at τ'. If no full-rank facet occurs, both sides have weight zero there. This proves equality of the cycles. □

Corollary 5.17.4 (A constant weighted degree)**.** *Let C be a finite balanced d-cycle and $f : N_{\mathbf{R}} \to \mathbf{R}^d$ an integral affine map. For a point b outside the images of all cells of dimension at most $d-1$ and all rank-deficient facets, the number*

$$\deg_f(C;b) = \sum_{x \in |C|,\ f(x)=b} w_C(\sigma_x)[\mathbf{Z}^d : f(N_{\sigma_x})]$$

is finite and independent of b. It is the constant weight of f_*C on $\mathbf{R}^d$, allowing zero.

Proof. Each permitted preimage is in a full-rank facet, and each such facet contains at most one preimage. Formula (P) gives the displayed sum. Extend a target subdivision to a subdivision of all of $\mathbf{R}^d$, assigning weight zero to the omitted regions. Across every codimension-one face, the two full-dimensional normal vectors are opposite primitive vectors, so balancing equates their weights. Any two generic points can be joined by a polygonal path avoiding the codimension-two faces and crossing only finitely many codimension-one faces: choose its intermediate vertices outside the finitely many affine subspaces causing a nontransverse crossing. For $d = 1$ an interval suffices; for $d = 0$ there is only one target point. The weight is therefore constant throughout the target. □

References. The lattice-index method is the one used by Gathmann–Kerber–Markwig, *Tropical fans and the moduli spaces of tropical curves*, Proposition 2.25, and by Allermann–Rau, *First steps in tropical intersection theory*, Proposition 4.8. The index and cancellation arguments have been given here for finite affine complexes and real weights.

5.18 Displacement through a standard Jacobian chart

Retain the standard algebra A and its integral coordinates from Lemma 5.15.1. Let $F = (F_1, \dots, F_m)$ be represented by restricted series in $X_0, \dots, X_r, T, Y_1, \dots, Y_m$ with coefficients in K°. Write $J = \partial F/\partial Y$ and consider the nonzero affinoid algebra

$$B = A\langle Y_1, \dots, Y_m, Q\rangle/(F_1, \dots, F_m, Q \det J - 1). \tag{J}$$

We use its displayed quotient norm. In particular the coordinate images and $J^{-1} = Q\,\mathrm{adj}(J)$ have norm at most one. All the statements below keep this presentation over the original valued field.

Lemma 5.18.1 (Hensel lifting at a Banach-algebra center)**.** *Let C be a complete non-Archimedean Banach algebra, let $G \in C\langle V_1, \dots, V_m\rangle^m$ have norm at most one, and let $v \in C^m$ have norm at most one. Suppose $D = G'(v)$ is invertible with $\|D^{-1}\| \le 1$ and $\|G(v)\| \le \delta < 1$. There is a unique root $v + h$ with $\|h\| < 1$, and it satisfies $\|h\| \le \delta$. Its Jacobian inverse has norm at most one. Moreover, if two such systems differ in coefficient norm by at most ϵ, and their roots both lie at distance less than one from the same center with an inverse Jacobian of norm at most one for the first system at that center, their roots differ by at most ϵ.*

Proof. Translation by the bounded tuple v is a contractive substitution. Expanding gives

$$G(v + H) = e + DH + N(H), \qquad e = G(v),$$

where N has terms of degree at least two and coefficient norms at most one. This assertion follows first for polynomials by the binomial formula, then for restricted series by uniform truncation. For $\|h\|, \|k\| \le \rho < 1$, telescoping each monomial gives

$$\|N(h)\| \le \|h\|^2, \qquad \|N(h) - N(k)\| \le \rho\|h - k\|.$$

Consequently $h \mapsto -D^{-1}e - D^{-1}N(h)$ maps the closed ball of radius δ to itself and is a contraction of ratio at most δ. Starting at zero, successive differences tend to zero geometrically; completeness gives a fixed point. Any other root at distance less than one lies with it in a ball of some radius $\rho < 1$, where the same estimate proves equality. The Jacobian changes by a matrix of norm at most δ, so a matrix geometric series gives the asserted inverse bound.

For the perturbation assertion, let the two roots be z, w, and write the first system as G. Telescoping its translated monomials gives

$$G(z) - G(w) = (D + E)(z - w), \qquad \|E\| \le \max(\|z - v\|, \|w - v\|) < 1.$$

The matrix $D + E$ has inverse norm at most one. One term on the left is zero; the other has norm at most ϵ because w is a root of the second system. This proves the bound. All constructions use Banach-algebra operations, so nilpotents are retained. □

Proposition 5.18.2 (The bounded displacement expansion)**.** *Put $U = (S_1, \dots, S_r, Z_1, \dots, Z_q)$. There are bounded K-linear maps $D_\nu : B \to B$, $\nu \in \mathbb{N}^{r+q}$, with $D_0 = \mathrm{id}$ and $\|D_\nu b\| \le \|b\|$, such that for every $0 < \delta < 1$ the series*

$$\sigma_\delta(b) = \sum_\nu D_\nu(b) U^\nu \in B\{\delta^{-1}U\}$$

defines a contractive homomorphism, extending the base displacement

$$X_i \mapsto X_i(1 + S_i)\ (i \ge 1), \quad X_0 \mapsto X_0 \prod_i (1 + S_i)^{-1}, \quad T_j \mapsto T_j + Z_j.$$

It is characterized by this base formula and $\|\sigma_\delta(Y) - Y\| < 1$. In fact

$$\|\sigma_\delta(b) - b\| \le \delta\|b\|, \qquad D_\nu(bc) = \sum_{\alpha+\beta=\nu} D_\alpha(b) D_\beta(c).$$

Proof. Work in $C_\delta = B\{\delta^{-1}U\}$. The base formulas define a contractive homomorphism by geometric inversion and bounded substitution. On each integral coordinate the difference from its original image has norm at most δ. Telescoping monomials, passing to restricted series, and taking quotient infima therefore give $\|\sigma_\delta(a) - a\| \le \delta\|a\|$ for $a \in A$.

Apply the base displacement to the coefficients of F. At the center $Y \in B^m$ the new error has norm at most δ, since $F(Y) = 0$. Its Jacobian differs from $J(Y)$ by a matrix of norm at most δ. As $J(Y)^{-1} = Q\,\mathrm{adj}(J(Y))$ has norm at most one, the new Jacobian also has inverse norm at most one. Lemma 5.18.1 gives the unique root $Y + h_\delta$, with $\|h_\delta\| \le \delta$. The determinant at that root has an inverse Q_δ of norm at most one and $\|Q_\delta - Q\| \le \delta$, again by the geometric inverse formula. These images kill all relations in (J) and give a contractive homomorphism $B \to C_\delta$. The same telescoping and quotient-infimum argument gives its displayed difference bound on every $b \in B$.

If $\delta' \le \delta < 1$, restriction from radius δ to radius δ' carries this root to a root at distance less than one from Y. Uniqueness identifies it with the root constructed at radius δ'. Thus all coefficient expansions agree. Evaluation at $U = 0$ is the identity, by the same uniqueness. Write their coefficients as $D_\nu(b)$. Contractivity at every radius gives

$$\|D_\nu(b)\|\delta^{|\nu|} \le \|b\|.$$

Letting δ increase to one proves $\|D_\nu(b)\| \le \|b\|$. The homomorphism identity at any positive radius, together with uniqueness of coefficients, gives the convolution identity and K-linearity. □

Theorem 5.18.3 (The strict-time analytic lift)**.** *For $x \in \mathcal{M}(B)$ and $0 \le t < 1$, the formula*

$$|b(H_B(x,t))| = \max_{\nu} |D_\nu(b)(x)| t^{|\nu|}, \qquad 0^0 = 1, \tag{E}$$

defines a jointly continuous map $H_B : \mathcal{M}(B) \times [0,1) \to \mathcal{M}(B)$ with $H_B(x,0) = x$. For the structure map $f : \mathcal{M}(B) \to V$,

$$f(H_B(x,t)) = H(f(x),t).$$

If b has quotient norm at most one, then $|b(H_B(x,t))| < 1$ if and only if $|b(x)| < 1$. Thus every strict-time trajectory preserves its reduction prime in the displayed integral model.

Proof. For $t > 0$, evaluate the coefficients of $\sigma_\delta(b)$ in $\mathcal{H}(x)$ with $t < \delta < 1$ and then use the multiplicative radius-t Gauss norm. This gives a bounded homomorphism into a complete Gauss field and hence an actual analytic point. Its norm is (E). At $t = 0$ the constant coefficient gives x. The base-coordinate formulas identify the composite with f.

On $\mathcal{M}(B) \times [0,\delta]$, choose $\delta < \delta' < 1$. The restricted series $\sigma_{\delta'}(b)$ has uniformly small tails on this product. Each finite truncation of (E) is a finite maximum of continuous functions, so its uniform limit is continuous. These intervals cover $[0,1)$ and prove joint continuity. For a norm-at-most-one element b, its constant coefficient is $b(x)$ and its nonconstant terms have norms at most t. Thus a constant coefficient of norm one stays of norm one; if it is smaller than one, every term is bounded by $\max(|b(x)|, t) < 1$. This proves the reduction assertion. □

Proposition 5.18.4 (Functoriality and the composition law)**.** *A contractive homomorphism between two presentations (J) over the same standard base commutes with their coefficient operators D_ν. The lifts therefore commute with such morphisms, with integral Laurent restrictions, and with complete isometric ground-field extension. They satisfy*

$$H_B(H_B(x,s),t) = H_B(x, \max(s,t)) \qquad (0 \le s,t < 1).$$

Proof. Let $\psi : B \to C$ be the homomorphism in question. Applying ψ to the lifted Y-tuple gives a root of the base-displaced B-equations in $C\{\delta^{-1}U\}$. Applying the C-displacement to $\psi(Y)$ gives another such root. Both differ

from $\psi(Y)$ by norm at most δ, and the original Jacobian inverse has norm at most one. Lemma 5.18.1 identifies them. The inverse determinant and then every element of B agree by bounded substitution. Comparing coefficients proves the assertion. The same proof treats a complete isometric scalar extension using the identical equations.

For an integral Laurent restriction adjoining g^{-1}, both g and g^{-1} have norm at most one. The displacement of g differs from g by norm at most δ; factoring out g and using geometric inversion extends the map uniquely to the inverse, with the same bound. This proves the restriction assertion. It also shows that two bounded presentations identified over the fixed base give the same displacement.

For the composition law, take independent variables (S, Z) and (S', Z') of radii $s, t < 1$. The two successive lifts solve the base-displaced equations whose relative coordinates are

$$W_i = S_i + S'_i + S_i S'_i, \qquad V_j = Z_j + Z'_j.$$

The resulting Y-tuple differs from the original one by norm at most $\max(s, t) < 1$. The single lift evaluated at (W, V) has the same property and solves the same equations. Hensel uniqueness identifies the two tuples. The isometric Gauss-coordinate change in Proposition 5.15.3 then identifies their norms with the single displacement of radius $\max(s, t)$. This gives the identity for all $b \in B$, and the zero-parameter cases are immediate. □

Lemma 5.18.5 (The pointwise endpoint)**.** *For every $x \in \mathcal{M}(B)$, the formula*

$$|b(H_B(x, 1))| = \sup_{\nu} |D_\nu(b)(x)| = \lim_{t \uparrow 1} |b(H_B(x, t))|$$

defines a point of $\mathcal{M}(B)$ and extends its trajectory continuously to $[0, 1]$. Each endpoint evaluation is lower semicontinuous as a function of x. The endpoint commutes with all strict-time maps and is idempotent:

$$H_B(H_B(x, 1), t) = H_B(x, 1) = H_B(H_B(x, t), 1), \qquad 0 \le t \le 1.$$

Proof. For each b, the strict-time value is nondecreasing and bounded by $\|b\|$. Its limit is the displayed coefficient supremum: each fixed coefficient is attained in the limit, and their supremum bounds every time value. Passing to limits in the multiplicative, ultrametric, and scalar identities proves that this is a bounded multiplicative seminorm extending the given absolute value.

Evaluation topology gives convergence to its point, hence continuity of the trajectory at time one. A supremum of continuous coefficient evaluations is lower semicontinuous.

Fix $t < 1$. Continuity of the strict-time map in x and Proposition 5.18.4 allow $s \uparrow 1$ in $H_B(H_B(x,s),t) = H_B(x,\max(s,t))$. The resulting identity is $H_B(H_B(x,1),t) = H_B(x,1)$. In the opposite order, pointwise convergence applied to the fixed point $H_B(x,t)$ gives $H_B(H_B(x,t),1) = H_B(x,1)$. Finally let $t \uparrow 1$ in the first equality, again using the continuous trajectory of the fixed point $H_B(x,1)$, to get idempotence. □

References. The construction is an explicit Banach-algebra Hensel lift of mixed Gauss displacement. The norm estimates are uniform in the real parameter below one.

5.19 Pure dimension and geometric weights

The initial scheme is taken in the sense of Theorem 5.13.6. A scheme is pure of dimension d if every irreducible component of its underlying space has dimension d; embedded components are allowed.

Lemma 5.19.1 (Finite filtrations and zero-dimensional algebras)**.** *Every finite module over a Noetherian ring has a finite filtration whose nonzero successive quotients are $A/\mathfrak{p}$ for prime ideals $\mathfrak{p}$. A zero-dimensional algebra of finite type over a field k is finite-dimensional over k.*

Proof. Finite free modules over a Noetherian ring are Noetherian by induction on their rank, using the first-coordinate ideal and the kernel of that coordinate; hence their quotients are Noetherian. In a nonzero finite module choose a nonzero element whose annihilator is maximal among annihilators of nonzero elements. Such a maximum exists by the ascending chain condition. Its annihilator $\mathfrak{p}$ is prime: if ab annihilates the element and b does not, the annihilator of its nonzero b-multiple is the same maximal annihilator, so $a \in \mathfrak{p}$. This yields a submodule $A/\mathfrak{p}$. Repeat in the quotient. The resulting ascending chain of submodules terminates.

For the second assertion, finite-type k-algebras are Noetherian by [StacksAlg, Tag 00FN]. Apply the filtration to the algebra itself. Each prime quotient is a zero-dimensional finite-type domain. Its fraction field has transcendence degree zero by [StacksAlg, Tag 00P0]. Its finitely

many algebra generators are therefore algebraic over k, so the quotient is a finite-dimensional field. A finite extension of these vector spaces is finite-dimensional. □

Proposition 5.19.2 (Pure dimension of initial schemes)**.** *Let $X \subset \operatorname{Spec} K[M]$ be pure of dimension d. For every $w \in \operatorname{Trop}(X)$, every initial scheme $\operatorname{in}_{w,t,L}(X)$ is pure of dimension d.*

Proof. By [StacksAlg, Tag 02NK], extension from K to L preserves pure dimension. Translate by t and work at weight zero over L. Write $R = L^\circ$, $k = \widetilde{L}$ and $I \subset L[M]$ for the translated ideal. Its finitely many minimal primes are $P_1, \dots, P_s$. Let

$$B = R[M]/(I \cap R[M]), \qquad B_i = R[M]/(P_i \cap R[M]).$$

Each B_i is a domain of finite type containing R, and its generic fibre is the dimension-d domain $L[M]/P_i$. The exact valuation-ring dimension theorem [StacksAlg, Tag 00QK] says that, whenever $B_i \otimes_R k$ is nonzero, its spectrum is equidimensional of dimension d. Its hypotheses require finite type, not finite presentation or a discrete valuation.

The identity

$$\sqrt{I \cap R[M]} = \sqrt{I} \cap R[M] = \bigcap_i (P_i \cap R[M])$$

shows that $\operatorname{Spec} B$ is the union of the closed subsets $\operatorname{Spec} B_i$. Taking the inverse image of this finite union in the closed fibre shows that $\operatorname{Spec}(B \otimes_R k)$ is the union of the nonempty pure dimension-d special fibres just described. A finite union of pure dimension-d closed subsets is pure of dimension d: every irreducible component is a maximal irreducible component among them, and a proper containment of irreducible closed subsets strictly lowers their finite dimensions. The closed fibre is nonempty by Theorem 5.13.6. □

Proposition 5.19.3 (The tangent torus of an initial stratum)**.** *Use the finite complex constructed in Theorem 5.16.5. Let w lie in the relative interior of a cell $\tau \subset \operatorname{Trop}(X)$, put $L_\tau = \operatorname{span}_{\mathbf{R}}(\tau - \tau)$ and $M_0 = M \cap L_\tau^\perp$. The ideal of $Y = \operatorname{in}_w(X)$ is generated by elements of $k[M_0]$, after multiplication of its generators by unit characters. Consequently it is extended from its intersection with $k[M_0]$, and*

$$Y \simeq T_{N_\tau} \times Z_\tau, \qquad Z_\tau = \operatorname{Spec}\big(k[M_0]/(I_Y \cap k[M_0])\big), \quad N_\tau = N \cap L_\tau.$$

The product uses a lattice splitting, while the quotient scheme Z_τ is intrinsic to Y and N_τ.

Proof. Use the finitely many homogeneous pivot rows in the proof of Theorem 5.16.5, and divide each row by its pivot character. A surviving exponent difference a satisfies one of the affine Plücker equalities defining the cell. That equality holds throughout the relative interior of τ, hence its linear part vanishes on L_τ. Thus $a \in M_0$ after dehomogenization. These rows generate the initial Laurent ideal, so it is extended from an ideal $J_0 \subset k[M_0]$.

The lattice N_τ is saturated. Lemma 5.14.1 splits $N = N_\tau \oplus Q$, and dually $k[M]$ is a Laurent polynomial ring over $k[M_0]$. Comparing coefficients in these additional Laurent variables shows $J_0 k[M] \cap k[M_0] = J_0$. The quotient ring is therefore $(k[M_0]/J_0)[N_\tau^\vee]$, proving the assertion including its scheme structure. □

Lemma 5.19.4 (A zero tropical support forces dimension zero)**.** *Let Z be a nonempty closed subscheme of a torus over a complete field k. If $\mathrm{Trop}(Z) \subseteq \{0\}$, then Z is zero-dimensional and its coordinate algebra is finite over k.*

Proof. Suppose an integral component has positive dimension, with function field F. By [StacksAlg, Tag 00P0], F/k has positive transcendence degree. At least one of its torus-coordinate generators, say z_1, is transcendental over k. Extend z_1 to a maximal algebraically independent subset $z_1, \dots, z_e$ of a finite field-generating set. Then F is finite over $k(z_1, \dots, z_e)$. Give the latter field its Gauss absolute value with $|z_1| \neq 1$ and arbitrary positive radii on the other variables, and complete it to E. The Gauss norm is multiplicative by Proposition 1.2.2.

The finite nonzero E-algebra $D = F \otimes_{k(z_1,\dots,z_e)} E$ has a maximal proper ideal: choose one of maximal E-dimension. Its quotient is a finite field extension E'/E, which has the extending complete absolute value by Lemma 1.12.1. The induced map $F \to E'$ is injective, since it is a unital map from a field. Restricting its norm to the coordinate algebra gives an analytic point of Z by Proposition 2.10.1, with $|z_1| \neq 1$. This contradicts the tropical-support hypothesis. All components therefore have dimension zero. Apply Lemma 5.19.1 to obtain finiteness over k. □

Theorem 5.19.5 (Pure dimension of algebraic tropicalization)**.** *If $X \subset \operatorname{Spec} K[M]$ is nonempty and pure of dimension d, then $\operatorname{Trop}(X)$ is a nonempty finite pure d-dimensional integral $v(K^\times)$-affine polyhedral complex. At the relative interior of each maximal cell σ, the quotient Z_σ of Proposition 5.19.3 is a nonempty finite scheme over the residue field.*

Proof. The Gauss-field construction in Lemma 5.19.4, with arbitrary radii and allowing an empty transcendence basis, gives an analytic point on each nonempty integral component. Thus the tropicalization is nonempty. The finite complex is Theorem 5.16.5. Fix a maximal cell σ, a relative-interior point w, and put $s = \dim \sigma$. The local star at w is the vector space L_σ. By Theorem 5.16.6, $Y = \operatorname{in}_w(X)$ has tropical support L_σ. By Proposition 5.19.3, $Y = T_{N_\sigma} \times Z_\sigma$. Every analytic point of Z_σ gives a point of this product by assigning value one to the first torus coordinates. It follows that $\operatorname{Trop}(Z_\sigma) \subseteq \{0\}$. The quotient is nonempty, since Y is nonempty. Lemma 5.19.4 makes Z_σ finite.

Every component of $T_{N_\sigma} \times Z_\sigma$ has dimension s: a prime quotient of its finite coefficient algebra is a finite field extension, and its Laurent polynomial ring has transcendence degree s, so [StacksAlg, Tag 00P0] applies. Proposition 5.19.2 gives dimension d for the same components. Thus $s = d$. This holds for every maximal cell. □

Definition 5.19.6 (The geometric tropical weight)**.** At $w \in \operatorname{relint}(\sigma)$ as in Theorem 5.19.5, define

$$m_X(\sigma) = \dim_k \Gamma(Z_\sigma, \mathcal{O}_{Z_\sigma}).$$

Proposition 5.19.7 (Geometric multiplicity and its invariance)**.** *The weight is a positive integer. It is independent of the chosen weight-realizing field, translating point, and lattice splitting. It equals the sum of the generic lengths of the irreducible components of the initial scheme after a residue extension splitting its finite transverse algebra. In particular it equals the usual sum of geometric generic lengths over an algebraic closure.*

Proof. Let $A = \Gamma(Z_\sigma, \mathcal{O})$, a nonzero finite-dimensional k-algebra. Finite-dimensional scalar extension preserves its dimension. A finite field extension k'/k splits the characteristic polynomials of a finite set of algebra generators of A. Every residue field of $A \otimes_k k'$ is then k', because the images of those

generators are roots in k'. Choose a composition series by successively taking a proper submodule of maximal vector-space dimension. Its factors are the one-dimensional residue fields. Localizing the series at each maximal ideal counts each factor exactly once, and gives

$$\dim_k A = \dim_{k'}(A \otimes_k k') = \sum_z \operatorname{length}\big((A \otimes_k k')_z\big).$$

Adjoining Laurent variables and localizing at a generic point tensors the local Artinian factor with the rational function field of the corresponding torus. Its composition series tensors to a composition series with the same number of simple factors. Thus the displayed summands are exactly the generic lengths of $Y_{k'}$. The intrinsic quotient description in Proposition 5.19.3 makes the lattice splitting irrelevant. Theorem 5.13.6 compares all other choices by residue extension and a torus translation; translation preserves the tangent subtorus and induces a translation on its quotient. The same finite dimension is therefore obtained from every choice. □

Proposition 5.19.8 (Constancy, refinement, and complete base change)**.** *The integer $m_X(\sigma)$ is constant on the relative interior of each maximal initial stratum. The resulting weighted polyhedral complex is independent of its choice of initial-stratum refinement, and every complete isometric extension of K preserves its support and weights.*

Proof. Theorem 5.16.5 compares the initial schemes at two relative-interior points by a single torus translation after residue extension. The cell has the same tangent lattice at both points, so the comparison descends to their transverse finite quotients. Proposition 5.19.7 equates the dimensions. A subdivision retains the tangent lattice on its dimension-d pieces and therefore retains the weights. Any two initial-stratum complexes have a common refinement; at a point belonging to both relative interiors their weights are computed from the identical initial scheme and tangent lattice. Finally, the initial scalar-extension identity in Proposition 5.13.4, together with the common-extension comparison in Theorem 5.13.6, gives the same finite quotient after residue extension. Its dimension is unchanged. □

References. The classical pure-dimension and multiplicity statements are reconstructed here from the exact valuation-ring dimension theorem of the Stacks Project, the finite Plücker construction above, and the finite transverse algebra of an initial stratum.

5.20 Stable intersection from the diagonal

Retain the finite real cycle convention of Section 5.14. Put $n = \operatorname{rank} N$. Choose a lattice basis of $N^\vee$, and let x_i, y_i be the corresponding coordinates on $N_{\mathbf{R}} \times N_{\mathbf{R}}$. Set

$$h_i(x,y) = \max\{0, x_i - y_i\}, \qquad \mathcal{D}_{xy} = D_{h_1} \cdots D_{h_n},$$
$$\Delta = \{(x,x) : x \in N_{\mathbf{R}}\}.$$

Lemma 5.20.1 (A basis-independent diagonal operator)**.** *For every balanced cycle Z in $N_{\mathbf{R}} \times N_{\mathbf{R}}$, the cycle $\mathcal{D}_{xy}Z$ is balanced, is supported in $|Z| \cap \Delta$, and is independent of the chosen basis of $N^\vee$. Interchanging x and y preserves this operator.*

Proof. By Theorem 5.14.5, successive corners are balanced and their order does not matter. A corner by $\max(0, \ell)$ is supported where $\ell = 0$, since off that hyperplane the function is affine. It follows inductively that the final support lies in Δ.

Every change of integral basis is a composition of row interchanges, sign changes, and addition of an integer multiple of one row to another. Row interchanges use commutation of corners. A sign change replaces $\max(0, \ell)$ by $\max(0, -\ell) = \max(0, \ell) - \ell$, which has the same corner operator. For a row operation $\ell_i \mapsto \ell_i + a\ell_j$, perform the j-th corner first. Its support is contained in $\ell_j = 0$, where the old and new i-th functions coincide. Restriction locality, Lemma 5.14.6, proves equality. The elementary row operations generate $\mathrm{GL}_n(\mathbf{Z})$ by Lemma 5.14.1, so this proves basis independence. Interchanging x, y changes each linear form to its negative and is already covered. □

Definition 5.20.2 (The stable product)**.** For balanced cycles C, E of dimensions p, q in $N_{\mathbf{R}}$, define

$$C \cdot E = \pi_*\big(\mathcal{D}_{xy}(C \times E)\big), \qquad \pi(x,y) = x.$$

The projection on the support in Δ is a lattice isomorphism. The product has dimension $p + q - n$, and is zero when that number is negative.

Theorem 5.20.3 (The ring of balanced cycles)**.** *The stable product is bilinear, commutative, associative, and compatible with weighted subdivision and integral affine lattice isomorphisms. Its unit is* $[N_{\mathbf{R}}]$ *with weight one, and* $|C \cdot E| \subseteq |C| \cap |E|$*.*

Proof. Bilinearity and refinement invariance follow from those of products, corners, and pushforwards. The preceding lemma gives the support assertion, commutativity, and invariance under changes of lattice basis. Simultaneous translation of x, y leaves their differences unchanged, proving affine invariance.

For the unit, begin with $N_{\mathbf{R}} \times E$. Impose $x_i = y_i$ one coordinate at a time by its corner. Before the i-th step, x_i is still a free lattice coordinate, so the two sides of $x_i - y_i = 0$ have opposite primitive normals and the slope jump of $\max(0, x_i - y_i)$ is exactly one. Each facet thus keeps the weight of its E factor. At a face inherited from E, the function has a common affine extension on either side away from that equality and contributes zero. The final cycle is the diagonal copy of E with its original weights. Projection therefore gives $[N_{\mathbf{R}}] \cdot E = E$.

For associativity, work on $C \times E \times F$ with coordinates x, y, z. By product locality, imposing the $x = y$ diagonal first gives the diagonal copy of $(C \cdot E) \times F$. On this support the functions $\max(0, x_i - z_i)$ and $\max(0, y_i - z_i)$ agree. Hence the lift of $(C \cdot E) \cdot F$ to the small diagonal is

$$\mathcal{D}_{yz}\mathcal{D}_{xy}(C \times E \times F).$$

Starting instead with $E \cdot F$ gives $\mathcal{D}_{xy}\mathcal{D}_{yz}(C \times E \times F)$. The corner operators commute, so the two cycles agree before projection to x. If an intermediate dimension is negative, both expressions vanish by the same commuting-operator calculation. This proves associativity in all degrees. □

Lemma 5.20.4 (Complementary fans and displacement)**.** *Let* A, B *be finite balanced fans in* $N_{\mathbf{R}}$*, of dimensions* p, q *with* $p+q = n$*. For a vector* b *outside the finitely many lower-dimensional images of faces under* $(x, y) \mapsto x - y$*, the coefficient of their stable product at the origin is*

$$\sum_{\substack{\sigma \in A^{(p)},\ \tau \in B^{(q)} \\ b \in \operatorname{relint}(\sigma - \tau) \\ N_{\sigma,\mathbf{R}} + N_{\tau,\mathbf{R}} = N_{\mathbf{R}}}} w_A(\sigma) w_B(\tau) [N : N_\sigma + N_\tau]. \tag{F}$$

In particular this sum is independent of the generic vector b, including for signed real weights.

Proof. Put $Z = A \times B$ and $f(x, y) = x - y$. Its dimension is n. By Corollary 5.17.4, $f_*Z = c[N_{\mathbf{R}}]$, where c is the generic weighted degree. On a full-rank product facet, f is injective because the two direction spaces have dimensions adding to n. Its lattice image is $N_\sigma + N_\tau$, and a generic inverse image exists precisely when $b \in \operatorname{relint}(\sigma - \tau)$. Thus c is the displayed sum.

On $N_{\mathbf{R}}$ let $g_i(z) = \max(0, z_i)$. Repeated use of Theorem 5.17.3 gives

$$f_*\big(D_{g_1 \circ f} \cdots D_{g_n \circ f} Z\big) = D_{g_1} \cdots D_{g_n}\big(c[N_{\mathbf{R}}]\big) = c[0].$$

The final equality is the successive unit slope jumps of the coordinate hyperplanes. The source is a zero-dimensional fan supported on the diagonal, so it is a multiple of the origin. Pushforward does not change a zero-dimensional point weight. By the definition of the diagonal product this multiple is also the coefficient of $A \cdot B$. It is therefore c, as required. □

Theorem 5.20.5 (The local fan displacement formula)**.** *Let C, E be finite balanced real cycles in $N_{\mathbf{R}}$, of dimensions p, q, and put $r = p + q - n \geq 0$. Choose a common polyhedral refinement of their intersection and let γ be an r-dimensional face. At $a \in \operatorname{relint}(\gamma)$, take the two local stars and quotient by $L = N_{\gamma,\mathbf{R}}$. Their dimensions are complementary in $N_{\mathbf{R}}/L$. The weight of $C \cdot E$ on γ is the sum (F) for these quotient fans. Equivalently it is the weighted small-displacement limit of the transverse intersections of C and $E + \varepsilon b$, with lattice factors $[N : N_\sigma + N_\tau]$.*

Proof. Stars commute with corners and products. Both stars at a have L as a lineality space: the minimal face of either original complex containing a contains the local directions of γ. Since N_γ is saturated, Lemma 5.14.1 allows us to choose $N = N_\gamma \oplus Q$. Write the two stars as $L \times A$ and $L \times B$. The diagonal cuts in the L coordinates give the diagonal copy of L with weight one, by the unit calculation in Theorem 5.20.3. The remaining cuts give $A \cdot B$. Their dimensions satisfy

$$\dim A + \dim B = (p - r) + (q - r) = n - r = \operatorname{rank} Q.$$

The preceding lemma computes the coefficient at their origin, which is the desired weight on γ. For every contributing pair of original facets, N_γ is contained in both direction lattices, so

$$[N/N_\gamma : (N_\sigma + N_\tau)/N_\gamma] = [N : N_\sigma + N_\tau].$$

Finally choose a small neighborhood of a meeting only the faces that contain its minimal faces. In this neighborhood the original cells are translates of their local tangent cones. For a generic b and sufficiently small $\varepsilon > 0$, a transverse displaced pair approaching a is therefore exactly a pair counted by the quotient-fan formula; the signs agree because $x \in C \cap (E + \varepsilon b)$ means $x - y = \varepsilon b$. Only finitely many cells occur, so the incidence conditions are constant for all sufficiently small positive ε. Summing their weights gives the claimed weighted limit. There is no additional support in the relative interior of an intersection cell of dimension $s > r$: quotienting its common s-dimensional lineality gives a product of dimension $r - s < 0$, which is zero. Cells of dimension less than r cannot carry an r-cycle. Thus refining the r-faces gives all coefficients of the cycle. □

Corollary 5.20.6 (Pointwise smooth weights)**.** *Suppose the weights of C, E are smooth functions on their cells, extending smoothly to their faces, and that their values satisfy balancing at every point of every face. Freezing the weights at each point and applying the local fan formula defines a smooth-weighted balanced product. It is independent of subdivision and generic displacement, and is bilinear, commutative, and associative.*

Proof. At a fixed point, the frozen stars are constant-weight balanced fans. Theorem 5.20.5 makes their product coefficient well-defined. On any fixed prospective intersection face, this coefficient is a finite sum of products of restrictions of the original weights multiplied by constant lattice indices. It is therefore smooth. At a lower face, freezing again identifies the normal equation with balancing of the product of the frozen fans. Refinement and the two bracketings of a triple product are compared by the same frozen fan calculation, using Theorem 5.20.3. The equalities hold at every point, hence as equalities of smooth coefficient functions. □

References. The diagonal construction is due to Allermann–Rau, *First steps in tropical intersection theory*, Section 9. For the stable fan description see Jensen–Yu, *Stable intersections of tropical varieties*, Section 2. Here basis independence is proved by elementary row operations, and the displacement formula by the balanced pushforward of the difference map.

5.21 Continuity at the endpoint of a Jacobian chart

Lemma 5.21.1 (Finite control of bounded coefficients)**.** *Let C be a nonzero affinoid algebra, and let $R \subseteq C$ be a Noetherian subring all of whose elements have norm at most one. For a family $c_\nu \in R$ indexed by $\mathbb{N}^d$, put*

$$q(x,t) = \max_\nu |c_\nu(x)| t^{|\nu|} \quad (0 \le t < 1), \qquad q(x,1) = \sup_\nu |c_\nu(x)|.$$

There is a finite set of indices E for which

$$q(x,1) = \max_{\nu \in E} |c_\nu(x)| \qquad (x \in \mathcal{M}(C)).$$

If the family is nonzero and $N = \max_{\nu \in E} |\nu|$, then $t^N q(x,1) \le q(x,t) \le q(x,1)$ for $0 < t \le 1$. Consequently q is jointly continuous on $\mathcal{M}(C) \times [0,1]$.

Proof. The ideal of R generated by all c_ν is finitely generated. Express a finite generating list in terms of the original family and take the union of its finite index sets; thus finitely many actual c_ν, $\nu \in E$, generate the same ideal. Every other coefficient is a finite sum of these generators multiplied by elements of R. Since all those multipliers have norm at most one, evaluation gives the claimed finite maximum at every x. If the ideal is zero, the conclusion is immediate. Otherwise retaining those same terms in $q(x,t)$ gives the lower bound $t^N q(x,1)$; the upper bound is its definition. In particular

$$0 \le q(x,1) - q(x,t) \le 1 - t^N.$$

At time one this is uniform convergence to a continuous finite maximum. For times bounded above by $\delta < 1$, the coefficient bound makes the tails at most δ^{n+1} after total degree n, so finite maxima converge uniformly and give joint continuity there as well. □

Lemma 5.21.2 (Polynomial implicit equations have finite endpoint control)**.** *Let C be an affinoid algebra receiving the standard algebra A contractively. Suppose the system $G \in K^\circ[X_0, \dots, X_r, T, Y]^m$ has a root $y \in C^m$ of norm at most one and its determinant has an inverse $q \in C$ of norm at most one. Lift this root under the base displacement by Lemma 5.18.1. For every polynomial $P \in K[X_0, \dots, X_r, T, Y, Q]$, the norm of P evaluated at the displaced base coordinates, the lifted root, and the inverse determinant extends jointly continuously to $\mathcal{M}(C) \times [0,1]$ by taking its coefficient supremum at time one.*

Proof. First assume the coefficients of P belong to K°. Let $R \subseteq C$ be the ring generated over the image of $\mathbb{Z}$ by the finitely many coefficients of G, P,

the base-coordinate images, the coordinates of y, and q. Every generator has norm at most one, hence so does every element of R. The ring $\mathbb{Z}$ is Noetherian, since each ideal is generated by its least positive element, or is zero. Its image is a quotient, and [StacksAlg, Tag 00FN] therefore makes R Noetherian.

We check that every formal displacement coefficient lies in this single ring. The base displacement has coefficients in R: the inverse factors $(1+S_i)^{-1}$ have integral coefficients. Write the lifted root as $y + h(U)$, with $h(0) = 0$. In each positive total degree, the coefficient of an as-yet-unknown term of h in $G_\sigma(y+h)$ is the original matrix $G'(y)$ times that coefficient; all remaining terms use only already determined lower degrees. The inverse matrix $q\,\mathrm{adj}(G'(y))$ has its entries in R. Induction on total degree therefore puts every coefficient of h in R. This formal recursion agrees with the analytic root at each radius less than one by uniqueness. Recursively inverting its determinant puts every coefficient of the new inverse determinant in R as well. Polynomial substitution then does the same for P.

Lemma 5.21.1 now applies to this coefficient family and proves the assertion. For arbitrary P, multiply it by a nonzero scalar making its finitely many coefficients integral, apply the result, and divide the real-valued norm function by the absolute value of that scalar. Such a scalar exists because the ground-field valuation is nontrivial. □

Theorem 5.21.3 (Joint continuity for restricted-series Jacobian charts)**.** *For every presentation* (J)*, the pointwise endpoint of Lemma 5.18.5 makes*

$$H_B : \mathcal{M}(B) \times [0,1] \longrightarrow \mathcal{M}(B)$$

jointly continuous. Its full homotopy commutes with the contractive morphisms, integral Laurent restrictions and complete isometric extensions of Proposition 5.18.4.

Proof. We first treat a polynomial representative $b = P(X,T,Y,Q) \in B$. Choose polynomial systems $F^{(n)} \in K^\circ[X,T,Y]^m$ with $\|F^{(n)} - F\| \le \epsilon_n < 1$ and $\epsilon_n \to 0$, using the fixed restricted-series representatives. Differentiation is contractive for the unit-radius Gauss norms, so the Jacobians are within the same bound. At the original tuple $Y \in B^m$, the system $F^{(n)}$ has error at

most ϵ_n and an inverse Jacobian of norm at most one. Thus Lemma 5.18.1, now in B, gives an exact root Y_n with

$$\|Y_n - Y\| \le \epsilon_n, \qquad Q_n = \det((F^{(n)})'(Y_n))^{-1},$$
$$\|Q_n\| \le 1, \qquad \|Q_n - Q\| \le \epsilon_n.$$

Displace the base and lift the two roots, obtaining Y_δ and $Y_{n,\delta}$ in $B\{\delta^{-1}U\}$ for $\delta < 1$. Both roots lie at distance at most $\max(\delta, \epsilon_n) < 1$ from the original tuple Y. Their displaced systems differ by at most ϵ_n, since base substitution is contractive. The perturbation part of Lemma 5.18.1 therefore gives, uniformly for every $\delta < 1$,

$$\|Y_{n,\delta} - Y_\delta\| \le \epsilon_n.$$

The determinant difference has the same bound, by telescoping and the derivative bound. Both inverses have norm at most one, so the identity $u^{-1} - v^{-1} = u^{-1}(v - u)v^{-1}$ gives $\|Q_{n,\delta} - Q_\delta\| \le \epsilon_n$. Let $P_n(U)$ denote P evaluated on the displaced base, $Y_{n,\delta}$ and $Q_{n,\delta}$. This definition is compatible with all radii. If C_P is the maximum absolute value of the coefficients of P, telescoping its finitely many monomials yields

$$\|P_n(U) - \sigma_\delta(b)\|_\delta \le C_P \epsilon_n \qquad (0 < \delta < 1). \tag{A}$$

By Lemma 5.21.2, the norm functions defined by $P_n(U)$, with coefficient suprema at time one, are jointly continuous on the full product. Inequality (A) bounds the differences of their real-valued norms from $|b(H_B(x,t))|$ by $C_P\epsilon_n$ for all x and $t < 1$. Passing to the already established pointwise limits gives the same bound at $t = 1$. Thus $|b(H_B(x,t))|$ is a uniform limit of continuous functions on the full product and is continuous there.

Finally polynomial representatives are dense in the quotient Banach algebra B. Contractivity of every strict-time evaluation and of the endpoint seminorm gives

$$\big|\,|b(H_B(x,t))| - |b'(H_B(x,t))|\,\big| \le \|b - b'\| \quad (0 \le t \le 1).$$

Uniform polynomial approximation proves continuity for every $b \in B$, hence joint continuity into its spectrum. The previously proved strict-time functorial identities pass to the endpoint by pointwise convergence. □

Theorem 5.21.4 (Retraction to the inverse-image skeleton)**.** *For the structure map $f : \mathcal{M}(B) \to V$, put $\Sigma_B = f^{-1}(\Sigma_a)$. Then H_B is a strong deformation retraction onto Σ_B. It satisfies the maximum-parameter composition law for all $s, t \in [0,1]$. Every fibre of $\Sigma_B \to \Sigma_a$ is finite.*

Proof. The fibre over any $z \in V$ is the affinoid spectrum of $B\widehat{\otimes}_A\mathcal{H}(z)$ by Theorem 2.33.11. The equations $F = 0$, $Q \det J - 1 = 0$ in the $m+1$ variables (Y, Q) have the block Jacobian

$$\begin{pmatrix} J & 0 \\ Q\,\partial(\det J)/\partial Y & \det J \end{pmatrix}, \qquad \det = (\det J)^2 \in B^\times.$$

The matrix criterion Theorem 2.41.7 therefore gives a rank-zero quasi-smooth presentation at every fibre point. Lemma 2.50.1 makes every such point isolated. The fibre is compact, so this discrete space is finite.

If $x \in \Sigma_B$, the projected trajectory is constant because the standard homotopy fixes Σ_a. Thus the continuous trajectory $H_B(x,t)$ lies in a finite discrete fibre; connectedness of $[0,1]$ makes it constant. Conversely every endpoint projects to $s(\mathrm{val}(f(x))) \in \Sigma_a$, so the endpoint image is precisely Σ_B. The time-zero identity, joint continuity and skeletal fixedness prove the strong deformation retraction assertion. The composition law was proved for strict times and, when a parameter is one, in Lemma 5.18.5. The preceding fibre calculation gives the final statement. □

References. The finite coefficient argument uses a finitely generated ring over the image of $\mathbb{Z}$; it imposes no Noetherian hypothesis on K°. Uniform Hensel perturbation then passes from polynomial to restricted-series Jacobian equations.

5.22 Initial multiplicities and balancing

Lemma 5.22.1 (Lengths on a curve and on its normalization)**.** *Let B be a pure one-dimensional finite-type algebra over a field k. Let $s \in B$ be a nonzerodivisor such that B/sB is finite-dimensional over k. For each minimal prime P_i, put*

$$\nu_i = \mathrm{length}_{B_{P_i}}(B_{P_i}), \qquad B_i = B/P_i,$$

and let $\overline{B}_i$ be the normalization of B_i in its fraction field. Then

$$\dim_k(B/sB) = \sum_i \nu_i \sum_{\substack{q \in \operatorname{Spec} \overline{B}_i \text{ closed} \\ s(q)=0}} [\kappa(q) : k] \operatorname{ord}_q(s). \tag{L}$$

Proof. For every finite B-module M, the kernel and cokernel of multiplication by s are finite over the finite-dimensional algebra B/sB. Define

$$\chi_s(M) = \dim_k(M/sM) - \dim_k \ker(s : M \to M).$$

The six-term kernel-cokernel sequence for a short exact sequence shows that χ_s is additive. Apply the prime filtration of Lemma 5.19.1 to B. A factor B/P with nonminimal P has dimension zero, hence is finite over k, and its kernel and cokernel have equal dimensions. It contributes zero. Localizing the filtration at a minimal prime P_i counts exactly ν_i copies of its residue field. The nonzerodivisor s avoids each minimal prime: in the finite-length local ring B_{P_i} every element of its maximal ideal is nilpotent, whereas multiplication by s remains injective. Thus

$$\dim_k(B/sB) = \sum_i \nu_i \dim_k(B_i/sB_i).$$

The normalization $\overline{B}_i$ is a finite B_i-module by [StacksAlg, Tag 0BXR]. Its quotient $Q_i = \overline{B}_i/B_i$ is annihilated by a nonzero element of B_i, obtained by clearing denominators of finitely many module generators. Hence Q_i has zero-dimensional support and is finite over k, by the same prime-filtration argument. Therefore $\chi_s(Q_i) = 0$. Multiplication by s is injective on B_i and on $\overline{B}_i$, so additivity gives

$$\dim_k(B_i/sB_i) = \dim_k(\overline{B}_i/s\overline{B}_i).$$

Every closed local ring of the normal curve $\operatorname{Spec} \overline{B}_i$ is a discrete valuation ring by [StacksAlg, Tag 0B8Y]. Its quotient by s has length $\operatorname{ord}_q(s)$, as is seen from the powers of a uniformizer. A composition series of the finite-dimensional quotient, localized at its finitely many maximal ideals, gives the residue-degree-weighted sum in (L). □

Proposition 5.22.2 (A ray multiplicity is a boundary-order sum)**.** *Let k have the trivial absolute value and let $C \subset \operatorname{Spec} k[M]$ be a pure one-dimensional closed subscheme. Write C_i for its integral components, with generic lengths ν_i, and let $\overline{C}_i$ be normal proper curves with function fields $k(C_i)$. At a closed point $p \in \overline{C}_i$, define $a_{i,p} \in N$ by*

$$\langle m, a_{i,p} \rangle = \operatorname{ord}_p(\chi^m).$$

If $u \in N$ is primitive and $\mathbf{R}_{\geq 0}u$ is a ray of $\operatorname{Trop}(C)$, its geometric initial multiplicity is

$$m_C(u) = \sum_i \nu_i \sum_{\substack{p \in \overline{C}_i \text{ closed} \\ a_{i,p} = e_{i,p}u,\ e_{i,p} > 0}} [\kappa(p) : k] e_{i,p}. \tag{B}$$

Proof. By Lemma 5.14.1, choose torus coordinates $x_1, \dots, x_n$ in which $u = e_1$. An integral lattice change transports weighted Laurent norms and their initial ideals, so it preserves the multiplicity definition. Let $I \subset k[x_1^{\pm 1}, \dots, x_n^{\pm 1}]$ define C, and put

$$J = I \cap k[x_1, x_2^{\pm 1}, \dots, x_n^{\pm 1}], \qquad B = k[x_1, x_2^{\pm 1}, \dots, x_n^{\pm 1}]/J.$$

This is the coordinate algebra of the schematic closure in $\mathbf{A}^1 \times \mathbf{G}_m^{n-1}$. Multiplication by x_1 is injective, and $B[x_1^{-1}]$ is the coordinate algebra of C. Every Laurent relation, multiplied by a suitable power of x_1, has lowest x_1-exponent zero and belongs to J. Its ordinary initial form in direction e_1 is its reduction modulo x_1. Conversely, every nonzero reduction of an element of J is such an initial form. Thus there is an equality of ideals, and hence of schemes,

$$\operatorname{in}_{e_1}(C) \simeq \mathbf{G}_m \times \operatorname{Spec}(B/x_1 B).$$

The ordinary initial ideal over a trivially valued field agrees with the initial-degeneration definition after extension and translation, by the explicit coefficient comparison in Theorem 5.16.6. The initial scheme is pure of dimension one by Proposition 5.19.2; consequently $B/x_1 B$ is zero-dimensional, hence finite by Lemma 5.19.1. Its dimension is exactly $m_C(u)$. The closure $\operatorname{Spec} B$ is pure one-dimensional: each of its minimal components meets $x_1 \neq 0$, and its function field is that of a component of C, of transcendence degree one. Its generic lengths are the same ν_i, since localization at the corresponding minimal primes is unchanged by inverting x_1.

For precision about the completion, take the closure of each C_i in $(\mathbf{P}^1)^n$ and normalize it. Normalization is finite by [StacksAlg, Tag 0BXR]. The resulting curve is proper: projective space is proper by [StacksAlg, Tag 01WC]; finite products follow from proper base change and composition, and closed subspaces from proper closed immersions [StacksAlg, Tags 01W3–01W5]. A finite morphism is proper because it is of finite type, separated, and universally closed by [StacksAlg, Tag 01WM]. Here finiteness implies integrality by the determinant trick: multiplication by an algebra element on finitely many module generators satisfies the monic determinant relation. The normal proper model of a one-variable function field is unique up to its unique function-field-preserving isomorphism by [StacksAlg, Tag 0BY1]; hence this model may be used to compute the stated orders. Normalization commutes with restriction to an open set, since integral closure commutes with localization. Indeed, clearing the finitely many denominators in a monic relation shows that an element integral after localization becomes integral before localization after multiplying by one denominator.

The normalization of each component of $\operatorname{Spec} B$ is therefore the inverse image of $\mathbf{A}^1 \times \mathbf{G}_m^{n-1}$ in $\overline{C}_i$. Its points above $x_1 = 0$ are exactly those with

$$\operatorname{ord}_p(x_1) > 0, \qquad \operatorname{ord}_p(x_j) = 0 \quad (2 \le j \le n),$$

equivalently $a_{i,p} = e_{i,p}u$ with $e_{i,p} > 0$. Applying Lemma 5.22.1 with $s = x_1$ gives (B), including the residue degrees and generic component lengths. □

Theorem 5.22.3 (Balancing for a trivially valued curve)**.** *For every pure one-dimensional closed torus subscheme C over a trivially valued field, its tropicalization with the geometric initial multiplicities is a balanced one-dimensional fan. In a pointed subdivision,*

$$\sum_{\rho} m_C(\rho) u_\rho = 0 \quad \text{in } N,$$

where u_ρ is the primitive generator of the ray ρ.

Proof. Since $v(k^\times) = 0$, all hyperplanes in the finite construction of Theorem 5.16.5 pass through zero. Theorem 5.19.5 therefore makes the tropicalization a finite pure one-dimensional fan. For every component C_i, only finitely many points of $\overline{C}_i$ have a nonzero vector $a_{i,p}$, because each of the finitely many coordinate rational functions has only finitely many zeros and poles. Every such vector lies in $\operatorname{Trop}(C_i)$: the absolute value $f \mapsto \exp(-\operatorname{ord}_p(f))$

on its function field is trivial on k and, after completion, gives an analytic point of C_i with that tropical vector. Its positive rescalings give the same ray.

Conversely, Proposition 5.22.2 expresses the positive weight on each tropical ray as a sum over these points, so none is missing. For every character $m \in M$, the degree of its principal divisor on each proper integral curve is zero by [StacksAlg, Tag 02RU]:

$$\sum_p [\kappa(p) : k]\langle m, a_{i,p}\rangle = 0.$$

Multiply by ν_i, sum over i, and group the nonzero vectors by their primitive rays. Formula (B) turns the result into $\langle m, \sum_\rho m_C(\rho)u_\rho\rangle = 0$. Since this holds for every m, it is the required lattice-vector equality. □

Proposition 5.22.4 (Weighted initial stars and tangent quotients)**.** *Let X be pure of dimension d, let τ be a cell of its initial-stratum complex of dimension s, and take $w \in \operatorname{relint}(\tau)$. Write $\operatorname{in}_w(X) = T_{N_\tau} \times Z_\tau$ as in Proposition 5.19.3. Give its residue field the trivial valuation. Then Z_τ is pure of dimension $d-s$, and*

$$\operatorname{Trop}(Z_\tau) = \big(\operatorname{Star}_w \operatorname{Trop}(X)\big)/L_\tau.$$

The equality preserves the weights on maximal cells, using the quotient lattice N/N_τ.

Proof. A prime quotient of the coordinate algebra of Z_τ, with s independent Laurent variables adjoined, has dimension increased by s, by [StacksAlg, Tag 00P0]. Proposition 5.19.2 therefore proves the pure-dimension assertion. For every analytic point of Z_τ, its completed residue field admits Gauss extensions with arbitrary values of the additional torus coordinates. Hence the tropical support of the product is exactly $L_\tau \times \operatorname{Trop}(Z_\tau)$. Apply Theorem 5.16.6 to obtain the displayed support equality.

Take a direction u whose class in $N_{\mathbf{R}}/L_\tau$ lies in the relative interior of a maximal cell of a common refinement of the quotient star and the initial complex of Z_τ. For small $\varepsilon > 0$, Theorem 5.16.6 identifies $\operatorname{in}_{w+\varepsilon u}(X)$ with $\operatorname{in}_u(\operatorname{in}_w(X))$ after residue extension and torus translation. In the split coordinate ring, all equations for Z_τ use quotient characters only. Taking their initial forms therefore gives

$$\operatorname{in}_u(\operatorname{in}_w(X)) \simeq T_{N_\tau} \times \operatorname{in}_{\bar{u}}(Z_\tau).$$

The maximal tangent lattice on the left is the inverse image in N of the maximal tangent lattice in N/N_τ. These are saturated lattices. Quotienting the two schemes by that maximal tangent torus gives the same finite transverse algebra after residue extension. Its dimension is unchanged. Proposition 5.19.7 gives equality of the weights; Proposition 5.19.8 removes the chosen refinements. □

Theorem 5.22.5 (Balancing with actual initial multiplicities)**.** *Let K be any complete real-valued non-Archimedean field, and let $X \subset \operatorname{Spec} K[M]$ be a pure d-dimensional closed subscheme. Its tropicalization, endowed with the geometric initial multiplicities of Definition 5.19.6, is a balanced integral weighted polyhedral complex. Thus at every codimension-one cell τ,*

$$\sum_{\sigma \supset \tau} m_X(\sigma) u_{\sigma/\tau} = 0 \quad \text{in } N/N_\tau,$$

where $u_{\sigma/\tau}$ denotes the primitive generator towards σ. The assertion is stable under subdivision and complete isometric base extension.

Proof. The case $d = 0$ has no balancing condition. If $d > 0$, choose $w \in \operatorname{relint}(\tau)$. Proposition 5.22.4 expresses the initial scheme as $T_{N_\tau} \times C$ with C a pure one-dimensional closed torus subscheme over a trivially valued residue field. Its tropical rays are precisely the images of the cells $\sigma \supset \tau$ in the quotient lattice. Their primitive vectors are $u_{\sigma/\tau}$, and their actual geometric weights are $m_X(\sigma)$ by that proposition. Theorem 5.22.3 gives exactly the displayed equation. Refinement and base-change compatibility are those of Proposition 5.19.8. □

References. This is the classical reduction of tropical balancing to the divisor of a character on a proper curve. The length calculation (L) and the exact identity $\operatorname{in}_{e_1}(C) = \mathbf{G}_m \times \operatorname{Spec}(B/x_1 B)$ identify the boundary-order coefficients with the scheme-theoretic initial weights.

5.23 The homotopy of a strictly semistable formal model

Throughout this section K is complete and nontrivially valued, $O = K^\circ$, and $\pi \in O$ satisfies $0 < |\pi| < 1$. Formal algebras carry their π-adic topology. A formally étalemap below has the unique lifting property for square-zero extensions of discrete algebras annihilated by a power of π.

Lemma 5.23.1 (A bounded presentation for a formal étalechart)**.** *Let $A_0 \to B_0$ be an adic, topologically finitely presented, formally étalehomomorphism of complete admissible O-algebras. There are polynomials $F_1, \dots, F_m \in A_0[Y_1, \dots, Y_m]$ and an isomorphism*

$$B_0 \simeq A_0[Y_1, \dots, Y_m, Q]/(\widehat{F_1, \dots, F_m}, Q \det(\partial F/\partial Y) - 1). \tag{FJ}$$

Here completion is π-adic. If A_0 is a standard semistable algebra, the generic fibre has a presentation (J)*, with all coefficients integral and all coordinates bounded by one.*

Proof. Put $\bar{A} = A_0/\pi A_0$ and $\bar{B} = B_0/\pi B_0$. Topological finite presentation makes $\bar{B}$ finitely presented over $\bar{A}$. Its unique square-zero lifting property follows from that of B_0: a target $\bar{A}$-algebra is annihilated by π, and every lifted A_0-map therefore factors through $\bar{B}$. By [StacksAlg, Tag 00UR], $\bar{A} \to \bar{B}$ is étale. The global presentation [StacksAlg, Tag 00U9] gives

$$\bar{B} = \bar{A}[Y_1, \dots, Y_m]/(\bar{F}_1, \dots, \bar{F}_m), \qquad \det(\partial \bar{F}/\partial Y) \in \bar{B}^\times.$$

Lift the finitely many polynomial coefficients to A_0, and write C for the uncompleted algebra on the right of (FJ). Then $C/\pi C \simeq \bar{B}$. We check its algebraic unique lifting property directly. Across a square-zero ideal I in a target ring, choose any lifts y of a prescribed solution modulo I. Its determinant is a unit: a lift of a unit modulo a nilpotent ideal is a unit, by a finite geometric inverse. The error $F(y)$ lies in I^m. The correction

$$h = -F'(y)^{-1} F(y) \in I^m$$

gives $F(y + h) = 0$, since all terms quadratic in h vanish. The same linear identity proves uniqueness; Q must be the inverse determinant at the corrected root. Thus C has the required unique lifting property.

The identity modulo π now lifts successively to mutually inverse maps

$$C/\pi^n C \;\simeq\; B_0/\pi^n B_0 \qquad (n \geq 1).$$

Indeed the kernels of the maps from level $n+1$ to level n are square-zero. The lifting properties of C and B_0 respectively lift the two directions, and uniqueness makes both composites the identity and makes the isomorphisms compatible in n. Taking inverse limits, and using the assumed completeness of B_0, proves (FJ). Finally Proposition 3.14.7 and Lemma 3.14.8 identify the generic algebra with the stated restricted-series quotient. Coefficients in a standard A_0 have integral restricted-series lifts in its defining coordinates, so this is exactly a bounded presentation of type (J). □

Lemma 5.23.2 (Intrinsic bounds on displacement coefficients)**.** *For a bounded presentation (J), every analytic unit $v \in B^\times$ satisfies*

$$|v(H_B(x,t))| = |v(x)|, \qquad |D_\nu(v)(x)| \le |v(x)| \quad (x \in \mathcal{M}(B),\ 0 \le t \le 1).$$

If $b \in B$ satisfies $|b(y)| \le 1$ at every $y \in \mathcal{M}(B)$, then $|D_\nu(b)(x)| \le 1$ for all ν, x. Consequently, for $0 < \delta < 1$ and $E = \mathcal{H}(x)$, the evaluated displacement has

$$\left\| \frac{\sigma_{\delta,x}(v)}{v(x)} - 1 \right\|_\delta \le \delta, \qquad \|\sigma_{\delta,x}(b) - b(x)\|_\delta \le \delta.$$

Proof. The constant coefficient in the displacement expansion gives $|c(H_B(x,t))| \ge |c(x)|$ for every $c \in B$. Apply this to v and v^{-1}. Multiplicativity makes the product of the two left sides and the product of the two right sides both equal to one, so both inequalities are equalities. For each coefficient,

$$|D_\nu(v)(x)|t^{|\nu|} \le |v(x)| \qquad (0 < t < 1).$$

Letting t increase to one proves the coefficient bound for a unit. For the second assertion, $H_B(x,t)$ is an actual point of $\mathcal{M}(B)$, so $|b(H_B(x,t))| \le 1$; the same limiting argument gives the coefficient bound. Since D_0 is the identity, the remaining terms have positive total degree, and their Gauss norms at radius δ are at most δ. These arguments use only the values of the functions on the analytic space, not a comparison of quotient norms. □

Theorem 5.23.3 (Independence of the semistable chart)**.** *Suppose the same affinoid algebra B has two bounded presentations of type (J), possibly over different standard semistable algebras. Their homotopies on $\mathcal{M}(B)$ are equal at every time in $[0,1]$.*

Proof. Use unprimed and primed notation for the two presentations. Fix x, put $E = \mathcal{H}(x)$, and fix $0 < \delta < 1$. In $E\{\delta^{-1}U\}$ define

$$\Phi_i = \frac{\sigma_{\delta,x}(X_i')}{X_i'(x)} - 1 \quad (1 \le i \le r'), \qquad \Psi_j = \sigma_{\delta,x}(T_j') - T_j'(x).$$

The functions X_i' are global analytic units because their product is the nonzero scalar a'. The T_j' and the primed implicit coordinates have values at most one everywhere. Lemma 5.23.2 therefore gives $\|\Phi_i\|, \|\Psi_j\| \le \delta$. Substitution $U' = (S', Z') \mapsto (\Phi, \Psi)$ defines a contractive E-homomorphism

$$\theta : E\{\delta^{-1}U'\} \longrightarrow E\{\delta^{-1}U\}.$$

The two maps $\sigma_{\delta,x}$ and $\theta\sigma'_{\delta,x}$ have identical images on the primed base coordinates: this is the definition for X'_i with $i \geq 1$ and for T'_j, and the product relation gives it for X'_0. Their images of the primed implicit tuple solve the same displaced equations and both lie within δ of $Y'(x)$. At that center the new Jacobian differs by at most δ from the original invertible Jacobian of inverse norm at most one. The geometric inverse formula and Lemma 5.18.1 therefore identify the two roots. Their inverse determinants coincide as well.

The primed presentation topologically generates B. Both maps are bounded for its topology, so equality on its coordinates implies equality on every $b \in B$. Contractivity of θ now gives

$$\|\sigma_{\delta,x}(b)\|_\delta \leq \|\sigma'_{\delta,x}(b)\|_\delta.$$

Reversing the two presentations gives the opposite inequality. These Gauss norms are precisely evaluation at the two time-δ points, so the points agree. They agree at zero by definition and at one by the pointwise endpoint formula. □

Proposition 5.23.4 (Restriction to formal open subsets)**.** *Let $\mathfrak{U} = \mathrm{Spf}(B_0)$ admit a topologically finitely presented formal étalemap to a standard semistable formal chart. Its homotopy preserves the generic fibre of every formal open subset. On an admissible affine formal open $\mathfrak{V} \subseteq \mathfrak{U}$, its restriction equals the homotopy obtained from the restricted chart, independently of its bounded presentation.*

Proof. Choose a bounded presentation by Lemma 5.23.1. A principal formal open $D(g)$, $g \in B_0$, has generic fibre $|g| = 1$ by Proposition 3.17.1. The integral function g has values at most one. The constant coefficient of its displacement gives $|g(H_B(x,t))| \geq |g(x)|$, so a point where $|g| = 1$ stays in that domain at every time. General formal opens are unions of principal formal opens, and their generic fibres are the corresponding unions by Proposition 3.17.2; hence they are preserved as well.

Write $\mathfrak{V} = \mathrm{Spf}(C_0)$. An open immersion is formally étale: a square-zero thickening does not change underlying points, so a map whose reduction factors through that open factors through it uniquely. Composing unique lifting properties shows that the restricted map to the standard base is formally étale. We also verify relative finite presentation. By Theorem 3.14.4, choose finite presentations $B_0 = O\langle W\rangle/I$ and $C_0 = O\langle Z\rangle/J$. Lift the images of the

finitely many W_i to integral restricted series $h_i(Z)$. The two substitution maps give the presentation

$$C_0 \simeq B_0\langle Z\rangle/(J(Z),\, W_i - h_i(Z) : i).$$

The relations are finite; the same construction applies directly to the map from the standard base to C_0. Thus Lemma 5.23.1 applies over that original base. The integral map $B_0 \to C_0$ gives a contractive map on the displayed generic algebras: each integral presentation coordinate of B maps into C_0, whose elements have norm at most one by Proposition 3.14.7; bounded substitution and quotient infima give contractivity. Thus Proposition 5.18.4 and Theorem 5.21.3 identify the restricted homotopy with that on $\mathfrak{V}_\eta$. Theorem 5.23.3 removes the chosen presentation. □

Theorem 5.23.5 (Global semistable deformation)**.** *Let $\mathfrak{X}$ be a quasi-compact admissible formal O-scheme with Hausdorff generic fibre X. Suppose it has a finite affine formal open cover $\mathfrak{U}_i$ with topologically finitely presented formal étalemaps*

$$f_i : \mathfrak{U}_i \longrightarrow \operatorname{Spf} O\langle X_{i0}, \dots, X_{ir_i}, T_{i1}, \dots, T_{iq_i}\rangle/(X_{i0}\cdots X_{ir_i} - a_i),$$
$$0 < |a_i| < 1.$$

There is a canonical jointly continuous homotopy $H_{\mathfrak{X}} : X \times [0,1] \to X$ whose restriction to each $U_i = (\mathfrak{U}_i)_\eta$ is the constructed chart homotopy. It is a strong deformation retraction onto the closed compact subset

$$\Sigma(\mathfrak{X}) = H_{\mathfrak{X}}(X, 1), \qquad \Sigma(\mathfrak{X}) \cap U_i = (f_i)_\eta^{-1}(\Sigma_{a_i}).$$

It satisfies the maximum composition law, is independent of the affine cover and the semistable coordinate maps, and restricts to the corresponding homotopy on every quasi-compact formal open. Under a complete isometric extension L/K, the projection $X_L \to X$ commutes with these homotopies.

Proof. The preceding presentation lemma and Theorem 5.21.4 give a jointly continuous strong deformation H_i on each U_i. On an overlap of two formal charts, choose a principal formal open of the first chart contained in the second. It is admissible by Proposition 3.17.1. Its generic fibre is preserved by both homotopies, and Proposition 5.23.4 identifies their restrictions with the two homotopies of that affine algebra. Those homotopies coincide by Theorem 5.23.3. Such formal affine opens cover the overlap, and their generic

fibres cover the analytic overlap by Proposition 3.17.2. Thus all H_i agree on overlaps.

Each U_i is compact and hence closed in the Hausdorff space X, and the finite family covers X. The product sets $U_i \times [0,1]$ consequently form a finite closed cover. The maps H_i glue to a continuous map: the inverse image of any closed subset of X is the finite union of its closed inverse images in these closed product sets. All homotopy and composition identities hold on each preserved U_i, hence globally.

A point in U_i is fixed by the global endpoint exactly when it is fixed by the local endpoint, namely when it lies over Σ_{a_i}. The endpoint is idempotent, so its image is precisely its fixed set. Since X is a finite union of compact sets, it is compact; its endpoint image is compact and hence closed. This proves the displayed local description and strong deformation assertion. A second formal atlas has common affine formal refinements with the first one; the same overlap argument proves independence. It also proves restriction to a quasi-compact formal open. Finally, base change of a chart retains its integral Jacobian presentation. The local scalar-extension compatibility of Theorem 5.21.3 therefore gives the asserted projection identity on the cover, and hence globally. □

5.24 The faces of an étalesemistable chart

Let $A_0 = O\langle X_0, \dots, X_r, T_1, \dots, T_q\rangle/(X_0 \cdots X_r - a)$, where $0 < |a| < 1$, and let $A_0 \to B_0$ be a topologically finitely presented formally étalemap of admissible algebras. Write $f : X = \mathcal{M}(B) \to \mathcal{M}(A)$ for the generic map, $\bar{f}$ for the special-fibre map, and $k = \widetilde{K}$. For a nonempty subset $I \subseteq \{0, \dots, r\}$ put

$$\begin{aligned} \Delta_I &= \{w \in \Delta_a : w_j = 0 \text{ for } j \notin I\}, \\ D_I &= \{X_i = 0 \ (i \in I), \quad X_j \neq 0 \ (j \notin I)\} \subseteq \operatorname{Spec}(A_0 \otimes_O k), \\ S_I &= \bar{f}^{-1}(D_I). \end{aligned}$$

The stratum D_I is the integral smooth variety with coordinates $X_j^{\pm 1}$ for $j \notin I$ and $T_1, \dots, T_q$. Denote its generic point by ξ_I and the finite set of generic points of S_I by Q_I. The empty inverse image has $Q_I = \varnothing$.

Lemma 5.24.1 (The residue field over a relative open face)**.** *Let $w \in \mathrm{relint}(\Delta_I)$ and let $z_w \in \Sigma_a$ be its standard Gauss point. Specialization sends z_w to ξ_I, and the induced extension*

$$F_I := \kappa(\xi_I) = k(X_j : j \notin I, T_1, \dots, T_q) \longrightarrow h_w := \widetilde{\mathcal{H}(z_w)}$$

is purely transcendental. In particular, for every finite extension l/F_I, the tensor product $l \otimes_{F_I} h_w$ is a field, of degree $[l : F_I]$ over h_w.

Proof. Choose $i_0 \in I$ and eliminate X_{i_0} using the product relation. The independent Gauss variables are the remaining X_i and the T_j. The variables X_j with $j \notin I$ and all the T_j have weight zero; all other original X_i have strictly positive weight. Their residues therefore give exactly the generic point ξ_I: every nonzero polynomial in the zero-weight variables has Gauss norm one after normalizing an integral coefficient.

In the residue-lattice proof of Proposition 3.8.1, let L_w be the lattice of exponent vectors whose weight belongs to $v(K^\times)$. The subgroup generated by the zero-weight coordinate vectors is a direct summand of the full exponent lattice, hence is saturated in L_w. Lemma 5.14.1 extends its displayed coordinate basis to a basis of L_w. The Gauss residue formula with this basis expresses h_w as the rational function field over k in the residues of the zero-weight variables and finitely many additional normalized Laurent monomials. It is therefore purely transcendental over the indicated subfield F_I.

Finally, write $h_w = F_I(U_1, \dots, U_s)$. The ring $l \otimes_{F_I} h_w$ is the localization of $l[U_1, \dots, U_s]$ by the nonzero polynomials over F_I. It is an integral domain and is finite-dimensional over h_w, hence is a field: multiplication by a nonzero element is an injective endomorphism of a finite-dimensional vector space and is therefore surjective. Tensoring a basis of l/F_I gives its stated degree. □

Proposition 5.24.2 (Actual skeletal fibres and residual strata)**.** *For $w \in \mathrm{relint}(\Delta_I)$, specialization induces a bijection*

$$f^{-1}(z_w) \xrightarrow{\sim} Q_I.$$

For the point $x_{\eta,w}$ labelled by $\eta \in Q_I$, put $E_w = \mathcal{H}(z_w)$ and $l_\eta = \kappa(\eta)$. Then $\mathcal{H}(x_{\eta,w})/E_w$ is the unramified finite extension lifting the finite separable residue extension

$$l_\eta \otimes_{F_I} h_w \,/\, h_w.$$

Its degree is $[l_\eta : F_I]$, and its value group is that of E_w.

Proof. Use Lemma 5.23.1 to write $B_0 = \widehat{C}$ with $C = A_0[Y,Q]/(F, Q\det J - 1)$. The square-zero correction in that proof and [StacksAlg, Tag 00UR] show that C is an étaleA_0-algebra. Base change along the bounded evaluation $A_0 \to E_w^\circ$ gives an étalealgebra C_E over E_w° by [StacksAlg, Tag 00U2, part (3)]. It is flat by part (6) of the same lemma, so multiplication by π is injective. Its π-adic completion D_0 is an admissible E_w°-algebra by Lemma 3.14.8 and Theorem 3.14.4. The explicit restricted presentation gives

$$D = D_0[1/\pi] = B\widehat{\otimes}_A E_w,$$
$$D_0/E_w^{\circ\circ} D_0 = (B_0 \otimes_O k) \otimes_{A_0 \otimes_O k} h_w.$$

For the second identity one simply reduces the finite list of equations in the restricted presentation: reduction of an integral restricted series is a polynomial, and reduction of the ideal is generated by the reductions of its displayed generators. The first identity is the completed-tensor fibre presentation of Theorem 2.33.11.

The special-fibre map is étale, and its fibre over ξ_I is a finite disjoint union $\coprod_{\eta \in Q_I} \operatorname{Spec}(l_\eta)$ with each l_η/F_I finite separable, by [StacksAlg, Tag 02GL]. Here the fibre points are exactly the generic points of S_I. Indeed S_I is smooth over k and hence normal by [StacksAlg, Tags 036U, 056T]; flat going down, [StacksAlg, Tag 00HS], makes every component dominate the integral D_I, and the zero-dimensional generic fibre has no proper chains of primes. The preceding lemma now identifies the special fibre of D_0 with

$$\prod_{\eta \in Q_I} (l_\eta \otimes_{F_I} h_w),$$

a finite product of fields. This is in particular reduced, so Lemma 4.12.1 identifies it with the canonical reduction of D. Every prime of this reduction is minimal. Theorem 3.16.7 therefore gives one and only one actual analytic point over each factor, and these exhaust the fibre. If the product is empty, the integral quotient norm would have 1 of norm less than one unless $D = 0$; thus the analytic fibre is empty in exactly that case. This proves the bijection and its specialization labels.

For the valued-field assertion, fix a factor $\lambda = l_\eta \otimes_{F_I} h_w$ and apply Lemma 4.15.2 over the complete field E_w. It supplies a finite complete field L/E_w of degree $[\lambda : h_w]$, residue field λ, and unchanged value group. Lift the coordinates of the corresponding special-fibre point arbitrarily into L°. The finitely many equation errors have norms strictly below one and the Jacobian determinant has norm one. Lemma 5.18.1 corrects them to an exact

bounded solution in L. This gives a point of $\mathcal{M}(D)$ with that residue label, hence the point already identified, and an isometric embedding

$$\mathcal{H}(x_{\eta,w}) \hookrightarrow L.$$

The embedding first holds for the fraction field of the evaluated affinoid algebra and then for its completion. Its residue field contains λ. Lifts of a basis of λ/h_w are E_w-linearly independent: normalize any putative relation by a coefficient of largest absolute value and reduce. Hence the left field has degree at least $[\lambda : h_w]$, while the embedding into L gives the opposite inequality. It equals L, proving the assertion. □

Lemma 5.24.3 (The unique stratum along a face)**.** *Let $\eta \in Q_I$ and let $\varnothing \neq J \subseteq I$. There is exactly one $\eta_J \in Q_J$ whose closure contains η. For $J' \subseteq J$, the generization of η_J labelled by J' is $\eta_{J'}$.*

Proof. The closed subscheme Z_J of the standard special fibre cut out by $X_j = 0$ for $j \in J$ is an affine space: at least one factor of the product relation is zero, so the remaining coordinates are free. Its pullback Y_J is étaleover Z_J, hence smooth and normal by [StacksAlg, Tags 036U, 056T]. Its local ring at η is therefore a domain. Flat going down for $\bar{f}$ gives a prime below η lying over the generic point ξ_J of Z_J. It lies in S_J. Every such prime is a component generic point of Y_J: going down forces minimal primes below it to lie over the generic point of Z_J, and the étalegeneric fibre is a finite disjoint union of fields. The domain $\mathcal{O}_{Y_J,\eta}$ has only one minimal prime, so there is precisely one such component through η. This proves existence and uniqueness. If $J' \subseteq J$, the successive generization lies over $\xi_{J'}$ and its closure contains η; uniqueness identifies it with $\eta_{J'}$. □

Nonempty face generizations. In the formally étalesemistable chart above, for each $\eta \in Q_I$ and $\varnothing \neq J \subseteq I$ there is exactly one $\eta_J \in Q_J$ whose closure contains η. For $\varnothing \neq J' \subseteq J$, the J'-generization of η_J is $\eta_{J'}$.

Here is the proof on this range. The formal chart is topologically finitely presented. Reduction modulo π has finite presentation and inherits the unique square-zero lifting property from discrete tests killed by π. It is étaleby [StacksAlg, Tag 00UR]. Base change to k and to the actual coordinate face Z_J preserves étaleness, and the resulting map $Y_J \to Z_J$ is flat [StacksAlg, Tag 00U2(3), (6)]. As J is nonempty, Z_J is an affine space over k. In the

local étalepresentation of Y_J over that polynomial base, the square Jacobian is invertible [StacksAlg, Tag 00U9]. The same minor in the presentation over k proves smoothness [StacksAlg, Tag 00T7(1)]. Thus the relevant local ring of Y_J at η is a normal domain [StacksAlg, Tag 056T].

Flat going down gives a prime below η over the generic point of Z_J [StacksAlg, Tag 00HS]. Every such prime is minimal in Y_J. Indeed any prime below it still lies over that generic point, whose étalefibre is a finite disjoint union of spectra of fields [StacksAlg, Tag 02GL(2)]. The local domain has one minimal prime, giving the required unique label. For nonempty J', the successive generization over the generic point of $Z_{J'}$ specializes to η and hence is the unique $\eta_{J'}$.

Theorem 5.24.4 (A finite simplex realization of the chart skeleton)**.** *For each $\eta \in Q_I$, the points $x_{\eta,w}$ on* $\mathrm{relint}(\Delta_I)$ *extend uniquely to a continuous map*

$$s_\eta : \Delta_I \longrightarrow X, \qquad s_\eta(w) = x_{\eta_J,w} \quad \text{if } w \in \mathrm{relint}(\Delta_J).$$

It is a homeomorphism onto its image. The finite collection of these closed simplices covers $\Sigma_B = f^{-1}(\Sigma_a)$, and the restriction to a face Δ_J is s_{η_J}. More precisely, Σ_B is homeomorphic to the quotient of the finite disjoint union of the Δ_I, one copy for each $\eta \in Q_I$, by exactly these face identifications. In these charts all face maps are the coordinate face inclusions, integral affine for the lattices

$$N_I = \{(n_i)_{i\in I} \in \mathbb{Z}^I : \textstyle\sum_i n_i = 0\}.$$

The intersection with the generic fibre of a formal open subset is a union of closed faces in this finite realization.

Proof. First work over the relative open face. The primes in Q_I are distinct and incomparable. Choose an integral function $g \in B_0$ whose reduction is outside η and inside every other member of Q_I, by choosing one element for each other prime and multiplying. If there is no other prime, take $g = 1$. By the actual fibre description, the locus $|g| = 1$ selects exactly $x_{\eta,w}$ over each w in this open face. For any compact subset $W \subset \mathrm{relint}(\Delta_I)$, the set

$$\{x \in f^{-1}(\{z_w : w \in W\}) : |g(x)| = 1\}$$

is closed in the compact affinoid space X, and maps continuously and bijectively onto W. It is therefore homeomorphic to W. Every point of the relative open face has a compact relative neighborhood contained in that face, proving continuity of $w \mapsto x_{\eta,w}$ throughout the relative open face.

Consider the closure of its graph in the compact space $\Delta_I \times X$. Let (w, x) be a point of that closure and let $J = \{j : w_j > 0\}$. Continuity of f gives $f(x) = z_w$, so the actual fibre theorem labels x by some $\theta \in Q_J$. If an integral function h has reduction outside η, then $|h(x_{\eta,u})| = 1$ at every interior u. Continuity makes $|h(x)| = 1$. Thus the reduction prime θ is contained in η. Since $\sum_i w_i = v(a) > 0$, J is nonempty. By nonempty face generization, $\theta = \eta_J$. Every $w \in \Delta_I$ is a limit of interior points; compactness supplies a graph limit above it. We have proved that this limit is unique. The closed graph therefore projects continuously and bijectively onto the compact Hausdorff simplex Δ_I, hence homeomorphically. Its second projection is the desired continuous extension. Its composition with the base coordinate map is the identity, so it is injective and is a homeomorphism onto its compact image.

The boundary formula and transitivity for nonempty faces prove the face restriction assertion. There are finitely many I and finitely many $\eta \in Q_I$, and the fibre theorem shows that their relative interiors partition Σ_B. Two closed cells meet at a point of support J exactly when their J-generizations agree; hence their intersection is a union of the indicated common closed faces. The induced map from the finite face quotient to Σ_B is therefore a continuous bijection. Its source is compact and its target Hausdorff, so it is a homeomorphism. Coordinate inclusions preserve the displayed integer lattices, giving the final affine assertion.

On a relative open cell the specialization label is constant. If this label belongs to a given formal open, all its generizations belong to that open as well. Consequently inclusion of an open cell includes its whole closed simplex. The specialization description of formal-open generic fibres then gives the asserted union of closed faces. □

5.25 Integral-affine coordinates on the skeleton

Lemma 5.25.1 (Units on an open polyannulus)**.** *Let L be a complete non-Archimedean field and let $\Omega \subset \mathbf{R}^d$ be a nonempty convex open set. Let $P_\Omega \subset (\mathbf{G}_{m,L}^d)^{\mathrm{an}}$ be the analytic domain defined by $v(Z) \in \Omega$, and denote its Gauss section by $w \mapsto z_w$. For every analytic unit $g \in \mathcal{O}(P_\Omega)^\times$ there are $c \in v(L^\times)$ and $m \in \mathbf{Z}^d$ such that*

$$v(g(z_w)) = c + \langle m, w \rangle \qquad (w \in \Omega).$$

The assertion includes $d = 0$, when $P_\Omega = \mathcal{M}(L)$.

Proof. Suppose first that $d > 0$. On the inverse image of a closed rectangular box $W = \prod_j [\alpha_j, \beta_j]$ contained in Ω, the arbitrary-radius domain presentations of Theorem 2.31.2 give the product of closed annulus algebras; their actual analytic sections are these algebras by Theorem 2.39.4. Iterate Theorem 2.13.2, with the other coordinates as Banach coefficients. This gives a unique Laurent expansion $\sum_{m \in \mathbf{Z}^d} c_m Z^m$, and the norm is

$$\max_m |c_m| \max_{w \in W} \exp(-\langle m, w \rangle).$$

The weighted coefficients tend to zero outside finite subsets. To check the multivariable assertion directly, apply the one-coordinate normal-form operators successively to polynomial families. Their bounds and commuting actions on different exponent pairs extend them to the complete weighted coefficient space. Their composite kernel is the sum of the coordinate relations, and their common section is the Laurent monomial representative. The finite-tail condition is exactly the weighted c_0 condition of Lemma 2.13.1. Thus this iteration also proves uniqueness and all restriction formulas.

Use boxes with nonempty interior. On overlapping interiors, uniqueness makes their coefficients equal. Every two such boxes can be connected by a finite chain of overlapping smaller boxes inside the convex set Ω. Hence a function on P_Ω has a single Laurent coefficient family, converging on every compact box, and

$$\log |g(z_w)| = \max_m \{\log |c_m| - \langle m, w \rangle\}.$$

This is convex in w. Apply the same argument to g^{-1}. Multiplicativity of the Gauss seminorm says that its logarithm is the negative of the displayed function. A function both convex and concave on an open convex set is affine: equality in the two convexity inequalities gives its affine interpolation on every line segment. At an interior point w_0, a nonzero coefficient c_m attains the maximum. The difference between the affine function and this one affine term is nonnegative on Ω and zero at w_0; an affine function with these properties is zero, by varying a small distance in both directions along every vector. Thus $v(g(z_w)) = v(c_m) + \langle m, w \rangle$. If $d = 0$, the unit is an element of $L^\times$, which proves the same claim. □

Lemma 5.25.2 (A rational-origin tube over a semistable chart)**.** *Let L be complete and nontrivially valued, and let $0 < |b| < 1$. Put*

$$D_0 = L^\circ\langle Z_0, \dots, Z_d\rangle/(Z_0 \cdots Z_d - b).$$

Let $D_0 \to E_0$ be a topologically finitely presented formally étalemap of admissible algebras, and let q be a rational point of its special fibre lying over $Z_0 = \cdots = Z_d = 0$. The generic map induces an analytic isomorphism

$$]q[\xrightarrow{\sim} P_b := \{z \in \mathcal{M}(D) : |Z_i(z)| < 1 \text{ for every } i\}.$$

After eliminating Z_0, this is the open polyannulus with logarithmic domain $w_j > 0$ and $\sum_{j=1}^{d} w_j < v(b)$.

Proof. Choose the bounded presentation of Lemma 5.23.1, with coordinates Y, Q, equations $F(Y) = 0$ and $Q \det F'(Y) = 1$. Lift the residue coordinates of q to constants y_0, q_0 in L°. Choose integral restricted-series lifts of all the coefficients in the variables $Z_0, \dots, Z_d$. Their evaluations at $Z = 0, Y = y_0$ have F-error of norm less than one, and the Jacobian determinant has norm one. These assertions follow by reduction at the specified rational point q.

Let W be a compact logarithmic box inside the displayed open simplex, with affinoid inverse image P_W. All $|Z_i|$ are at most some $\rho < 1$ there. Every nonconstant monomial in their integral series has norm at most ρ. Thus, in the Banach algebra $\mathcal{O}(P_W)$, the error $F(y_0)$ has norm at most some $\delta < 1$, and $F'(y_0)$ has inverse of norm at most one. Indeed its determinant differs by a term of norm less than one from its constant unit, so the geometric inverse applies. Lemma 5.18.1 produces the unique root y_W with $|y_W - y_0| \le \delta$; set $q_W = (\det F'(y_W))^{-1}$. This gives a bounded analytic section $P_W \to \mathcal{M}(E)$, specializing to q. Uniqueness makes the sections agree on overlaps, so they glue on all of P_b. When $d = 0$ use the same argument in L, where $Z_0 = b$.

We check the inverse as an analytic map. Over P_W, cover the tube by affinoid subdomains on which $|Y - y_0| \le \lambda < 1$, increasing λ if necessary so that $\lambda \ge \delta$; one may impose the analogous bound on $Q - q_0$. The original coordinate tuple and the pullback of y_W are roots of the same system in the Banach algebra of such a domain. Both lie within a radius less than one of y_0, where the same Jacobian inverse estimate holds. Hensel uniqueness makes them equal as algebra elements, and then the inverse-determinant equation identifies Q. Consequently the section and the generic map are inverse on these subdomains. Every point of the tube lies in one of them, since its

residue coordinates are those of q. This proves the analytic isomorphism, including its compatibility for every compact box in the open simplex. □

Theorem 5.25.3 (Units along an étaleskeletal simplex)**.** *Use the notation and hypotheses of Theorem 5.24.4. Put* $\Gamma = v(K^\times)$*. For every* $\eta \in Q_I$ *and every* $g \in B^\times$*, the function*

$$w \longmapsto v(g(x_{\eta,w})) \qquad (w \in \Delta_I)$$

is Γ*-integral-affine: after eliminating any one coordinate in* I*, it has an integral linear part and a constant term in* Γ*.*

Proof. Let H_0 be the completion of $K(X_j : j \notin I, T_1, \dots, T_q)$ in the unit Gauss norm. Its residue field is F_I, by Proposition 3.8.1, and its value group is $|K^\times|$: a nonzero polynomial attains its Gauss norm at a coefficient, fractions have the same property for their values, and completion does not change the value group since a nonzero convergent limit has the same norm as every sufficiently close term.

Send the zero-weight variables to these fixed elements of H_0°. The remaining formal base is

$$H_0^\circ\langle X_i : i \in I\rangle / \left(\prod_{i\in I} X_i - b\right), \qquad b = a\left(\prod_{j\notin I} X_j\right)^{-1}, \qquad |b| = |a|.$$

Base-change the algebraic square-Jacobian presentation of Lemma 5.23.1 and then complete. The result is an admissible formally étalealgebra over this base. The justification is the same explicit completion argument in Proposition 5.24.2: the algebraic presentation is flat, so it has no scalar torsion; Lemma 3.14.8 preserves this under completion, and Theorem 3.14.4 gives the admissible finite presentation.

Above the all-zero special point this model has the residual point with field $l_\eta = \kappa(\eta)$, a finite separable extension of F_I. Lemma 4.15.2 supplies one finite extension L_0/H_0 with residue field l_η and unchanged value group. Base-change the presentation once more to L_0°. The multiplication map $l_\eta \otimes_{F_I} l_\eta \to l_\eta$ chooses a rational residual point q above the origin. Thus all fields, models, and the point q have been fixed independently of w.

Lemma 5.25.2 now gives an analytic map from the entire open simplex polyannulus over L_0 to X, by its inverse section followed by the two base-change projections. Its Gauss point with logarithms w maps to z_w on the

original standard base. Indeed, after eliminating one X_i with $i \in I$, the coefficient Gauss norm in the zero-weight variables followed by the Gauss norm in the remaining positive-weight variables is exactly the original Gauss norm. This identity first holds for Laurent polynomials and then for all functions by bounded continuity. The specialization of the image is η, by the chosen multiplication map of residue fields. Proposition 5.24.2 therefore identifies this image with the actual point $x_{\eta,w}$.

The pullback of g is an analytic unit on this single open polyannulus. Lemma 5.25.1 gives the required integral-affine formula on $\operatorname{relint}(\Delta_I)$, with constant term in $v(L_0^\times) = \Gamma$. The closed-cell section is continuous by Theorem 5.24.4, and g is nowhere zero. Hence both sides extend continuously and agree on all of Δ_I. The proof also covers a zero-dimensional face. □

Theorem 5.25.4 (The integral-affine skeleton of a formal model)**.** *Let $\mathfrak{X}$ satisfy Theorem 5.23.5. Its canonical fixed set $\Sigma(\mathfrak{X})$ is a finite Γ-integral-affine face-glued cell complex of closed simplices. Distinct cells may have the same vertex set. Each affine formal semistable chart supplies exactly the cells of Theorem 5.24.4. The cell structure and its integral-affine transition maps are independent of the chosen formal chart atlas. The homotopy of Theorem 5.23.5 is a jointly continuous strong deformation retraction onto this finite complex.*

Proof. Write sp for specialization to $\mathfrak{X}_s$. In one chart, the relative interior of the cell labelled by η is precisely

$$E_\eta = \{x \in \Sigma(\mathfrak{X}) : \operatorname{sp}(x) = \eta\}.$$

This is the actual-fibre classification in Proposition 5.24.2. There is no restriction to the chart on the right: the inverse image under specialization of its formal open set is its generic domain, by Proposition 3.17.2. Thus whenever a second chart contains η, the same set E_η is one of its relative open cells. For clarity, choose $x \in E_\eta$. The canonical fixed-set identity makes its image in the second standard base a Gauss point. Its specialization is the generic point of the unique coordinate stratum whose vanishing coordinates are those belonging to η. The actual-fibre classification therefore puts η in that chart's corresponding Q_I. The same classification identifies its whole relative open cell with E_η. This proves intrinsically which residual generic points label cells, without choosing a global ordering of the special-fibre branches. Its closure in the global Hausdorff generic fibre is the closed simplex supplied by either

chart, since each generic affinoid chart is compact and closed. Consequently the cells themselves are independent of charts.

Compare two coordinate systems on such a cell. Choose a common principal formal neighbourhood of η in their overlap. Its generic domain contains the entire closed cell: it contains E_η and is closed, or equivalently one may use the formal-open subcomplex assertion of Theorem 5.24.4. It is admissible by Proposition 3.17.1, and its map to either standard base has a bounded presentation by Proposition 5.23.4. Every monomial coordinate of the second chart is an analytic unit on this common domain, since the product of those coordinates is a nonzero scalar. Theorem 5.25.3 therefore makes each of its logarithmic coordinates a Γ-integral-affine function of the first ones.

Reverse the two charts to obtain the same assertion for the inverse coordinate change. The linear parts are mutually inverse maps of the integer tangent lattices $N_I = \{(n_i) \in \mathbf{Z}^I : \sum n_i = 0\}$. They are therefore unimodular isomorphisms. Indeed, the coordinate compositions are identities on a relative open simplex, so their derivatives are inverse real linear maps; both preserve the displayed lattices. The affine constants belong to Γ, and all face maps are the already proved coordinate face inclusions.

There are finitely many cells because the given formal atlas and the cell lists in its charts are finite. Their intersections are unions of common faces. To see this for cells in different charts, first intersect the second cell with the first formal open set. The formal-open subcomplex assertion expresses this intersection as a finite union of its closed faces. Each such face now lies in the first chart, where the common-face property has already been proved. These faces are the same global cells by the intrinsic description E_η above. Finally the map from the finite face-gluing quotient of the compact simplices to $\Sigma(\mathfrak{X})$ is a continuous bijection from a compact space to a Hausdorff space, hence is a homeomorphism. This proves the asserted finite complex and its intrinsic integral-affine structure. The previously proved global homotopy has exactly this fixed set and remains the claimed strong deformation retraction. □

5.26 Faithful rational coordinates on a curve skeleton

Throughout this section, K is algebraically closed, complete and nontrivially valued. Let X be a smooth projective integral K-curve and let $\mathcal{X}/K^\circ$ be a

projective model satisfying Theorem 4.23.3. Write $\Sigma = \Sigma(\mathcal{X})$. It is a compact finite metric graph. Its finite edges have the logarithmic length defined by the nodal annuli.

Lemma 5.26.1 (Rational approximation of a nonzero germ)**.** *Every point of Σ has algebraic support the generic point of X. If $x \in \Sigma$ and g is an analytic germ with $g(x) \neq 0$, there is $f \in K(X)^\times$ such that $|f| = |g|$ on an ordinary neighborhood of x on which both are defined. If $|g(x)| = 1$, $f(x)$ and $g(x)$ can be required to have the same residue.*

Proof. At a component vertex, Proposition 4.24.2 gives residual transcendence degree one. At an interior annular Gauss point, Proposition 3.8.1 gives either residual transcendence degree one or a nonzero relative value-group rank. A point supported at an algebraic closed point would have completed residue field K, by algebraic closedness and Proposition 2.10.1. These alternatives exclude closed algebraic support; an integral algebraic curve has only generic and closed points.

By the same description of analytification, $\mathcal{H}(x)$ is the completion of $K(X)$ for the norm of x. Choose $f \in K(X)$ with $|f(x) - g(x)| < |g(x)|$. This makes $f \neq 0$. The rational function and its inverse are regular on a Zariski open containing the generic point, so their analytifications are defined near x. Continuity preserves the displayed strict inequality on a smaller ordinary neighborhood. The ultrametric inequality gives $|f| = |g|$ there. When $|g(x)| = 1$, the same inequality says that the residues agree. □

Lemma 5.26.2 (Prescribing finitely many residual orders)**.** *Let C be an irreducible component of the special fibre of $\mathcal{X}$, and let $p_1, \dots, p_m$ be distinct closed points of its normalization C^ν. For each i there is $u_i \in k(C)^\times$ with*

$$\operatorname{ord}_{p_j}(u_i) = \delta_{ij}.$$

Proof. The field $k = \widetilde{K}$ is algebraically closed: lift a monic polynomial to K° and factor it over K; dominance of the leading term makes every root integral, and reduction gives the factorization over k. Choose a projective embedding of C. A hyperplane avoiding the finitely many images of the p_j exists: the forbidden coefficients form a finite union of proper linear subspaces over the infinite field k. Its complement on C is affine. The normalization is finite by [StacksAlg, Tag 0BXR], so its inverse image is an affine normal curve $\operatorname{Spec} B$

containing all p_j. Its local rings at these points are discrete valuation rings by [StacksAlg, Tag 0B8Y].

Write $\mathfrak{m}_j$ for their maximal ideals. A local uniformizer at p_i can be written a_i/b_i, with $a_i, b_i \in B$ and $b_i \notin \mathfrak{m}_i$; hence a_i has order one at p_i. The ideals $\mathfrak{m}_i^2$ and $\mathfrak{m}_j$, $j \neq i$, are pairwise comaximal. Indeed, powers of comaximal ideals remain comaximal by expanding a sufficiently high power of $1 = a + b$. For two comaximal ideals I, J, write $a + b = 1$ with $a \in I, b \in J$; then $br + as$ has prescribed residues r modulo I and s modulo J. Induction gives the same assertion for finitely many such ideals. Choose $u_i \in B$ congruent to a_i modulo $\mathfrak{m}_i^2$ and to 1 modulo each $\mathfrak{m}_j$, $j \neq i$. Its orders are exactly those claimed, so it is a nonzero rational function. □

Proposition 5.26.3 (Rational functions are piecewise integral affine)**.** *For every $f \in K(X)^\times$, the function $-\log|f|$ is finite and continuous on Σ, and is integral affine on every edge of a finite subdivision.*

Proof. All skeletal points have generic algebraic support, so f and f^{-1} are analytic near Σ. At a vertex, the finitely many incident graph branches are among the residual directions of Theorem 4.25.3. Theorem 4.24.5 makes $-\log|f|$ integral affine on a sufficiently short initial segment of every one of them.

For an open nodal edge choose an algebraic affine neighborhood of its residual node. Its formal generic fibre contains the entire nodal tube. Express $f = P/Q$ in the fraction field of the generic coordinate algebra. The functions P, Q are analytic on that tube. In its pointed annulus coordinate, their norms on every compact subinterval of radii are finite maxima of Laurent monomial norms, by Proposition 4.4.1 and its first, nonunit, assertion. The two nonzero functions have positive Gauss norm at every radius. Subtracting their logarithmic profiles proves finite piecewise integral affineness on each compact interior subinterval. The already affine endpoint segments leave one such compact subinterval. There are finitely many edges, so one finite common subdivision works. □

Proposition 5.26.4 (Local rational coordinates of lattice slope one)**.** *Every point of Σ has a graph neighborhood W and finitely many rational functions whose negative logarithmic norms give an injective map $W \to \mathbf{R}^m$. On each sufficiently short edge of W, one coordinate has slope 1 or -1. At a model*

vertex the incident branches can be sent to distinct positive coordinate axes, after subtracting the value at the vertex.

Proof. For a point interior to an edge, its nodal annulus coordinate z is an analytic unit, and $-\log|z|$ is its length coordinate. Lemma 5.26.1 gives a rational function with the same norm on a neighborhood of the point. Restricting to a small interval proves the assertion there, for every real radius.

At a vertex v_C, label its incident branches by the distinct normalization points $p_1, \dots, p_m$, counting the two ends of a loop separately. Choose the residual functions u_i of Lemma 5.26.2. By Proposition 4.24.2, each is the residue of a norm-one element of $\mathcal{H}(v_C)$. The density of $K(X)$ in this field gives $f_i \in K(X)^\times$ of norm one with residue u_i. The slope formula Theorem 4.24.5 then gives, on the j-th short branch with length parameter τ,

$$\big(-\log|f_1|, \dots, -\log|f_m|\big)(\gamma_j(\tau)) = \tau e_j.$$

There are only finitely many pairs (i, j), so one shortening works for all of them. The resulting star is mapped injectively, with primitive edge direction vectors. An isolated vertex needs no local coordinates. □

Theorem 5.26.5 (Faithful tropicalization of a compact model skeleton)**.** *There is a nonempty Zariski open $U \subset X$ containing Σ in U^{an} and a closed immersion $\varphi : U \hookrightarrow \mathbf{G}_m^n$ such that $\varphi_{\mathrm{trop}}|_\Sigma$ is a homeomorphism onto its image. After a finite subdivision of Σ, its restriction to each edge is integral affine with primitive derivative vector. Thus each edge has its original logarithmic length measured in the primitive lattice length of its tropical image.*

Proof. Compactness gives finitely many neighborhoods from Proposition 5.26.4. Collect their coordinate functions into a map $F : \Sigma \to \mathbf{R}^a$. It is injective on each of these neighborhoods. Let V be the union of their Cartesian squares in $\Sigma \times \Sigma$. This is an open neighborhood of the diagonal. The compact set $E = (\Sigma \times \Sigma) \setminus V$ contains no diagonal point.

Any two distinct points $x, y \in \Sigma$ are separated by the absolute value of a nonzero rational function. Indeed, choose an algebraic affine open of X. It contains the algebraic support of every skeletal point, so its analytification contains x, y. Their distinct seminorms on its coordinate ring are separated by some element of that ring. By generic support, its two values are nonzero. The inequality of its two norms persists on a neighborhood of (x, y). Finitely many such neighborhoods cover E; append their rational functions to F. The

resulting map G is injective on all of Σ. It is a homeomorphism onto its image because its source is compact and its target is Hausdorff.

Proposition 5.26.3 gives a finite common subdivision on which all coordinates of G are integral affine. On the interior of each resulting edge, one of the original local coordinates has slope 1 or -1. Its derivative vector is therefore primitive. Refining further retains this property.

It remains to realize these coordinates in a closed torus immersion. Choose a nonempty affine open $U_0 = \operatorname{Spec} A$ of X. Write the finitely many rational functions of G as fractions of nonzero elements of A, and invert all their numerators and denominators. This gives a finite-type algebra B and an affine open on which these functions are units. Choose finitely many nonzero algebra generators of B, and invert them as well, obtaining B'. The chosen generators and their inverses generate B', so they give a surjection from a Laurent polynomial algebra onto B'. Append the functions defining G to this generating list. The resulting map $U = \operatorname{Spec} B' \to \mathbf{G}_m^n$ is a closed immersion. Every inverted element is nonzero in $K(X)$, so its zero locus contains no skeletal point; hence $\Sigma \subset U^{\mathrm{an}}$. Adding coordinates retains injectivity and a derivative coordinate equal to 1 or -1. Apply Proposition 5.26.3 once more to the appended functions and take a finite common refinement. All coordinates of the closed immersion are then affine on every subdivided edge, while the primitive derivative coordinate is retained. The primitive derivative formula identifies the two edge lengths, as asserted. □

References. This is the rational-coordinate form of faithful tropicalization for compact curve skeleta. The proof constructs local lattice-slope-one coordinates first, then uses compact pair separation and an affine algebra presentation to obtain a closed torus immersion.

5.27 Faithful curve coordinates over the original field

Lemma 5.27.1 (An affine neighborhood of finitely many projective points)**.** *Let Z be a projective scheme over any field k and let $q_1, \dots, q_m$ be distinct closed points. They lie in a common affine open of Z. If C is a projective integral curve and $p_1, \dots, p_m$ are distinct closed points of its normalization, there are functions $u_i \in k(C)^\times$ satisfying*

$$\operatorname{ord}_{p_j}(u_i) = \delta_{ij}.$$

Proof. Embed Z in $\mathbf{P}^n_k$ and let P_i be the homogeneous prime defining q_i. The P_i are pairwise incomparable. For each $j \neq i$, choose a homogeneous element of $P_j \setminus P_i$, and let g_i be their product; if $m = 1$, put $g_1 = 1$. Then g_i vanishes at the other selected points and not at q_i. Choose a coordinate $x_{a_i} \notin P_i$ and an integer $D \geq \max(1, \max_i \deg g_i)$. The homogeneous polynomial

$$F = \sum_i g_i x_{a_i}^{D - \deg g_i}$$

is outside every P_i: modulo P_i its only nonzero summand is the i-th. The standard affine open $D_+(F)$ in projective space therefore gives the required affine open on Z. This construction works over finite fields as well.

Apply this to the finitely many distinct images of the p_j on C. Its inverse image under normalization is affine, because normalization is finite by [StacksAlg, Tag 0BXR]. Write it as $\operatorname{Spec} B$, and let $\mathfrak{m}_j$ correspond to p_j. By [StacksAlg, Tag 0B8Y], $B_{\mathfrak{m}_i}$ is a discrete valuation ring. A local uniformizer is a_i/b_i with $a_i, b_i \in B$ and $b_i \notin \mathfrak{m}_i$, so a_i has order one at p_i. The ideals $\mathfrak{m}_i^2$ and $\mathfrak{m}_j$, $j \neq i$, are pairwise comaximal. The elementary Chinese remainder construction in Lemma 5.26.2 uses only these comaximalities, not any assumption on k: for $I + J = B$ and $a + b = 1$ with $a \in I, b \in J$, the element $br + as$ has prescribed residues r modulo I and s modulo J, and induction treats finitely many ideals. Choose u_i congruent to a_i modulo $\mathfrak{m}_i^2$ and to 1 modulo every other $\mathfrak{m}_j$. This gives precisely the displayed orders, regardless of the residue degrees of the p_j. □

In the rest of this section, K is complete and nontrivially valued, with its original absolute value. Let X be a smooth projective integral K-curve with a projective model $\mathcal{X}/K^\circ$ satisfying Theorem 4.23.3, or its characteristic-zero form Theorem 4.28.5. Thus all nodes used for the finite graph are split rational nodes with the stated pointed charts. Put $\Sigma = \Sigma(\mathcal{X})$.

Lemma 5.27.2 (Generic support and rational approximation over K)**.** *Every $x \in \Sigma$ has generic algebraic support. If g is an analytic germ at x with $g(x) \neq 0$, some $f \in K(X)^\times$ satisfies $|f| = |g|$ on an ordinary neighborhood of x. If $|g(x)| = 1$, the residues of $f(x)$ and $g(x)$ can also be made equal.*

Proof. For a finite extension E/K, Lemma 1.12.1 makes E complete, and its proof shows that every value in $v(E^\times)$ has a positive integer multiple in $v(K^\times)$. Moreover $\widetilde{E}/\widetilde{K}$ is algebraic: for $b \in E$ of norm one, take a polynomial relation over K, divide its coefficients by a coefficient of maximal norm, and

reduce. The resulting polynomial over $\widetilde{K}$ is nonzero and annihilates the residue of b. Thus the residual transcendence degree and relative rational value-group rank of a finite extension are both zero.

At a component vertex, Proposition 4.24.2 gives residual transcendence degree one. At an annular Gauss point, Proposition 3.8.1 gives the sum of these two invariants equal to one. If a skeletal point had closed algebraic support, its residue field would be a finite extension of K by [StacksAlg, Tag 00P0], and Proposition 2.10.1 would identify its completed residue field with that same finite field. This contradicts the preceding invariants. An integral algebraic curve has only generic and closed points, so its support is generic.

Consequently $\mathcal{H}(x)$ is the completion of $K(X)$ for the norm of x. Choose $f \in K(X)$ with $|f(x) - g(x)| < |g(x)|$. The rational function and its inverse are regular on a Zariski open containing the generic support; their analytifications are defined near x. Continuity preserves the strict inequality on an ordinary neighborhood, and the ultrametric inequality gives equality of the norms there. For norm-one values the error has norm less than one, which also identifies the residues. □

Proposition 5.27.3 (Integral affine coordinates on the original skeleton)**.** *For every $f \in K(X)^\times$, the function $-\log|f|$ is finite and continuous on Σ and integral affine on the edges of a finite subdivision. Every point of Σ has a graph neighborhood on which finitely many such functions give an injective map with a derivative coordinate equal to 1 or -1 on each short edge.*

Proof. By Lemma 5.27.2, f and its inverse are analytic near every skeletal point. At a vertex, each incident graph branch is a rational normalization point above a split node, by Lemma 4.24.1. Theorem 4.24.5, over the original field, makes the logarithmic norm affine with integral slope on a short initial segment. On the interior of a nodal edge, express $f = P/Q$ on an algebraic affine neighborhood of the residual node. Both functions are analytic on the nodal tube. On each compact radius subinterval their nonzero Gauss norms are finite maxima of Laurent monomial norms by Proposition 4.4.1. Hence their logarithmic difference has finitely many integral affine pieces. The endpoint segments leave a compact interior interval; doing this for the finitely many edges proves the first assertion.

At an interior point, approximate its annular coordinate z by Lemma 5.27.2. The rational norm agrees near that point with $|z|$, so its negative logarithm is an oriented length coordinate of slope one. At a vertex v_C, list

the finitely many distinct normalization points p_j corresponding to incident edges, counting the two branches of a loop separately. Lemma 5.27.1 gives $u_i \in k(C)^\times$ with orders δ_{ij}. Proposition 4.24.2 identifies these with norm-one residues in $\mathcal{H}(v_C)$. Approximate their lifts by $f_i \in K(X)$ with error of norm less than one. Theorem 4.24.5 gives, after a simultaneous shortening of finitely many branches,

$$(-\log|f_1|,\dots,-\log|f_m|)(\gamma_j(t)) = te_j.$$

These coordinates embed the small graph star in distinct positive coordinate axes and have primitive derivative vectors. An isolated vertex requires no coordinates. □

Theorem 5.27.4 (Original-field faithful tropicalization of a split model skeleton)**.** *There is a nonempty Zariski open $U \subset X$ with $\Sigma \subset U^{\mathrm{an}}$ and a closed immersion over the original field K,*

$$\varphi : U \hookrightarrow \mathbf{G}_{m,K}^n$$

whose tropicalization restricts to a homeomorphism on Σ. On a finite subdivision of its edges, it is integral affine with primitive derivative vector. Consequently it preserves every edge length with the original absolute value, when the image is measured by primitive lattice length.

Proof. Take finitely many graph neighborhoods from Proposition 5.27.3 covering the compact graph. Gather their rational coordinate functions into F. The union V of the squares of these neighborhoods is open in $\Sigma \times \Sigma$ and contains the diagonal. On every pair in V the coordinates of F separate distinct points. The complement E is compact and disjoint from the diagonal.

Any two distinct $x, y \in \Sigma$ are distinguished by a nonzero rational function over K. Indeed, any algebraic affine open of X contains their generic algebraic supports, and the two distinct seminorms on its coordinate ring differ on some element. Both values are nonzero by generic support. The strict inequality of absolute values persists on an ordinary neighborhood of (x, y). Finitely many such pair neighborhoods cover E. Append their rational functions to F, obtaining a globally injective continuous map G. A continuous injection of this compact graph into a Hausdorff real vector space is a homeomorphism onto its image.

Choose a nonempty affine open $\operatorname{Spec} A \subset X$. Invert the finitely many nonzero numerators and denominators of the coordinates of G, obtaining B,

and then invert finitely many nonzero algebra generators of B, obtaining B'. Those generators and their inverses generate B'. Together with the coordinates of G they therefore give a surjection from a Laurent polynomial K-algebra onto B', hence the required closed immersion for $U = \operatorname{Spec} B'$. Every function inverted is nonzero at every generic-support point, so $\Sigma \subset U^{\mathrm{an}}$. All choices and functions are defined over K.

Apply Proposition 5.27.3 to all final coordinates and take a finite common subdivision. On each resulting edge, one of the local coordinates has derivative 1 or -1 on a nonempty subinterval, hence on the entire edge because it is affine there. The full integer derivative vector is therefore primitive. Appending coordinates does not remove that coordinate or destroy injectivity. The primitive lattice parameter on the image is exactly the original annular length parameter, which proves the length assertion. □

References. The construction extends the compact-model-skeleton argument to the original field. Homogeneous finite-point separation replaces infinite-field hyperplane avoidance, and the residue/value invariants of finite extensions replace algebraic closedness in the support argument.

5.28 Geometric degrees and tropical lattice indices

Write $R = K^\circ$, $\mathfrak{m} = K^{\circ\circ}$ and $k = \widetilde{K}$. In the first two lemmas, K is complete and nontrivially valued, and $\pi \in R$ satisfies $0 < |\pi| < 1$. The formal algebras carry their quotient π-adic topologies. For a lattice M, the notation $R\langle M\rangle$ denotes the Gauss unit ball in $K\langle M\rangle$.

Lemma 5.28.1 (The quotient model of an initial degeneration)**.** *Let $I \subset K[M]$ be an ideal and set*

$$P = K\langle M\rangle, \qquad P_0 = R\langle M\rangle, \qquad J = IP.$$

Then

$$B_0 = P_0/(J \cap P_0)$$

is an admissible topologically finitely presented R-algebra, with generic algebra $B = P/J$. Its special algebra is

$$B_0/\mathfrak{m}B_0 \simeq k[M]/\overline{I \cap R[M]},$$

where the bar denotes coefficientwise reduction in $k[M]$.

Proof. The ideal J is closed by Theorem 1.18.3. The algebra B_0 embeds in P/J, so it has no R-torsion. It is a quotient of a restricted power-series algebra in finitely many variables: use generators for M and their inverses. Consequently Theorem 3.14.4 gives a finite presentation, and Proposition 3.14.5 gives completeness and separatedness. Every restricted Laurent series becomes integral after multiplication by a power of π. The same is true of every element of J, whence

$$B_0[1/\pi] = P/J.$$

The elements of P_0 of Gauss norm less than one form $\mathfrak{m}P_0$. To see this, choose a coefficient of maximal absolute value in a nonzero restricted series. Dividing by that coefficient gives an element of P_0; the coefficient belongs to $\mathfrak{m}$ precisely when the original norm is less than one. The reverse inclusion follows from the ultrametric inequality applied to a finite sum. Thus $P_0/\mathfrak{m}P_0 = k[M]$. Proposition 5.13.5 identifies the image of $J \cap P_0$ in this ring with $\overline{I \cap R[M]}$, proving the special-fibre formula. □

Lemma 5.28.2 (Finite formal models at the Gauss point)**.** *Let*

$$A_0 = R\langle U_1^{\pm 1}, \dots, U_d^{\pm 1}\rangle, \qquad A = A_0[1/\pi],$$

and let $A_0 \to B_0$ be a formal homomorphism to an admissible topologically finitely presented R-algebra. Suppose that $\overline{B}_0 = B_0/\mathfrak{m}B_0$ is finite over $k[U_1^{\pm 1}, \dots, U_d^{\pm 1}]$. Then B_0 is finite over A_0, and the generic algebra $B = B_0[1/\pi]$ has its canonical finite-A-module topology. If H is the completed residue field of the Gauss point of $\mathcal{M}(A)$, then

$$\dim_H (B \widehat{\otimes}_A H) = \dim_{k(U)} \left(\overline{B}_0 \otimes_{k[U^{\pm 1}]} k(U) \right). \tag{5.28.1}$$

Proof. Choose bounded formal generators $y_1, \dots, y_s$ of B_0, giving a surjection $A_0\langle Y_1, \dots, Y_s\rangle \to B_0$. Each $\overline{y}_i$ satisfies a monic polynomial over the residual Laurent ring. Lift its coefficients to obtain $P_i \in A_0[Y_i]$, monic of degree $r_i > 0$, with all lower coefficients of Gauss norm at most one. Since $P_i(y_i) \in \mathfrak{m}B_0$, this element is a finite sum of scalars in $\mathfrak{m}$ times elements of B_0. Lift those elements through the formal presentation. This produces $G_i \in A_0\langle Y\rangle$ with

$$G_i(y) = P_i(y_i), \qquad \|G_i\| < 1.$$

There are finitely many equations, so $\theta = \max_i \|G_i\| < 1$ is a common contraction bound.

Apply Lemma 3.16.4 over A. Its convergent division formula expresses every bounded restricted series, modulo the $P_i - G_i$, as a linear combination of the monomials Y^ν with $0 \leq \nu_i < r_i$. The coefficient maps have norm at most one, so a series in $A_0\langle Y\rangle$ has all its remainder coefficients in A_0. The images of these finitely many monomials therefore generate B_0 over A_0.

The same calculation compares the generic norms. Give B the quotient norm from $A\langle Y\rangle$ and let $\|\cdot\|_{\mathrm{fin}}$ be the quotient norm from the finite free A-module on the remainder monomials. A finite remainder expression gives $\|b\|_B \leq \|b\|_{\mathrm{fin}}$. Conversely, apply the bounded division formula to each representative of b and take the infimum of its norms. It gives $\|b\|_{\mathrm{fin}} \leq \|b\|_B$. Hence these quotient norms agree; the equivalent admissible norms give the same Banach topology.

Let $S \subset A_0$ consist of the elements of Gauss norm one, and put $V = S^{-1}A_0$. The Gauss norm is multiplicative by Proposition 1.2.2. Every nonzero restricted Laurent series a has a coefficient $c \in K^\times$ of maximal absolute value, so that $a = cs$ with $s \in S$. Every element of $\mathrm{Frac}(A)^\times$ is consequently of the form cs/t, where $c \in K^\times$ and $s, t \in S$. It belongs to V exactly when $|c| \leq 1$. Thus V is the Gauss valuation ring in $\mathrm{Frac}(A)$, with residue field $k(U)$: the reductions of S are all the nonzero Laurent polynomials. Its completion is H°. Indeed, an element of norm at most one in the completion of $\mathrm{Frac}(A)$ can be approximated, with error less than one, by elements of norm at most one, which belong to V.

The finite V-module $M = S^{-1}B_0$ is torsion-free. Every nonzero element of V is a nonzero scalar from R times a unit; multiplication by that scalar is injective on B_0 and remains injective after localization. A finite torsion-free module over a valuation ring is free. One can see this directly by choosing a generating set of minimal size: a nonzero relation has a coefficient dividing all the others, and torsion-freeness then expresses the corresponding generator in terms of the rest. This contradicts minimality.

The rank of M is therefore its residue dimension over $k(U)$, which is the right-hand side of (5.28.1). Tensoring its free basis with H computes $\dim_H(B \otimes_A H)$ with the same value. The norm comparison above and Proposition 2.33.19 identify this algebraic tensor product with $B\widehat{\otimes}_A H$. □

Proposition 5.28.3 (Initial multiplicity and an actual fibre degree)**.** *Let $X \subset T_N$ be a pure d-dimensional closed subscheme over a complete real-valued non-Archimedean field K. Let w belong to the relative interior of a maximal cell σ of an initial-stratum complex, and suppose that $q : N \to \mathbf{Z}^d$ restricts to an injective map on N_σ with finite index*

$$e = [\mathbf{Z}^d : q(N_\sigma)].$$

After a complete isometric extension realizing w, made nontrivially valued, translate w to zero. The induced monomial map from the actual tropical fibre X_w to the d-dimensional unit polycircle is finite and norm-admissible. Its fibre algebra over the completed Gauss residue field H has dimension $e\, m_X(\sigma)$. Multiplying the target coordinates by constants of absolute value one preserves these conclusions.

Proof. Theorem 5.13.6 supplies the required complete extension and translation, and Proposition 5.19.8 preserves the weight. The quotient model of Lemma 5.28.1 has the full initial algebra as its special algebra. By Proposition 5.19.3 and Theorem 5.19.5, a lattice splitting identifies it with

$$D[N_\sigma^\vee], \qquad \dim_k D = m_X(\sigma),$$

where D is a finite k-algebra.

In this presentation the target characters reduce to $d_j \chi^{a_j}$, with $d_j \in D^\times$. The a_j form a basis of a sublattice of index e in $N_\sigma^\vee$. Choose representatives for its cosets. Every character has a unique expression as one of these representatives times a product of the χ^{a_j}. Substitution of $\chi^{a_j} = d_j^{-1} U_j$ consequently makes $D[N_\sigma^\vee]$ free of rank e over $D[U^{\pm 1}]$. The asserted independence follows by comparing character exponents, since the d_j are units. A k-basis of D then gives a basis of size $e \dim_k D$ over $k[U^{\pm 1}]$.

The normalized monomials and their inverses belong to the quotient formal model, so this is the reduction of a formal homomorphism from the unit-polycircle model. Apply Lemma 5.28.2. It proves the finiteness, norm comparison and actual Gauss fibre dimension. A unit constant changes only one of the coefficients d_j in the preceding calculation. The calculation uses a basis of the entire finite algebra D, including its nilpotents. □

Lemma 5.28.4 (A finite free locus)**.** *Let $f : X \to Y$ be a dominant morphism of affine finite-type K-schemes. Suppose that Y is integral and that the generic fibre is nonempty and zero-dimensional. Put $F = K(Y)$ and*

$$\delta = \dim_F \Gamma(X_F, \mathcal{O}_{X_F}).$$

There is a nonzero $h \in \Gamma(Y, \mathcal{O}_Y)$ such that $f^{-1}(Y_h) \to Y_h$ is finite free of rank δ.

Proof. Write $Y = \operatorname{Spec}(A)$ and $X = \operatorname{Spec}(B)$. Lemma 5.19.1 makes the generic algebra B_F finite-dimensional. Each of a finite set of A-algebra generators of B satisfies a monic polynomial over F. Clear the finitely many coefficient denominators. Each resulting polynomial equality holds in B_F, so its error in the localized B is killed by a further nonzero element of A. After inverting the product of these finitely many elements, all the monic equalities hold. The bounded monomials in the generators then give a finite set of module generators for this localization of B.

Choose $c_1, \ldots, c_\delta$ among those monomials whose images form an F-basis of B_F. Express the other module generators in that basis. Clear their finitely many coefficient denominators and then kill their finitely many errors by another localization in $A \setminus \{0\}$. The c_i now generate the localized module. They are independent: a relation maps to an F-linear relation between their images, and its coefficients vanish because the localized A injects into F. The product of all elements inverted is the required h, and the displayed basis has size δ. □

Theorem 5.28.5 (The algebraic tropical degree formula)**.** *Let $\varphi : T_N \to T_{N'}$ be a homomorphism of split tori over a complete real-valued non-Archimedean field K, and write $a : N \to N'$ for its lattice map. Let $X \subset T_N$ be a pure d-dimensional closed subscheme and $Y \subset T_{N'}$ an integral d-dimensional closed subscheme. Suppose that $\varphi|_X : X \to Y$ is dominant with nonempty zero-dimensional generic fibre of scheme degree δ.*

There is a finite union E_{trop} of polyhedra of dimension less than d in $\mathrm{Trop}(Y)$ such that, for $w' \notin E_{\mathrm{trop}}$, its tropical preimages form a finite set $\{w_i\}_i$. Each w_i lies in the relative interior of a maximal initial cell σ_i, while w' lies in the relative interior of a maximal initial cell σ', and

$$\delta\, m_Y(\sigma') = \sum_i m_X(\sigma_i)[N'_{\sigma'} : a(N_{\sigma_i})]. \tag{5.28.2}$$

For the polyhedral pushforward of Theorem 5.17.2, this is the weighted-cycle identity

$$a_* \operatorname{Trop}(X) = \delta \operatorname{Trop}(Y).$$

Proof. Step 1: choose the finite free locus and the regular weights. Choose h by Lemma 5.28.4, and let $E = Y \setminus Y_h$ have its reduced closed structure. Every irreducible component of E has dimension less than d: a chain of primes above a nonzero prime of the domain $\Gamma(Y, \mathcal{O}_Y)$ becomes one step longer after adjoining its zero prime. Apply Theorem 5.19.5 to the finitely many components of E. Their tropicalizations form a finite union of lower-dimensional polyhedra.

Also exclude the nonmaximal cells of $\operatorname{Trop}(Y)$, the images of nonmaximal cells of $\operatorname{Trop}(X)$, and the images of maximal source cells on which a has rank less than d. Intersect these images with the target complex. The finite polyhedral elimination and refinement in Theorem 5.17.2 give a finite union E_{trop} of polyhedra of dimension less than d. It cannot contain the relative interior of a maximal target cell.

Fix $w' \notin E_{\mathrm{trop}}$. Each of its tropical preimages is in the relative interior of a maximal source cell on whose direction space a is injective. Each of finitely many such cells contributes at most one point. Thus the preimage set is finite. Near each w_i, the image of its full-dimensional source cell is contained in the local tropical support at w', which is the direction space of σ'. The dimensions are equal, so

$$a(N_{\sigma_i})_{\mathbf{R}} = N'_{\sigma',\mathbf{R}}.$$

The indices in (5.28.2) are therefore finite.

Step 2: decompose the actual inverse-image algebra. Use Theorem 5.13.6 to make one complete isometric extension L/K realizing w' and all the w_i, with nontrivial valuation. The finite free algebra on Y_h remains free of rank δ after extension, and Proposition 5.19.8 preserves all the weights. In particular, the subsequent argument uses the same finite free module even if Y_L is reducible or nonreduced.

Write $Y_{w'} = \mathcal{M}(C)$ for the actual target tropical fibre over L. Since $w' \notin \operatorname{Trop}(E)$, h has no zero on this fibre. It is therefore a unit in C by Theorem 1.20.1, and $Y_{w'} \subset (Y_h)^{\mathrm{an}}$. The explicit tensor description in Theorem 2.33.26 shows that the inverse image is $\mathcal{M}(D)$, where D is a finite C-algebra free of rank δ.

Every point of this inverse image has tropical weight one of the w_i. Its subset of weight w_i is the actual affinoid domain $X_{w_i} = \mathcal{M}(B_i)$ of Proposition 5.13.2. These subsets are open and closed: they are fibres of a continuous map with values in a finite Hausdorff set. Applying the structure sheaf property of Theorem 2.39.4 to this finite disjoint cover gives

$$D \simeq \prod_i B_i. \tag{5.28.3}$$

The inverse image is nonempty. Indeed, $C \neq 0$ and $\delta > 0$, so $D \neq 0$; the affinoid nonemptiness theorem 1.20.1 gives a point of $\mathcal{M}(D)$. Consequently the set of w_i is nonempty.

Step 3: compare all degrees over one Gauss field. The saturated lattice $N'_{\sigma'}$ is a direct summand of N' by Lemma 5.14.1. Choose $q : N' \to \mathbf{Z}^d$ whose restriction to it is an isomorphism. Divide the corresponding target monomials by their values at a translating point of weight w'. This gives one unit-polycircle algebra $A = L\langle U_1^{\pm 1}, \dots, U_d^{\pm 1}\rangle$ mapping to C and to every B_i. After the respective source translations, the induced monomials differ from those for $q \circ a$ by constants of absolute value one, because $a(w_i) = w'$.

Let H be the completed Gauss residue field of A. Proposition 5.28.3 gives

$$\begin{aligned} \dim_H(C \widehat{\otimes}_A H) &= m_Y(\sigma'), \\ \dim_H(B_i \widehat{\otimes}_A H) &= m_X(\sigma_i)[N'_{\sigma'} : a(N_{\sigma_i})]. \end{aligned}$$

All the maps are finite with the canonical finite-module norms, so Proposition 2.33.19 identifies these completed tensors with the algebraic ones. Since D is free of rank δ over C, tensoring its free basis over A with H gives

$$\dim_H(D \otimes_A H) = \delta \dim_H(C \otimes_A H).$$

Taking dimensions in (5.28.3) proves (5.28.2).

Theorem 5.22.5 makes both weighted tropicalizations balanced cycles. Choose compatible source and target subdivisions as in the polyhedral pushforward theorem. The equality holds on a dense relative open subset of every maximal target cell. Both weights are constant on each such cell by Proposition 5.19.8 and the definition of polyhedral pushforward. This proves the weighted-cycle identity. □

Remark 5.28.6 (Finite algebras and nonreduced targets). Every degree in the proof is the dimension of a finite algebra. For the map $t \mapsto t^p$ in characteristic p, both this degree and the lattice index are p, although each geometric fibre has one underlying point.

The same proof applies to a pure d-dimensional target Y if there is an open subset meeting all its generic points on which the source algebra is finite free of one fixed rank δ. The complement again has dimension less than d, and Steps 2 and 3 use precisely this free module. For comparison, the closed immersion

$$T^d \hookrightarrow T^d \times \operatorname{Spec} K[\epsilon]/(\epsilon^2), \qquad \epsilon \longmapsto 0,$$

is finite and dominant on underlying spaces, but its generic module is not free. The source weight is one and the target weight is two. Thus its residue-field degree one does not give the displayed degree formula. Realize the target as a torus subscheme by writing $\epsilon = V - 1$ and imposing $(V-1)^2 = 0$.

References. The weighted-cycle identity is the classical Sturmfels–Tevelev multiplicity formula; its trivial- and nontrivial-valuation forms are reviewed in [GRW16, §8]. The proof above derives it from the initial quotient model and the actual finite analytic fibres. The short valuation-module and generic-basis arguments agree with the algebraic facts in the Stacks Project, Tags 0539, 00NZ, 02NW and 051S.

5.29 Analytic coordinates on a skeletal chart

Let K be complete and nontrivially valued, with its specified real-valued absolute value. Put $O = K^\circ$, $k = \widetilde{K}$, $v = -\log|\cdot|$, and $\Gamma = v(K^\times)$. Consider a topologically finitely presented formally étalemap of admissible algebras

$$A_0 = O\langle X_0, \dots, X_r, T_1, \dots, T_q\rangle/(X_0 \cdots X_r - a) \longrightarrow B_0, \qquad 0 < |a| < 1.$$

Write $B = B_0 \otimes_O K$, $Y = \mathcal{M}(B)$, and $\Sigma \subset Y$ for the inverse image of the standard skeleton. The notation Δ_I, Q_I, and $x_{\eta,w}$ is that of Proposition 5.24.2 and Theorem 5.24.4. In particular, Σ is a compact finite complex, and a point over the relative interior of Δ_I is specified by w and $\eta \in Q_I$. A finite piecewise Γ-integral-affine function has integral linear parts and constants in Γ on a finite subdivision defined by integral linear inequalities with constants in Γ.

Proposition 5.29.1 (Finite piecewise-affine values)**.** *Let $g \in B$ be nonzero at every point of Σ. Then $v(g)|_\Sigma$ is finite piecewise Γ-integral-affine. One finite hyperplane subdivision of the standard simplex induces a suitable subdivision on every skeletal cell.*

Proof. Assume that Σ is nonempty. Compactness gives $\alpha = \min_\Sigma |g| > 0$. Use the bounded square-Jacobian presentation of Lemma 5.23.1, with root coordinates $Y_1, \dots, Y_m$, inverse determinant Q, and integral polynomial equations $F(Y) = 0$ whose coefficients belong to A_0. Give its generic algebra the quotient Banach norm in which all these coordinates have norm at most one. Choose a polynomial $P(X, T, Y, Q)$ such that

$$\|g - P(X, T, Y, Q)\| < \varepsilon < \alpha.$$

Let $M \geq 1$ bound the absolute values of its coefficients. The difference of two monomials, expanded one factor at a time, shows that P is M-Lipschitz on tuples of norm at most one.

Approximate the finitely many restricted coefficients of F by integral polynomials in X, T, with error $\delta < 1$ and $M\delta < \varepsilon$, obtaining G. At the original root, both $G(Y)$ and $G'(Y) - F'(Y)$ have norm at most δ. The inverse of $F'(Y)$ has norm at most one, since its adjugate is integral and Q has norm at most one. The geometric inverse gives the same bound for $G'(Y)^{-1}$. Lemma 5.18.1 produces $Y_G \in B^m$ with

$$G(Y_G) = 0, \qquad \|Y_G - Y\| \leq \delta, \qquad \|Y_G\| \leq 1.$$

The determinant and reciprocal identities imply that $Q_G = (\det G'(Y_G))^{-1}$ has norm at most one and $\|Q_G - Q\| \leq \delta$. Hence

$$g_G = P(X, T, Y_G, Q_G), \qquad \|g_G - g\| < \alpha, \qquad |g_G(x)| = |g(x)| \quad (x \in \Sigma).$$

Put

$$R = K[X_0, \dots, X_r, T]/(X_0 \cdots X_r - a),$$
$$C = R[Y, Q]/(G, Q \det G' - 1), \qquad F_0 = \mathrm{Frac}(R).$$

Eliminating X_0 identifies R with a Laurent polynomial ring in $X_1, \dots, X_r$ and a polynomial ring in T, so it is a domain. The square-zero correction by the inverse Jacobian proves that C/R is formally étale. It is finitely presented, and therefore étaleby [StacksAlg, Tag 00UR]. Its affine generic fibre is a finite product of finite separable extensions of F_0 by [StacksAlg,

Tag 02GL]; finiteness here follows from quasi-compactness of this discrete fibre. Thus the image of P satisfies a polynomial over F_0.

At a skeletal point, evaluation on R is its standard Gauss norm and has zero kernel. The evaluation $C \to \mathcal{H}(x)$ therefore extends to $C \otimes_R F_0$. In particular this generic fibre is nonzero. Clear the denominators of an annihilating polynomial and remove its largest common power of the variable. Because $g_G(x) \neq 0$, the resulting relation holds at every skeletal point and has nonzero constant and leading coefficients:

$$\sum_{i=0}^{s} A_i g_G^i = 0, \qquad A_i \in R.$$

There are at least two nonzero terms. Write $\lambda_i(w) = v(A_i(z_w))$ for each nonzero A_i. A Laurent polynomial Gauss norm makes λ_i the minimum of finitely many Γ-integral-affine functions. At least two terms of the displayed relation have the smallest valuation, whence

$$v(g(x_{\eta,w})) \in \left\{ \frac{\lambda_i(w) - \lambda_j(w)}{j - i} : i < j,\ A_i A_j \neq 0 \right\}.$$

Subdivide the standard simplex by comparisons of coefficient monomials and then by comparisons of the resulting affine candidates. Multiplying the equations by positive integers leaves integral hyperplanes with constants in Γ. On a connected relative open piece the distinct candidates have a fixed strict order. A continuous selection from them must select one throughout that piece. This gives finitely many rational-affine formulas, with a common subdivision on all the skeletal cells.

To establish integrality, fix a relative open cell. The proof of Theorem 5.25.3, before its use of the unit hypothesis, constructs a single coefficient field L_0 with $v(L_0^\times) = \Gamma$ and an open polyannulus parametrizing this cell's Gauss points. Pull back g to that polyannulus. The Laurent expansion constructed in Lemma 5.25.1 gives

$$\log |g(z_w)| = \max_m \{\log |c_m| - \langle m, w \rangle\}.$$

On a full-dimensional open piece where the left side is affine, choose a Laurent term attaining the maximum at an interior point. The difference between the left side and this term is affine, nonnegative, and zero at an interior point, so it is identically zero there. That piece consequently has an integral slope and a constant in Γ. Continuity gives the same assertion on its faces. Each

lower-dimensional piece is a face of a full-dimensional piece in its original cell. An original zero-dimensional cell is evaluated in L_0 itself. This proves the assertion on every cell. □

Lemma 5.29.2 (Small scalar shifts)**.** *For $h \in B$, at most finitely many $c \in K$ make $h + c$ vanish at a point of Σ. Consequently a nonvanishing shift can be chosen with arbitrarily small positive $|c|$.*

Proof. On each relative open cell use the fixed coefficient field and polyannulus from the preceding proof. If $h + c$ vanishes at one Gauss point, every Laurent coefficient vanishes. Its pullback is then the zero function on that polyannulus. Since the inclusion of K is isometric, at most one scalar has this property on a given cell. The same argument for a zero-dimensional cell takes place in its coefficient field. There are finitely many cells. Powers of any $\pi \in K$ with $0 < |\pi| < 1$ give infinitely many distinct nonzero scalars converging to zero, so they avoid the finite exceptional set. □

Theorem 5.29.3 (Faithful analytic coordinates)**.** *There are an ordinary open analytic neighbourhood V of Σ in Y and an analytic map $\varphi : V \to (\mathbf{G}^N_{m,K})^{\mathrm{an}}$ whose tropicalization is a homeomorphism on Σ onto its image. On every cell of a finite subdivision it is integral affine and induces an isomorphism onto the saturated lattice of its image.*

Proof. Include the units $X_0, \dots, X_r$, whose product is a; their valuations distinguish the base weights. For each I and $\eta \in Q_I$, choose $\bar{h}_\eta$ in the special-fibre algebra that belongs to every other prime in Q_I and does not belong to η. Indeed these primes are incomparable, since they lie in the same zero-dimensional étalefibre; multiplying elements of $\eta' \setminus \eta$ for $\eta' \neq \eta$ gives the required element. Omit the construction when Q_I has fewer than two members. Lift $\bar{h}_\eta$ to $h_\eta \in B_0$ and choose $0 < |c_\eta| < 1$ by Lemma 5.29.2 so that $g_\eta = h_\eta + c_\eta$ is nonzero on Σ. Specialization gives, for $w \in \operatorname{relint} \Delta_I$,

$$|g_\eta(x_{\eta,w})| = 1, \qquad 0 < |g_\eta(x_{\eta',w})| < 1 \quad (\eta' \neq \eta).$$

Thus this finite list separates points over the same weight.

Let V be the complement of the zero loci of the g_η. It is an ordinary open neighbourhood of Σ. Each g_η is an analytic unit on V: near any point choose a positive lower bound for its norm and use the inverse on the corresponding rational domain, as in Theorem 2.31.2. These units and the X_i define φ. Its

tropicalization is continuous and injective on Σ, hence is a homeomorphism onto its image by compactness.

Apply Proposition 5.29.1 to the finite list. The union of its hyperplanes gives a common finite subdivision, compatible with all coordinate faces and their identifications. On a subcell the linear map is, after eliminating one standard coordinate, the graph $n \mapsto (n, Ln)$ of an integral map. Projection to the first coordinates is an integral left inverse. If a point of its real image belongs to the ambient integer lattice, its first coordinates belong to the subcell's saturated tangent lattice; the entire point is then the corresponding integral graph point. This proves the claimed lattice equality. □

5.30 Rational coordinates on a projective model

The passage to rational functions uses an algebraic model. The projective assumption also provides a common affine open on which the functions separating residual strata are bounded. The following elementary construction works over a finite residue field as well.

Lemma 5.30.1 (Common affine neighbourhoods of residual points)**.** *Let O be a local ring with residue field k, and let $P \hookrightarrow \mathbf{P}^n_O$ be a closed immersion. Every finite subset $Z \subset |P_k|$ is contained in an affine open of P. If P_k is of finite type over k, there is a finite family of affine opens $U_j \subset P$ such that each U_j contains Z and every two points of P_k lie together in some U_j.*

Proof. Represent the points of Z by homogeneous primes of $k[x_0, \dots, x_n]$. Discard any prime contained in another one in this finite list. Avoiding the remaining maximal primes also avoids all the discarded ones. Denote these pairwise incomparable primes by $\mathfrak{p}_1, \dots, \mathfrak{p}_s$. For $i \neq j$ choose a homogeneous element $a_{ij} \in \mathfrak{p}_j \setminus \mathfrak{p}_i$; one exists because both ideals are homogeneous. Put $h_i = \prod_{j \neq i} a_{ij}$. Choose a coordinate x_{ℓ_i} outside $\mathfrak{p}_i$ and an integer $D \geq 1$ at least all the degrees of the h_i. Then

$$\bar{H} = \sum_{i=1}^{s} h_i x_{\ell_i}^{D - \deg h_i}$$

is homogeneous of positive degree and is outside every $\mathfrak{p}_i$: modulo $\mathfrak{p}_i$ only its ith summand survives, and that summand is nonzero. For $s = 1$ the empty product is one, so the same construction applies. For $Z = \varnothing$ any coordinate suffices.

Lift the coefficients to a homogeneous polynomial H over O. The standard open $D_+(H)$ in projective space is affine by [StacksAlg, Tag 01MB]. Its intersection with P is therefore an affine open containing Z.

Apply the first assertion to $Z \cup \{p, q\}$ for every $p, q \in P_k$. The open products $U_k \times_k U_k$ obtained in this way cover $P_k \times_k P_k$: the two projections of a point of the product form such a pair. This product has a finite affine cover, obtained from the pairwise products of a finite affine cover of P_k. Each affine scheme is quasi-compact: refine an open cover by standard opens $D(f_\alpha)$. Their elements generate the unit ideal, since otherwise [StacksAlg, Tag 00E0(2)] would give a maximal ideal outside the cover. An expression for 1 uses finitely many f_α and gives a finite subcover. Choose a finite subcover. Finally, every underlying pair (p, q) is the image of a point of the scheme product. Indeed $\kappa(p) \otimes_k \kappa(q)$ is a nonzero ring: if $1 \otimes 1 = 0$, this equality is witnessed by finitely many defining bilinear relations. Let $E \subset \kappa(p)$ and $F \subset \kappa(q)$ be the finite-dimensional k-subspaces spanned by 1 and every entry in these relations. Choose linear functionals on E and F that take 1 to 1. Their product annihilates all the chosen relations but takes $(1, 1)$ to 1, a contradiction. By [StacksAlg, Tag 00E0(2)], the nonzero tensor ring has a maximal ideal, which is prime and provides the desired point. Thus the finite subcover has the stated pair property. □

Fix a projective, flat, finitely presented O-scheme $\mathcal{X}$ with smooth integral generic fibre X. Assume that $\mathcal{X}_s$ has a finite affine open cover $\mathcal{U}_\lambda = \operatorname{Spec} C_\lambda$, where each $\mathcal{U}_\lambda$ admits an étale$O$-morphism to

$$\operatorname{Spec} O[X_0, \dots, X_{r_\lambda}, T_1, \dots, T_{q_\lambda}]/(X_0 \cdots X_{r_\lambda} - a_\lambda), \qquad 0 < |a_\lambda| < 1.$$

Here an affine open cover of $\mathcal{X}_s$ means affine opens of $\mathcal{X}$ whose special fibres cover $\mathcal{X}_s$. Complete along any $\pi \in O$ with $0 < |\pi| < 1$. Lemma 4.13.1 and Theorem 4.13.2 identify the completion with an admissible model of X^{an}. The completed charts are formally étaleand form a finite formal-open cover: a square-zero lifting problem modulo π^m is the algebraic étalelifting problem, and its compatible solutions give the completed lifting property. Consequently Theorem 5.25.4 gives its compact finite integral-affine skeleton S.

Proposition 5.30.2 (Skeletal valuations of rational functions)**.** *Every point of S is a norm on $K(X)$. For every $f \in K(X)^\times$, the function $v(f)|_S$ is continuous and finite piecewise Γ-integral-affine. Moreover the set of specializations of points of S is finite and is the set of generic residual-stratum points occurring in the completed charts.*

Proof. Consider a chart meeting S, and write $C_K = C_\lambda \otimes_O K$. It is a nonzero domain because $\mathcal{U}_{\lambda,K}$ is a nonempty affine open of the integral scheme X. The algebraic generic chart base

$$R = K[X_0, \dots, X_r, T]/(X_0 \cdots X_r - a)$$

is a domain. The map $R \to C_K$ is étale, hence flat by [StacksAlg, Tag 00U2(3),(6)]. A nonzero flat algebra over a domain is torsion free, so this map is injective. For $F_0 = \mathrm{Frac}(R)$, the algebra $C_K \otimes_R F_0$ is a nonzero domain and an affine étalealgebra over F_0. By [StacksAlg, Tag 02GL] it is a finite separable field extension. Since it contains C_K and is contained in $\mathrm{Frac}(C_K)$, it equals $\mathrm{Frac}(C_K) = K(X)$.

For a point x of the chart skeleton, evaluation on R is the standard Gauss norm. It is nonzero on every nonzero element of R. Thus the map $C_K \to \mathcal{H}(x)$ extends to $C_K \otimes_R F_0 = K(X)$. This is a unital map from a field, hence injective. The absolute value on $\mathcal{H}(x)$ gives the asserted norm on $K(X)$. All points of S belong to one of these charts.

On each chart write $f = g/h$ with nonzero $g, h \in C_K$. Their images are analytic on its completed generic fibre and are nonzero at every skeletal point by the preceding argument. Proposition 5.29.1 applies to both. Their valuation difference is continuous and has finitely many integral-affine formulas there. The finite cover gives the assertion globally, with the formulas agreeing on common faces by evaluation of the same rational function.

By Proposition 5.24.2, a point of a chart skeleton over $w \in \mathrm{relint}\,\Delta_I$ specializes to its label $\eta \in Q_I$. Conversely every such label has its nonempty relative open simplex. Each Q_I is finite, there are finitely many I and charts, and the formal specializations agree on overlaps. This proves the last assertion. □

Theorem 5.30.3 (Faithful rational tropicalization of a projective skeleton)**.** *In the stated projective algebraic model setting, there are a dense open $U \subset X$ with $S \subset U^{\mathrm{an}}$ and a closed immersion $\varphi : U \hookrightarrow \mathbf{G}_{m,K}^{N}$ such that $\operatorname{trop} \circ \varphi^{\mathrm{an}}|_{S}$ is a homeomorphism onto its image. On every cell of a finite subdivision of S, this map is Γ-integral-affine and identifies the tangent lattice with the saturated lattice of its image. All coordinates belong to the original field $K(X)$ and use the specified absolute value of K.*

Proof. Algebraic chart coordinates. For each chart include its multiplicative coordinates $X_0, \dots, X_r$ as nonzero rational functions on X. Proposition 5.30.2 makes all their norms finite and positive on all of S. On each relative open cell of their own chart their valuations are the standard simplex coordinates. Thus they distinguish two points with the same residual label and provide an integral left inverse on each cell's tangent lattice.

Separation of residual labels. Let $Z \subset \mathcal{X}_s$ be the finite set of skeletal specializations from the preceding proposition. Use Lemma 5.30.1 to choose one affine open $\mathcal{W} = \operatorname{Spec} D$ of $\mathcal{X}$ containing all of Z. Every point of S belongs to the generic fibre of $\widehat{\mathcal{W}}$, because this generic fibre is the inverse image of $\mathcal{W}_s$ under specialization; see Lemma 4.13.1 and the formal-open restriction statement in Proposition 5.23.4. Elements of D are therefore bounded by one at every point of S.

View the members of Z as distinct prime ideals of $D \otimes_O k$. For each unordered distinct pair choose an orientation $(\mathfrak{p}, \mathfrak{q})$ with $\mathfrak{p} \not\subseteq \mathfrak{q}$, choose $\bar{h} \in \mathfrak{p} \setminus \mathfrak{q}$, and lift it to $h \in D$. Flatness embeds D in the coordinate ring of its generic open, hence in $K(X)$. Since $\bar{h} \neq 0$, this is a nonzero rational function. At a skeletal point specializing to $\mathfrak{p}$ its norm is less than one; at one specializing to $\mathfrak{q}$ its norm is one. These values follow directly from the definition of specialization for a bounded formal function. Add all these finitely many lifts to the coordinate list.

The resulting tropical map is injective on S. Indeed the new functions distinguish different specializations. If x, y have the same specialization η, choose an algebraic chart containing η. Both points belong to its completed generic fibre and its skeleton, by formal-open restriction. In that chart they have the same residual label, and equality of the multiplicative coordinate values gives the same w. The bijection in Proposition 5.24.2 then gives $x = y$.

A closed immersion of a dense open. Let $f_1, \dots, f_M$ denote the list just constructed. Choose a nonempty affine open $V = \operatorname{Spec} A$ of X and nonzero

algebra generators $t_1, \dots, t_b$ for the finitely generated integral K-algebra A; zero generators can be omitted. Write $f_i = p_i/q_i$ with nonzero $p_i, q_i \in A$, and put

$$s = \prod_j t_j \prod_i p_i q_i, \qquad U = \operatorname{Spec} A[1/s].$$

Append the functions t_j, p_i, q_i to the list. They are units on U, and the induced homomorphism from the Laurent polynomial coordinate ring of the torus onto $A[1/s]$ is surjective: it contains the generators t_j of A and the inverse of their displayed product s. This gives a closed immersion. The norm statement in Proposition 5.30.2 says that every point of S has generic scheme support. It therefore belongs to the analytification of every nonempty open of X, in particular to U^{an}.

Lattices and topology. All coordinates of the final list are finite piecewise Γ-integral-affine on S. Subdivide each original cell so that these finitely many coordinates are affine. Its original chart coordinates remain among them, and projection to those coordinates gives an integral left inverse. The graph argument in Theorem 5.29.3 shows that the resulting map on every such subcell is unimodular. Their images are finitely many Γ-integral polyhedra. To see this explicitly, the coordinate projection identifies each image with its source polyhedron, and its other coordinates are the graphs of integral-affine formulas with constants in Γ. Cut the finite family of image polyhedra by their supporting hyperplanes. As in Lemma 5.14.2, this gives a finite common polyhedral subdivision. Pulling it back under the injective map gives a subdivision compatible with every face identification in S, and preserves the integral left inverses on tangent lattices. Finally S is compact, and its continuous injective map to $\mathbf{R}^N$ is a homeomorphism onto its image. □

References. The faithful tropicalization theorem is a reconstruction, for the stated projective unmarked algebraic models, of the method in Gubler–Rabinoff–Werner, *Skeletons and tropicalizations*, arXiv:1404.7044v3, Section 9. The affine construction above uses homogeneous prime avoidance; its projective standard-open input is [StacksAlg, Tag 01MB].

5.31 Finite projections of analytic tropical fibres

Let K be complete for its given real-valued non-Archimedean absolute value. The first two results allow the trivial valuation and generalized affinoid algebras. For an affinoid space X, write

$$\partial_K X = X \setminus \mathrm{Int}(X/\mathcal{M}(K)).$$

For a tuple $r = (r_1, \dots, r_d)$ of positive real numbers put

$$A_r = K\{r^{-1}T, rS\}/(T_iS_i - 1)_{i=1}^d, \qquad \mathbb{T}_r = \mathcal{M}(A_r).$$

Thus $\mathbb{T}_r$ is the exact-radius polytorus $|T_i| = r_i$. All quotient ideals below are actual algebraic ideals, and all tensor products with a hat are separated completed tensor products.

Theorem 5.31.1 (Boundary avoidance gives an actual finite algebra)**.** *Let $X = \mathcal{M}(B)$ be a generalized K-affinoid space and let $g_1, \dots, g_d \in B^\times$. For $r_i > 0$ set*

$$F_r = \{x \in X : |g_i(x)| = r_i \text{ for every } i\},$$
$$B_r = B\{r^{-1}U, rV\}/(U_i - g_i, V_i - g_i^{-1})_{i=1}^d.$$

Suppose $F_r \cap \partial_K X = \varnothing$. Then B_r is finite over A_r under $T_i \mapsto U_i$, $S_i \mapsto V_i$, and its given affinoid norm is equivalent to its canonical finite-module norm. The spectrum of this algebra is the actual affinoid domain F_r, with its induced analytic structure. The assertion includes the empty domain and uses the original field and absolute value.

Proof. The equations defining B_r are a joint Weierstrass presentation: they impose $|g_i| \le r_i$ and $|g_i^{-1}| \le r_i^{-1}$. Theorems 2.31.1 and 2.31.2 identify its spectrum, algebra, and domain mapping property with F_r. They also cover the zero algebra. We may therefore assume $B \neq 0$.

Choose positive real numbers a_i, b_i such that

$$a_i < r_i < b_i, \qquad \|g_i\| < b_i, \qquad \|g_i^{-1}\| < a_i^{-1}.$$

The larger closed polyannulus has algebra

$$C = K\{b^{-1}T, aS\}/(T_iS_i - 1)_{i=1}^d.$$

Substitution gives a bounded map $C \to B$ by Proposition 1.9.3. The exact-radius polytorus is an affinoid domain of $\mathcal{M}(C)$. Its algebra is A_r: applying

the rational universal property in both directions identifies the joint inequalities $|T_i| \le r_i$ and $|S_i| \le r_i^{-1}$ with its displayed presentation.

For $x \in F_r$, the hypothesis says that $x \in \mathrm{Int}(\mathcal{M}(B)/\mathcal{M}(K))$. Apply the affinoid composition formula 2.44.1 to

$$\mathcal{M}(B) \longrightarrow \mathcal{M}(C) \longrightarrow \mathcal{M}(K).$$

It gives $x \in \mathrm{Int}(\mathcal{M}(B)/\mathcal{M}(C))$. By the actual rational base-change presentation and Proposition 2.33.8,

$$B\widehat{\otimes}_C A_r \simeq B_r$$

boundedly, with bounded inverse. The bounded maps from B and A_r to B_r agree on C, so the pushout gives one map. In the pushout the images of g_i and g_i^{-1} are the images of the two coordinates of A_r; their powers therefore have bounds by constant multiples of r_i^m and r_i^{-m}. Bounded substitution gives the reverse map from B_r. Both composites fix all coefficient and coordinate images, hence are identities by polynomial density. The base-change assertion of Proposition 2.33.21 now puts every point of $\mathcal{M}(B_r)$ in its relative interior over $\mathbb{T}_r$. Theorem 2.43.8 proves both finite generation over A_r and equivalence with the canonical finite module norm. □

Proposition 5.31.2 (The factors of a finite projected level)**.** *Let $f_1, \dots, f_n \in B^\times$ define*

$$t : X \longrightarrow \mathbb{R}^n, \qquad t(x) = (-\log|f_1(x)|, \dots, -\log|f_n(x)|).$$

Let $Q = (q_{ji}) \in M_{d\times n}(\mathbb{Z})$ and $w' \in \mathbb{R}^d$. Suppose

$$w' \notin Q(t(\partial_K X)),$$
$$Q^{-1}(w') \cap t(X) = \{w_1, \dots, w_s\}$$

is finite. Put $g_j = \prod_i f_i^{q_{ji}}$ and $r_j = \exp(-w'_j)$. Then the actual algebras of the fibres $t^{-1}(w_i)$ give a bounded product decomposition

$$B_r \simeq \prod_{i=1}^{s} B_{w_i}.$$

Each B_{w_i} is finite over A_r with its canonical module norm. For every $\xi \in \mathbb{T}_r$, with $H = \mathcal{H}(\xi)$, these are actual finite analytic fibre algebras and

$$\dim_H(B_r\widehat{\otimes}_{A_r}H) = \sum_{i=1}^{s} \dim_H(B_{w_i}\widehat{\otimes}_{A_r}H).$$

The empty finite set has zero product algebra and degree zero.

Proof. The monomials g_j are analytic units and satisfy $(-\log|g_j|)_j = Q \circ t$. The boundary condition therefore gives the hypothesis of Theorem 5.31.1. Its finite algebra B_r represents $(Q \circ t)^{-1}(w')$. The continuous map t on this space has the finite image $\{w_1, \dots, w_s\}$. Each inverse image is consequently open and closed. It is also the actual rational domain defined by

$$|f_j| = \exp(-(w_i)_j) \quad (1 \le j \le n).$$

The rational universal property identifies this domain with the one obtained by imposing the same equalities directly on X. These domains are pairwise disjoint and form a finite affinoid cover of $\mathcal{M}(B_r)$. The norm-strict equalizer of Theorem 2.38.1 is thus precisely the asserted bounded product isomorphism, since all intersections have zero algebra. Each factor is a direct summand of the finite A_r-module B_r. Theorem 1.18.3 identifies its induced and canonical module norms.

By Proposition 2.33.19, tensoring these finite modules with H is already complete. Algebraic tensor product preserves the finite direct sum underlying the product, so dimensions add as displayed. Theorem 2.33.11 identifies these tensor algebras with the actual analytic fibres over ξ. □

5.32 Finite quotient models retaining moment coordinates

Now assume that K is nontrivially valued, and put $O = K^\circ$, $\mathfrak{m} = K^{\circ\circ}$, $k = O/\mathfrak{m}$. Choose $\pi \in O$ with $0 < |\pi| < 1$ and set

$$A_0 = O\langle T_1^{\pm 1}, \dots, T_d^{\pm 1}\rangle, \qquad A = A_0[1/\pi].$$

The integral algebra A_0 is the unit ball for the Laurent Gauss norm, and $\widetilde{A} = k[T_1^{\pm 1}, \dots, T_d^{\pm 1}]$. These identifications follow from the actual Laurent normal form 1.17.2 and the multiplicative Gauss norm 1.2.2.

Theorem 5.32.1 (A finite formal model containing prescribed bounded elements)**.** *Let $A \to D$ be a bounded map of generalized K-affinoid algebras. Assume that D is finite over A and its given norm is equivalent to its canonical finite-A-module norm. Let $h_1, \dots, h_m \in D$ be power-bounded elements. There is an admissible topologically finitely presented O-algebra $D_0 \subset D$, finite over A_0, such that*

$$D_0[1/\pi] = D, \qquad h_1, \dots, h_m \in D_0.$$

It can be chosen as the actual image of a finite restricted-series presentation $A_0\langle Y\rangle \to D$. Its generic-fibre Banach structure is the given one on D.

Let ξ be the Gauss point of $\mathcal{M}(A)$ and $H = \mathcal{H}(\xi)$. For this model put

$$C_0 = (D_0/\mathfrak{m}D_0) \otimes_{k[T^{\pm 1}]} k(T_1, \dots, T_d).$$

Then C_0 is a finite-dimensional algebra, and

$$\begin{aligned} \dim_H(D\widehat{\otimes}_A H) &= \dim_{k(T)} C_0 \\ &= \sum_{\mathfrak{n}\in \operatorname{Max} C_0} \operatorname{length}_{(C_0)_\mathfrak{n}}((C_0)_\mathfrak{n})[\kappa(\mathfrak{n}) : k(T)]. \end{aligned} \tag{5.32.1}$$

For fixed $A \to D$, this total degree is independent of the chosen presentation and of the chosen admissible finite A_0-model with generic algebra D.

Proof. For $D = 0$ use $D_0 = 0$. Otherwise choose finite A-module generators $b_1, \dots, b_\ell$. Multiplying each by a sufficiently small nonzero power of π, obtain generators $e_1, \dots, e_\ell$ with $\|e_j\| \le 1$. Append the prescribed h_i to this list, and denote the resulting power-bounded elements by $z_1, \dots, z_N$. By Proposition 1.9.3, evaluation defines a bounded surjection

$$q : P = A\langle Y_1, \dots, Y_N\rangle \longrightarrow D, \qquad Y_i \longmapsto z_i.$$

It is norm-admissible. Indeed the first ℓ images still generate D as an A-module, and Theorem 1.18.3 gives uniformly controlled coefficients for a linear lift in these generators. That linear polynomial is a lift through q. Consequently the quotient norm from P is equivalent to the given norm on D. This presentation also proves that D is strict over K.

Put $P_0 = A_0\langle Y_1, \dots, Y_N\rangle$, $J = \ker q$, and

$$D_0 = P_0/(J \cap P_0) \subset D.$$

The map on the right is injective by construction. In particular D_0 has no O-torsion. Since P_0 is topologically finite type over O, Proposition 3.14.5, applied to the finite P_0-module $P_0/(J \cap P_0)$, proves that its quotient π-adic topology is complete and separated. Theorem 3.14.4 makes it topologically finitely presented. Also $P_0[1/\pi] = P$, by bounding the coefficients of a restricted series, whence $D_0[1/\pi] = D$. All the h_i lie in D_0.

It remains to prove finiteness over A_0. The finite map $A \to D$ is a map of strict affinoids. By Theorem 3.16.5, $\widetilde{D}$ is finite over $\widetilde{A}$. For each z_i choose a

monic relation for its residue over $k[T^{\pm 1}]$, and lift its coefficients to a monic $p_i(Z) \in A_0[Z]$. Then

$$w_i = p_i(z_i) \in D^{\circ\circ}.$$

In the quotient norm from q, $\|w_i^n\| \to 0$; topological nilpotence is unchanged by the equivalent norm just established. For each of the finitely many i, choose $a_i \geq 1$ and an actual lift $G_i \in P$ of $w_i^{a_i}$ with $\|G_i\| < 1$. Such a lift exists by the definition of the quotient infimum once $\|w_i^{a_i}\| < 1$. Since there are finitely many lifts,

$$\theta = \max_i \|G_i\| < 1.$$

In particular $G_i \in P_0$ and $p_i(Y_i)^{a_i} - G_i \in J \cap P_0$. The strict Laurent coefficient norm of a nonzero G_i attains its maximum at a coefficient in K. Choosing such a coefficient c_i gives $G_i = c_i G_i'$ with $G_i' \in P_0$ and $c_i \in \mathfrak{m}$. The zero lift has the same conclusion. Thus every G_i vanishes modulo $\mathfrak{m} D_0$.

Reduction of P_0 is the polynomial algebra $k[T^{\pm 1}, Y_1, \ldots, Y_N]$, since restricted coefficients are eventually smaller than one. The images of the Y_i in $D_0/\mathfrak{m}D_0$ satisfy the monic equations $\overline{p}_i(Y_i)^{a_i} = 0$. The bounded powers below their degrees span this quotient over $k[T^{\pm 1}]$. Lemma 5.28.2 now applies to the actual admissible quotient $A_0 \to D_0$. It proves that D_0 is finite over A_0, compares its generic norm with the canonical finite module norm, and gives the first equality in (5.32.1).

For the second equality, decompose the finite-dimensional Artinian algebra C_0 into its local factors by [StacksAlg, Tag 00JB]. A composition series of the factor $(C_0)_{\mathfrak{n}}$ has $\mathrm{length}_{(C_0)_{\mathfrak{n}}}((C_0)_{\mathfrak{n}})$ successive quotients equal to $\kappa(\mathfrak{n})$. Taking vector-space dimensions proves the formula. In particular the local lengths are those of the actual quotient algebra. Finally any admissible finite A_0-model of the same D has finite reduction, so Lemma 5.28.2 identifies its total degree with the same left side. This proves independence. □

For an application to the preceding projected fibres, suppose $r_j = |c_j|$ with $c_j \in K^{\times}$; the change of coordinate $T_j \mapsto c_j T_j$ identifies the target with the unit polytorus over K. If the full moment weight w_i also has $\exp(-(w_i)_a) = |b_a|$ with $b_a \in K^{\times}$, the functions f_a/b_a and b_a/f_a have absolute value one on $t^{-1}(w_i)$. They are power bounded by Theorem 1.20.2. Including both in the prescribed list places the normalized moment characters and their inverses in D_0. The resulting finite model and the degree in (5.32.1) use these original-field coordinates with the original absolute value.

5.33 Common models for finite moment projections

Fix a complete nontrivially valued field K with its given real-valued absolute value, and write

$$O = K^{\circ}, \qquad \mathfrak{m} = K^{\circ\circ}, \qquad k = O/\mathfrak{m}.$$

Choose $\pi \in O$ with $0 < |\pi| < 1$. An *actual admissible model* of a K-affinoid algebra D is an admissible topologically finitely presented O-subalgebra $D_0 \subset D$ for which $D_0[1/\pi] = D$ and the generic-fibre Banach topology is the given topology of D. The special algebra is always the actual quotient $\overline{D}_0 = D_0/\mathfrak{m}D_0$.

Proposition 5.33.1 (Simultaneous finite models)**.** *For $1 \le i \le r$, let*

$$A_{i,0} = O\langle U_{i,1}^{\pm 1}, \dots, U_{i,d}^{\pm 1} \rangle, \qquad A_i = A_{i,0}[1/\pi],$$

and let $A_i \to D$ be bounded homomorphisms. Assume that D is finite over every A_i and that its given norm is equivalent to each canonical finite-module norm.

Every actual admissible model $D_0 \subset D$ containing the images of all the $U_{i,j}$ and $U_{i,j}^{-1}$ is finite over every $A_{i,0}$. Such models exist and may contain any prescribed finite list of power-bounded elements of D.

More generally, let $E_{1,0}, \dots, E_{s,0}$ be actual admissible models of D, each containing the target coordinates and their inverses for at least one of the maps $A_i \to D$. There is an actual admissible model $C_0 \subset D$ containing all the $E_{j,0}$ and all target coordinates and inverses. It is finite over every $A_{i,0}$ and over every $E_{j,0}$.

Proof. An actual admissible model D_0 is a bounded open O-submodule of D. Indeed, take a formal presentation $O\langle Z \rangle \twoheadrightarrow D_0$. Its generic presentation has the quotient Banach topology. The image of the Gauss unit ball is bounded and contains every element whose quotient norm is strictly less than one, by the definition of the quotient infimum. Equivalence with the given norm proves the assertion. In particular, every element of D_0 is power bounded: all its powers lie in the bounded set D_0. The same argument shows that πD_0 is open in D.

The images of $U_{i,j}$ and their inverses define a continuous formal map $A_{i,0} \to D_0$. Restricted-series substitution is valid in the complete π-adic

ring D_0, and agrees in D with the given bounded homomorphism. Fix i, and choose formal generators $z_1, \dots, z_N$ of D_0 over O. The generic algebra D is strict, since it is the generic fibre of this model. Theorem 3.16.5 makes its canonical reduction $\widetilde{D}$ finite over $k[U_i^{\pm 1}]$. For each z_a, lift a monic equation of its canonical residue to a monic polynomial $p_a(Z) \in A_{i,0}[Z]$. Its value $p_a(z_a)$ is topologically nilpotent in D. Since πD_0 is open, some positive power of this value belongs to πD_0. Consequently the image $\overline{z}_a \in \overline{D}_0$ satisfies a monic equation $\overline{p}_a(Z)^{n_a} = 0$ over $k[U_i^{\pm 1}]$.

The algebra $\overline{D}_0$ is generated by the finitely many $\overline{z}_a$ over this Laurent ring. The powers below the degrees of these monic equations span it as a module. Thus $\overline{D}_0$ is finite over $k[U_i^{\pm 1}]$. Lemma 5.28.2 gives finiteness of D_0 over $A_{i,0}$. This argument applies separately to every i and does not require flatness over $A_{i,0}$.

For existence, use Theorem 5.32.1 with $A_1 \to D$. Append to its prescribed list all target coordinates and inverses, and all formal generators of all $E_{j,0}$. The target elements are power bounded because the maps $A_i \to D$ are bounded. The model generators are power bounded by the first paragraph. The resulting actual model C_0 contains every $E_{j,0}$: restricted series in its formal generators converge in C_0, and their values in D are the original values. It is finite over all $A_{i,0}$ by the part already proved. If $A_{i,0}$ maps into $E_{j,0}$, any finite list of $A_{i,0}$-module generators of C_0 also generates it over $E_{j,0}$. This proves the last assertion. For $D = 0$ all the models may be taken to be zero. □

Definition 5.33.2 (Top-dimensional special cycles)**.** For a finite-type k-algebra R of dimension at most d, put

$$[\operatorname{Spec} R]_d = \sum_{\substack{\mathfrak{p} \in \operatorname{Min} R \\ \dim(R/\mathfrak{p}) = d}} \operatorname{length}_{R_{\mathfrak{p}}}(R_{\mathfrak{p}})[\operatorname{Spec}(R/\mathfrak{p})].$$

For a finite morphism of finite-type k-schemes, the pushforward of an integral component is its image multiplied by the full degree of the extension of function fields. Pushforward of cycles is extended additively. These are cycles before passage to rational equivalence.

Proposition 5.33.3 (Component lengths under a finite model comparison)**.** *Let $D_0 \subset C_0 \subset D$ be actual admissible models of the same affinoid algebra, both finite over*

$$A_0 = O\langle U_1^{\pm 1}, \dots, U_d^{\pm 1}\rangle.$$

The inclusion induces a finite morphism $\nu : \operatorname{Spec} \overline{C}_0 \to \operatorname{Spec} \overline{D}_0$, and

$$\nu_*[\operatorname{Spec} \overline{C}_0]_d = [\operatorname{Spec} \overline{D}_0]_d.$$

More precisely, for every d-dimensional minimal prime $\mathfrak{p}$ of $\overline{D}_0$,

$$\operatorname{length}((\overline{D}_0)_{\mathfrak{p}}) = \sum_{\mathfrak{q} \mapsto \mathfrak{p}} \operatorname{length}((\overline{C}_0)_{\mathfrak{q}})[\kappa(\mathfrak{q}) : \kappa(\mathfrak{p})], \tag{5.33.1}$$

where the sum is over the d-dimensional minimal primes of $\overline{C}_0$ above $\mathfrak{p}$.

Proof. Finite A_0-module generators of C_0 also generate it over D_0, so ν is finite. Both special algebras are finite over $k[U^{\pm 1}]$ and are Noetherian by [StacksAlg, Tag 00FN]. Their components have dimension at most d. By [StacksAlg, Tag 00P0], a component has dimension d exactly when it dominates $\operatorname{Spec} k[U^{\pm 1}]$: its function field is finite over the fraction field of the corresponding prime quotient of $k[U^{\pm 1}]$, and a nonzero prime imposes a nonzero polynomial relation on its d Laurent generators.

Let $S \subset A_0$ be the elements of Laurent Gauss norm one. The Gauss-localization argument of Lemma 5.28.2 identifies

$$V = S^{-1}A_0, \qquad F = \operatorname{Frac}(A_0), \qquad \kappa(V) = k(U).$$

Here V is a valuation ring, and every nonzero element of V is a nonzero scalar from O times a unit. The finite modules $M = S^{-1}D_0$ and $N = S^{-1}C_0$ are therefore torsion free over V and free by the finite-generator argument in that lemma. They are subalgebras of the same generic algebra

$$E = D \otimes_{A_0[1/\pi]} F.$$

Both span E over F. They consequently have the same rank n. Their residue algebras are

$$B = \overline{D}_0 \otimes_{k[U^{\pm 1}]} k(U), \qquad C = \overline{C}_0 \otimes_{k[U^{\pm 1}]} k(U).$$

They retain the full generic local rings of the corresponding special fibres. If $n = 0$, there are no components to compare.

By [StacksAlg, Tag 00JB], B and C are products of their Artinian local factors. Fix a maximal ideal $\mathfrak{p}$ of B, and let $\bar{b} \in B$ be the idempotent which is one on $B_{\mathfrak{p}}$ and zero on the other factors. Choose any lift $b \in M$. Multiplication by b on the two free V-modules M and N has the same characteristic polynomial: after scalar extension to F, both operators are multiplication by the same element on E. Equality over V follows from $V \subset F$.

Reducing this equality to $k(U)$ gives

$$t^{n-a}(t-1)^{a} = t^{n-a'}(t-1)^{a'}, \qquad a = \dim_{k(U)} B_{\mathfrak{p}}, \quad a' = \dim_{k(U)}(\bar{b}C).$$

The factors t and $t-1$ are relatively prime in every characteristic, so $a = a'$. The idempotent $\bar{b}$ selects exactly the local factors $C_{\mathfrak{q}}$ whose maximal ideals contract to $\mathfrak{p}$ in B. Taking a composition series of each Artinian local factor therefore gives

$$\operatorname{length}(B_{\mathfrak{p}})[\kappa(\mathfrak{p}) : k(U)] = \sum_{\mathfrak{q} \mapsto \mathfrak{p}} \operatorname{length}(C_{\mathfrak{q}})[\kappa(\mathfrak{q}) : k(U)].$$

Divide by the positive integer $[\kappa(\mathfrak{p}) : k(U)]$ and use the tower formula for field degrees. Localization identifies these local rings with those in (5.33.1), proving that formula and the cycle identity. No local factor has been replaced by its reduced quotient. □

5.34 The residual cycle of a finite analytic moment fibre

Let N be a lattice, $M = N^{\vee}$, and $\mathbb{T}_N = \operatorname{Spec} k[M]$. A normalized moment tuple on D is a homomorphism

$$h : M \longrightarrow D^{\times}$$

such that every character value and its inverse are power bounded. A basis and its inverses suffice for this condition. For $Q : N \to \mathbf{Z}^d$, put

$$A_Q = K\langle U_1^{\pm 1}, \dots, U_d^{\pm 1} \rangle, \qquad U_j \longmapsto h(Q^{*} e_j).$$

We consider those Q for which this map is finite and the given norm on D is equivalent to the canonical finite-A_Q-module norm. Write H_Q for the completed residue field of the Gauss point of $\mathcal{M}(A_Q)$, and put

$$\delta_Q = \dim_{H_Q}(D \mathbin{\widehat{\otimes}}_{A_Q} H_Q).$$

An actual model is *compatible with h* if it contains the values of a basis of M and their inverses.

Theorem 5.34.1 (A residual moment cycle independent of the projection)**.** *Suppose at least one such finite projection Q exists. For any actual model D_0 compatible with h, the residual moment morphism*

$$\phi_0 : \operatorname{Spec} \overline{D}_0 \longrightarrow \mathbb{T}_N$$

is finite, and the effective cycle

$$\mathcal{C}_d(D, h) = (\phi_0)_*[\operatorname{Spec} \overline{D}_0]_d$$

is independent of the model and of the finite projection used to construct it. If $\mathcal{C}_d(D, h) = \sum_Z c_Z[Z]$, then every finite projection Q restricts to a finite dominant map $q_Z : Z \to \mathbb{T}_{\mathbf{Z}^d}$, and

$$\delta_Q = \sum_Z c_Z[k(Z) : k(U_1, \dots, U_d)]. \tag{5.34.1}$$

The cycles also respect monomial changes of moment coordinates. Precisely, let $a : N \to N'$ and $h' = h \circ a^*$, and suppose that h' admits a finite projection to a d-dimensional unit polytorus for the same actual algebra D. The residual monomial map is finite on every component of $\mathcal{C}_d(D, h)$ and

$$\mathcal{C}_d(D, h') = a_* \mathcal{C}_d(D, h).$$

Proof. Proposition 5.33.1 supplies compatible models and makes every such model finite over the formal target of every finite projection. Fix one projection Q. The map $k[U^{\pm 1}] \to \overline{D}_0$ factors through the residual moment homomorphism $k[M] \to \overline{D}_0$. Its finite module generators therefore also generate $\overline{D}_0$ over $k[M]$. This proves that ϕ_0 is finite.

For two compatible models, the same proposition gives a common model C_0 containing both and finite over both. All three models are finite over the target of the fixed Q. Proposition 5.33.3 identifies the pushforwards of the top-dimensional cycle of $\operatorname{Spec} \overline{C}_0$ with those of both models. Their residual moment maps agree. Pushforwards of these finite cycles compose because degrees of finite extensions of function fields multiply. Pushing to $\mathbb{T}_N$ proves the asserted independence, including comparison of models initially constructed using different projections.

For any other finite projection, use the same compatible model. Each d-dimensional component of its special fibre dominates $\mathbb{T}_{\mathbf{Z}^d}$ by the dimension argument in Proposition 5.33.3. Its residual moment image Z is also d-dimensional. The coordinate ring of Z lies between the image of $k[U^{\pm 1}]$ and the coordinate domain of the source component. The latter is finite over $k[U^{\pm 1}]$. Every generator of the intermediate ring is consequently integral over $k[U^{\pm 1}]$, and finitely many generators satisfying monic equations make it finite. Thus q_Z is finite and dominant.

By Lemma 5.28.2 and the Artinian length formula in Theorem 5.32.1,

$$\delta_Q = \sum_{\dim(\overline{D}_0/\mathfrak{p})=d} \operatorname{length}((\overline{D}_0)_{\mathfrak{p}})[\kappa(\mathfrak{p}) : k(U)].$$

Group the terms having the same residual moment image Z. The definition of c_Z and the field-degree tower formula give exactly (5.34.1).

For the last assertion, a model compatible with h is also compatible with h'. It is finite over a target of a finite projection for h'. On every component, the coordinate ring of the residual h-image is intermediate between the ring of the residual h'-image and a finite algebra over the latter. The same monic-equation argument proves finiteness of the induced map of image components. The two residual moment maps now compose through a, and multiplication of the full field degrees proves the cycle identity. □

Theorem 5.34.2 (The degree of a subtorus-invariant residual cycle)**.** *In the preceding theorem let $L \subset N$ be a saturated sublattice of rank d. Suppose every reduced integral support Z of $\mathcal{C}_d(D,h)$ is stable, as a closed subscheme, under translation by the split subtorus $\mathbb{T}_L$. Let $\rho : \mathbb{T}_N \to \mathbb{T}_{N/L}$ be the quotient map. There are distinct closed points $s_1, \dots, s_t$ of $\mathbb{T}_{N/L}$ and positive integers $c_1, \dots, c_t$ with*

$$\mathcal{C}_d(D,h) = \sum_{j=1}^{t} c_j[\rho^{-1}(s_j)].$$

The empty sum is allowed. For every finite projection Q for which $Q|_L$ is injective, put

$$e_Q = [\mathbf{Z}^d : Q(L)].$$

Then

$$\delta_Q = e_Q \mu, \qquad \mu = \sum_{j=1}^{t} c_j[\kappa(s_j) : k] \in \mathbf{Z}_{\geq 0}. \tag{5.34.2}$$

In particular, δ_Q/e_Q is independent of all these projections and is positive exactly when the residual cycle is nonzero.

Proof. Lemma 5.14.1 gives a splitting $N = L \oplus N_1$. Put $M_0 = (N/L)^\vee$ and $M_L = L^\vee$. Then $k[M] = k[M_0][M_L]$, and translation by $\mathbb{T}_L$ is the character grading by M_L.

Let $I \subset k[M]$ be the prime ideal of an integral support Z. The scheme-theoretic invariance hypothesis says that the coaction sends I to $I \otimes_k k[M_L]$. If $f = \sum_\alpha f_\alpha \chi^\alpha \in I$, with $f_\alpha \in k[M_0]$, independence of the characters in the second tensor factor shows that each $f_\alpha \chi^\alpha$ belongs to I. Multiplication by the inverse character then puts f_α in $I \cap k[M_0]$. Thus

$$I = (I \cap k[M_0])k[M], \qquad k[Z] = (k[M_0]/(I \cap k[M_0]))[M_L].$$

The coefficient algebra is a finite-type domain. Since $\dim Z = d$, the dimension–transcendence-degree equality [StacksAlg, Tag 00P0] makes its fraction field algebraic over k. Its finitely many algebra generators are therefore algebraic over k. They span a finite-dimensional domain by their monic equations, and this domain is a field. It is $\kappa(s)$ for a closed point s of $\mathbb{T}_{N/L}$. This proves that $Z = \rho^{-1}(s)$. Distinct integral supports give distinct points, establishing the first formula.

Fix one of these points, and write $k' = \kappa(s)$. Under the splitting its fibre has coordinate ring $k'[M_L]$. The target characters for Q have the form

$$U_i \longmapsto d_i \chi^{a_i}, \qquad d_i \in (k')^\times.$$

The a_i generate a sublattice of M_L of index e_Q; equivalently, this is the dual index of the injective map $Q|_L$. Choose one representative for each coset. Every character has a unique expression as a representative times a product of the χ^{a_i}, and the units d_i can be absorbed into its coefficient. These representatives are therefore a basis of $k'[M_L]$ over $k'[U^{\pm 1}]$. A k-basis of k' gives a basis of size $e_Q[k' : k]$ over $k[U^{\pm 1}]$. This is the same character-coset calculation as in Proposition 5.28.3. The generic field degree of $\rho^{-1}(s) \to \mathbb{T}_{\mathbf{Z}^d}$ is consequently $e_Q[k' : k]$. Substitution in (5.34.1) of Theorem 5.34.1 gives (5.34.2). Full residue-field degrees, including inseparable degrees, enter this computation. The positive coefficients c_j already contain the unreduced generic lengths from the actual models. □

Theorem 5.34.3 (Projection comparison at a flat analytic tropical germ)**.** *Let $X = \mathcal{M}(B)$ be a generalized K-affinoid space and let $f_1, \dots, f_n \in B^\times$ define the moment map*

$$t : X \longrightarrow \mathbf{R}^n, \qquad t(x) = (-\log|f_1(x)|, \dots, -\log|f_n(x)|).$$

Let $w \in \mathbf{R}^n$, and choose $b_j \in K^\times$ with $|b_j| = \exp(-w_j)$. Put $h_j = f_j/b_j$, let $D = B_w$ be the actual algebra of $F_w = t^{-1}(w)$, and set $N = \mathbf{Z}^n$. Suppose there are a saturated rank-d sublattice $L \subset N$ and a neighborhood W of w such that

$$t(X) \cap W \subset w + L_{\mathbf{R}}, \qquad F_w \cap \partial_K X = \varnothing.$$

Assume that the normalized moment tuple on D admits a finite projection to a d-dimensional unit polytorus with its canonical finite-module norm.

Every integral support of $\mathcal{C}_d(D, h)$ is a fibre of $\mathbb{T}_N \to \mathbb{T}_{N/L}$ over a closed point. Consequently, for any finite projections Q_0, Q_1 of this same actual algebra with $Q_i|_L$ injective,

$$\frac{\dim_{H_{Q_0}}(D \widehat{\otimes}_{A_{Q_0}} H_{Q_0})}{[\mathbf{Z}^d : Q_0(L)]} = \frac{\dim_{H_{Q_1}}(D \widehat{\otimes}_{A_{Q_1}} H_{Q_1})}{[\mathbf{Z}^d : Q_1(L)]} = \sum_s c_s [\kappa(s) : k] \in \mathbf{Z}_{\geq 0},$$

where $\mathcal{C}_d(D, h) = \sum_s c_s [\rho^{-1}(s)]$.

Proof. The functions h_j and h_j^{-1} have absolute value one on F_w, so they are power bounded in D by Theorem 1.20.2. Theorem 5.34.1 therefore applies. If its cycle is zero, its support assertion is empty and the degree formula follows from Theorem 5.34.2.

Choose $\varepsilon > 0$ so small that the closed box $\{v : |v_j - w_j| \leq \varepsilon \text{ for all } j\}$ is contained in W. Let $Y \subset X$ be its inverse image, the actual rational affinoid domain

$$e^{-\varepsilon} \leq |h_j| \leq e^{\varepsilon} \quad (1 \leq j \leq n).$$

Its presentation by the h_j and h_j^{-1} is the actual joint Laurent presentation of Theorem 2.31.2. At every $x \in F_w$, all the relative coordinate inequalities are strict, since $1 < e^{\varepsilon}$. Thus $x \in \operatorname{Int}(Y/X)$. The boundary hypothesis and the composition inclusion in Proposition 2.33.21 give

$$F_w \subset \operatorname{Int}(Y/K).$$

Imposing the equalities $|h_j| = 1$ on Y gives the same actual algebra D as imposing them on X, again by the rational universal property.

Put $M_0 = M \cap L_{\mathbf{R}}^{\perp}$. For $u \in M_0$, the unit $h_u = \prod_j h_j^{u_j}$ has absolute value one at every point of Y, because $t(Y) - w \subset L_{\mathbf{R}}$. Theorem 1.20.2 and bounded substitution, Proposition 1.9.3, give a morphism

$$h_u : Y \longrightarrow \mathcal{M}(K\langle T^{\pm 1}\rangle).$$

For $x \in F_w$, apply the forward implication for absolute evaluation to the actual collar Y, using $x \in \operatorname{Int}(Y/K)$. The image S_x of $\widetilde{\mathcal{O}(Y)}^{\mathrm{gr}}$ in $\widetilde{\mathcal{H}(x)}^{\mathrm{gr}}$ is finite over $\widetilde{K}^{\mathrm{gr}}$. Choose finitely many homogeneous module generators for S_x. The component of $\widetilde{K}^{\mathrm{gr}}$ that takes any given generator to degree one has dimension at most one over k. Thus $(S_x)_1$ is a finite-dimensional k-algebra. The identity $|h_u| = 1$ on Y gives spectral radius one, and $|h_u(x)| = 1$ makes its degree-one initial image the nonzero residue of $h_u(x)$ in $\widetilde{\mathcal{H}(x)}$. This residue lies in $(S_x)_1$ and is therefore algebraic over k.

Choose an actual model D_0 compatible with h and a d-dimensional minimal prime $\mathfrak{p}$ of $\overline{D}_0$. The formal specialization theorem 3.16.15 supplies $x \in \mathcal{M}(D) = F_w$ specializing to $\mathfrak{p}$. By the definition of specialization, evaluation induces an injection

$$\overline{D}_0/\mathfrak{p} \hookrightarrow \widetilde{\mathcal{H}(x)},$$

and hence an injection of its fraction field. The preceding paragraph shows that the residue of every h_u, $u \in M_0$, is algebraic over k in this fraction field.

Let Z be the residual moment image of this component. Its coordinate ring is the image of $k[M]$ in that field, and $\dim Z = d$ by finiteness of the residual moment map. The image of $k[M_0]$ is a finitely generated algebraic domain over k, hence a finite field k' by monic equations and finite-dimensional linear algebra. It corresponds to a closed point s of $\mathbb{T}_{N/L}$. Split $N = L \oplus N_1$ using Lemma 5.14.1. The coordinate ring of Z is then an integral quotient of $k'[L^{\vee}]$. A nonzero kernel would give a nonzero Laurent polynomial relation on its d character generators and lower the transcendence degree below d. This contradicts $\dim Z = d$ and [StacksAlg, Tag 00P0]. The quotient map is therefore an isomorphism. Thus $Z = \rho^{-1}(s)$ as a closed subscheme. This treats every support of the residual cycle, and Theorem 5.34.2 now gives the displayed degree comparison. □

5.35 Purity and degrees near a projected analytic level

Throughout this section K is complete for its specified real-valued non-Archimedean absolute value. Generalized affinoid algebras and the trivial valuation are allowed. An affinoid algebra B is pure of analytic dimension d if $\dim_K \mathcal{M}(B/\mathfrak{p}) = d$ for every minimal prime $\mathfrak{p}$ of B. We use analytic dimension before strictification; it need not equal the Krull dimension of a generalized affinoid algebra.

Lemma 5.35.1 (Components under a free-radius extension)**.** *Let B be a generalized K-affinoid algebra, let r be a finite K-free polyradius, and put $L = K_r$ and $B_L = B\widehat{\otimes}_K L$. If B is integral, then B_L is integral. For arbitrary nonzero B, extension of ideals gives a bijection*

$$\operatorname{Min}(B) \longrightarrow \operatorname{Min}(B_L), \qquad \mathfrak{p} \longmapsto \mathfrak{p}B_L.$$

Moreover

$$B_L/\mathfrak{p}B_L \simeq (B/\mathfrak{p})_L, \qquad \dim_L \mathcal{M}(B_L/\mathfrak{p}B_L) = \dim_K \mathcal{M}(B/\mathfrak{p}).$$

Consequently B is pure of analytic dimension d if and only if B_L is pure of analytic dimension d.

Proof. Suppose first that B is integral. By Lemma 2.52.1, there is $x \in \mathcal{M}(B)$ with kernel zero. In the coefficient description of Theorem 1.16.2, its Gauss lift is

$$\left|\sum_{\nu} b_\nu T^\nu\right|_{\sigma_r(x)} = \max_{\nu} |b_\nu(x)| r^\nu$$

by Theorem 1.19.1. A nonzero coefficient family has a nonzero coefficient, whose value at x is positive. Thus this multiplicative seminorm has kernel zero, and B_L is a domain. No freeness over $\mathcal{H}(x)$ is used.

The actual quotient identity follows from Theorem 1.18.8. Applied to $B/\mathfrak{p}$, the preceding argument shows that $\mathfrak{p}B_L$ is prime. Its contraction is $\mathfrak{p}$, by the constant embedding in $(B/\mathfrak{p})_L$. Every prime of B_L contracts to a prime of B containing a minimal prime, by [StacksAlg, Tag 00E0(4)]. It therefore contains one of the primes $\mathfrak{p}B_L$. These extended primes cannot contain one another, since their contractions are distinct minimal primes. They are exactly the minimal primes of B_L. Finally apply Theorem 3.21.8 to each quotient. This proves the dimension formula and both purity implications. □

Lemma 5.35.2 (Dimension at maximal ideals of a strict affinoid)**.** *Let B be a nonzero strict K-affinoid algebra and let $\mathfrak{m}$ be a maximal ideal. Then*

$$\dim B_{\mathfrak{m}} = \max_{\substack{\mathfrak{p}\in \operatorname{Min}(B)\\ \mathfrak{p}\subseteq \mathfrak{m}}} \dim(B/\mathfrak{p}).$$

In particular, if B is pure of dimension d, then every maximal localization has dimension d.

Proof. First let $R = K\langle T_1, \dots, T_e\rangle$ and let $\mathfrak{n}$ be maximal. Theorem 1.12.3 makes $E = R/\mathfrak{n}$ a finite extension of K. Write a_i for the image of T_i; boundedness of the residue point gives $|a_i| \leq 1$. A finite K-basis of E, together with the norm comparison of Lemma 1.12.1, identifies $E\langle T\rangle$ with the finite free R-module $R\otimes_K E$: expanding coefficients in that basis preserves convergence in both directions. This ring extension is integral by [StacksAlg, Tag 00GK].

In $E\langle T\rangle$, the coordinate ideals

$$(0) \subset (T_1 - a_1) \subset \cdots \subset (T_1 - a_1, \dots, T_e - a_e)$$

form a strict chain of prime ideals. Translation by the a_i is a bounded automorphism, and each quotient is a Tate algebra in the remaining variables. The last ideal contracts to $\mathfrak{n}$. Incomparability for an integral extension, [StacksAlg, Tag 00GT], makes all contractions in this chain distinct. Hence $\dim R_{\mathfrak{n}} \geq e$. The reverse inequality follows from $\dim R = e$, proved in Proposition 3.21.1.

Now suppose that B is integral, of dimension e. Choose a finite injection $R = K\langle T_1, \dots, T_e\rangle \hookrightarrow B$ by Theorem 1.12.2 and Proposition 3.21.1. The contraction $\mathfrak{n} = \mathfrak{m} \cap R$ is maximal: its quotient is a K-subalgebra of the finite extension $B/\mathfrak{m}$, hence is a finite-dimensional domain and a field by [StacksAlg, Tag 00GS(1)]. The ring R is normal by Theorem 1.13.1. Going down for an integral extension over a normal domain, [StacksAlg, Tag 00H8], lifts a chain of length e ending at $\mathfrak{n}$ to a chain ending at the specified $\mathfrak{m}$. Thus $\dim B_{\mathfrak{m}} = e$.

For general B, apply this result to $B/\mathfrak{p}$ for each minimal prime contained in $\mathfrak{m}$. These are finitely many, by [StacksAlg, Tag 00FR] and Theorem 1.11.5. Their localized spectra cover $\operatorname{Spec}(B_{\mathfrak{m}})$: any prime in a chain contains a minimal prime of B, by [StacksAlg, Tag 00E0(4)]. A chain is therefore a chain in one such quotient. Taking the maximal possible length gives the displayed equality. □

Theorem 5.35.3 (Purity of affinoid domains)**.** *Let $X = \mathcal{M}(B)$ be pure of analytic dimension d. Every nonempty affinoid domain $V = \mathcal{M}(C) \subseteq X$ is pure of analytic dimension d.*

Proof. First assume that K is nontrivially valued and that B and C are strict. The restriction $B \to C$ is flat by Proposition 2.38.2. If $\mathfrak{n}$ is maximal in C, then $C/\mathfrak{n}$ is finite over K by Theorem 1.12.3. The image of B in this field is a finite-dimensional domain, hence a field by [StacksAlg, Tag 00GS(1)]. Thus $\mathfrak{m} = \mathfrak{n} \cap B$ is maximal. Flat going down, [StacksAlg, Tag 00HS], and Lemma 5.35.2 give

$$\dim C_{\mathfrak{n}} \geq d.$$

On the other hand, Proposition 3.22.8 gives $\dim C \leq d$. Analytic and Krull dimensions agree here because both algebras are strict.

Fix a minimal prime $\mathfrak{q}$ of C. The minimal primes are finite by [StacksAlg, Tag 00FR]. Choose an element h in all the other minimal primes and outside $\mathfrak{q}$: for each other prime choose an element outside $\mathfrak{q}$ and take their product; take $h = 1$ if there is no other prime. By Lemma 2.52.1, the integral affinoid $C/\mathfrak{q}$ has a point where h does not vanish. Choose $c \in K^{\times}$ with $|c| \leq |h|$ at that point. The strict Laurent domain

$$\mathcal{M}\big((C/\mathfrak{q})\langle U\rangle/(hU - c)\big)$$

is nonempty by Theorem 2.31.1. A maximal residue field of its algebra is finite over K. Its map from C has maximal kernel $\mathfrak{n}$, contains $\mathfrak{q}$, and does not contain h. Hence $\mathfrak{q}C_{\mathfrak{n}}$ is the only minimal prime of $C_{\mathfrak{n}}$. The spectra of this local ring and its quotient by that prime have the same prime chains. It follows that

$$d \leq \dim C_{\mathfrak{n}} = \dim(C/\mathfrak{q})_{\mathfrak{n}} \leq \dim(C/\mathfrak{q}) \leq d.$$

Every minimal-prime quotient of C consequently has dimension d.

For arbitrary K, B, and C, choose one free-radius extension $L = K_r$ making both algebras strict, by Theorem 1.17.6. If K is trivially valued, include a radius different from 1 among the additional radii, so that L is nontrivially valued. Theorem 2.36.9 identifies $\mathcal{M}(C_L)$ with the corresponding affinoid domain in $\mathcal{M}(B_L)$. Lemma 5.35.1 makes B_L pure of Krull dimension d and ensures $C_L \neq 0$. The strict case makes C_L pure of dimension d. Apply the same lemma to C to descend this purity, with analytic dimension, to the original field. □

For a nonempty closed rectangular box $P = \prod_{j=1}^{d}[\alpha_j, \beta_j] \subset \mathbb{R}^d$, allow $\alpha_j = \beta_j$ and put

$$\ell_j = e^{-\beta_j}, \qquad u_j = e^{-\alpha_j}, \qquad A_P = K\{u^{-1}T, \ell S\}/(T_j S_j - 1)_j.$$

Its spectrum $\mathbb{T}_P$ is the closed polyannulus $\ell_j \le |T_j| \le u_j$. For $s \in P$, let η_s be its Gauss point, with $|\sum_m a_m T^m|_{\eta_s} = \max_m |a_m| e^{-\langle m,s\rangle}$, and put $H_s = \mathcal{H}(\eta_s)$.

Proposition 5.35.4 (Gauss degrees over a closed polyannulus)**.** *The algebra A_P is an integral domain of analytic dimension d, and every η_s has kernel zero. Let D be a finite A_P-algebra with its canonical affinoid norm. Then*

$$\dim_{H_s}(D \widehat{\otimes}_{A_P} H_s) = \dim_{\mathrm{Frac}(A_P)}(D \otimes_{A_P} \mathrm{Frac}(A_P))$$

for every $s \in P$. In particular this integer is independent of s.

If $D \neq 0$ is pure of analytic dimension d, then every minimal prime of D contracts to zero in A_P, the displayed integer is positive, and $\mathcal{M}(D) \to \mathbb{T}_P$ is surjective. Every point above η_s satisfies $d_K(x) = d$.

Proof. Iterating Theorem 2.13.2 gives unique Laurent expansions in A_P, with the finite-tail condition for the norm

$$\max_m |a_m| \max_{s \in P} e^{-\langle m,s\rangle}.$$

The operators for different coordinate pairs commute on polynomials, and their bounds extend this assertion to the completed coefficient spaces. Thus their common section and actual relation kernel give the indicated expansion also when some intervals have length zero. The weighted Gauss argument of Proposition 1.2.2 is multiplicative at each s. Every nonzero expansion has a nonzero coefficient, so its value at every η_s is positive. This proves both assertions about integrality and kernels.

At any point of $\mathbb{T}_P$, Laurent polynomials are dense in the evaluated affinoid algebra. Approximating a nonzero denominator closely enough preserves its value and approximates its inverse. The completed residue field is therefore the completion of a field generated by at most d elements over K. Lemma 3.22.3 bounds its residual dimension by d. At η_s this field is the weighted Gauss completion of $K(T_1, \dots, T_d)$, whose residual dimension is d by Lemma 3.22.4. Theorem 3.22.7 now gives $\dim_K \mathbb{T}_P = d$.

The kernel-zero map $A_P \to H_s$ extends to its fraction field. Since D is finite, Proposition 1.18.7 identifies the completed tensor in the statement with the ordinary tensor. Extension of a finite-dimensional vector space from $\mathrm{Frac}(A_P)$ to H_s preserves its dimension. This proves the displayed equality, without a flatness assumption on D.

Suppose now that $D \neq 0$ is pure of analytic dimension d, and fix a minimal prime $\mathfrak{q}$ of D. Set $E = D/\mathfrak{q}$. Choose a free-radius extension L/K making A_P and E strict. Then E_L is integral by Lemma 5.35.1, and has Krull dimension d by Theorem 3.21.8. The same statements hold for $(A_P)_L$. The finite-module comparison in Theorem 1.18.8 preserves the finite module presentation, so E_L is finite over $(A_P)_L$. If the kernel J of this map were nonzero, any prime chain in $(A_P)_L/J$ could be extended by the zero prime of the domain $(A_P)_L$. Hence $\dim((A_P)_L/J) \leq d-1$. The finite injection $(A_P)_L/J \hookrightarrow E_L$ is integral by [StacksAlg, Tag 00GK], so [StacksAlg, Tag 00OK] gives a contradiction. Thus $J = 0$. The isometric scalar embedding then shows that $A_P \to E$ is injective as well. This holds for every minimal prime, and in particular $A_P \to D$ is injective.

The generic algebra is consequently nonzero, proving positivity. For an arbitrary $y \in \mathbb{T}_P$ with kernel $\mathfrak{p}$, lying over for the integral injection $A_P \hookrightarrow D$, [StacksAlg, Tag 00GQ], makes $D \otimes_{A_P} \kappa(\mathfrak{p})$ nonzero. Extending this vector space to $\mathcal{H}(y)$ preserves nonzeroness. The finite tensor comparison and Theorem 1.20.1 therefore give a point of the actual analytic fibre, identified by Theorem 2.33.11. This proves surjectivity. Finally Lemma 3.22.6 and the Gauss residual-dimension calculation give $d_K(x) = d$ at every point above η_s. □

Theorem 5.35.5 (A finite polyannulus neighborhood of a level)**.** *Let $X = \mathcal{M}(B)$, let $g_1, \dots, g_d \in B^\times$, and set*

$$q : X \longrightarrow \mathbb{R}^d, \qquad q(x) = (-\log|g_1(x)|, \dots, -\log|g_d(x)|).$$

Suppose $s_0 \in q(X) \setminus q(\partial_K X)$. There is a closed rectangular neighborhood P of s_0, with s_0 in its interior, such that $Y = q^{-1}(P)$ is an actual affinoid domain of X, $Y \subset \mathrm{Int}(X/K)$, and

$$g : Y \longrightarrow \mathbb{T}_P$$

is finite with the canonical finite-module norm on its algebra.

If X is pure of analytic dimension d, this map is surjective. Its Gauss-fibre dimension is one fixed positive integer on P. For every $s \in P$, its

restriction to the exact-radius polytorus at s is the actual algebra of the whole level $q^{-1}(s)$.

Proof. The set $\partial_K X$ is closed, by the openness of affinoid interior in Proposition 2.33.21. It is compact by Proposition 2.24.1; its image under q is compact and hence closed. Choose a closed box P around s_0 disjoint from that image. The simultaneous inequalities on g_j and g_j^{-1} give the domain Y with its actual affinoid algebra, by Theorems 2.31.1 and 2.31.2.

Choose a larger closed polyannulus $\mathbb{T}_{P^+}$ whose coordinate bounds strictly exceed the norms of all g_j and g_j^{-1} and which contains $\mathbb{T}_P$. Bounded substitution, as in Theorem 5.31.1, gives $X \to \mathbb{T}_{P^+}$. At every point of Y, the affinoid composition formula 2.44.1 makes this morphism inner, since the point is in $\mathrm{Int}(X/K)$. The actual relative pushout of Proposition 2.33.8 identifies the algebra of Y with

$$B\widehat{\otimes}_{A_{P^+}} A_P.$$

Indeed both presentations impose exactly the stated bounds on the images of g_j and g_j^{-1}; the rational universal maps in both directions fix these images and the coefficients. Interior is preserved by base change, by Proposition 2.33.21. Hence every point of Y is inner over $\mathbb{T}_P$. Theorem 2.43.8 proves finiteness and the norm assertion.

If X is pure of analytic dimension d, then Y is nonempty and pure of the same dimension by Theorem 5.35.3. Proposition 5.35.4 gives surjectivity and a constant positive Gauss degree. Base change from A_P to the exact-radius polytorus algebra imposes the equalities $|g_j| = e^{-s_j}$, so the same actual rational universal property identifies it with the whole level algebra. This includes every real s, without changing the original absolute value. □

Proposition 5.35.6 (Constant degrees for separated groups of moment fibres)**.** *Let $X = \mathcal{M}(B)$ be pure of analytic dimension d, let $f_1, \dots, f_n \in B^\times$ define $t : X \to \mathbb{R}^n$, and let $Q \in M_{d\times n}(\mathbb{Z})$. Suppose*

$$s_0 \notin Q(t(\partial_K X)), \qquad Q^{-1}(s_0) \cap t(X) = \{w_1, \dots, w_m\} \neq \varnothing$$

is finite. Choose pairwise disjoint neighborhoods N_i of the w_i. There are closed rectangular boxes $W_i \subset N_i$ with $w_i \in \mathrm{Int}(W_i)$ and a closed rectangular neighborhood P of s_0 such that

$$Y = (Q \circ t)^{-1}(P) = \coprod_{i=1}^{m} Y_i, \qquad Y_i = Y \cap t^{-1}(W_i), \qquad t(Y_i) \subset \mathrm{Int}(W_i).$$

This is a finite disjoint affinoid cover and gives a bounded product decomposition $D = \prod_i D_i$ over A_P. Each D_i is finite over A_P, and there are positive integers δ_i such that

$$\dim_{H_s}(D_i \widehat{\otimes}_{A_P} H_s) = \delta_i \qquad (s \in P).$$

At $s = s_0$, the algebra being measured is the actual finite analytic fibre of B_{w_i} over the projected Gauss point. Thus each original moment fibre has positive projected Gauss degree, extending to the constant Gauss degree of its separated group. Whenever $Q^{-1}(s) \cap t(X)$ is finite, δ_i is the sum of the actual projected Gauss degrees of its moment fibres whose values lie in W_i.

Proof. Take closed boxes W_i as stated, still pairwise disjoint. Put $q = Q \circ t$; its coordinates are the logarithms of the units $g_j = \prod_k f_k^{q_{jk}}$. The compact set

$$X \setminus t^{-1}\left(\bigcup_i \operatorname{Int}(W_i)\right)$$

has q-image disjoint from s_0. Shrink the box supplied by Theorem 5.35.5 to avoid this compact image. Then every point of Y belongs to exactly one Y_i, and its t-image lies in the interior of the corresponding box. Each Y_i is the actual Laurent domain obtained by imposing the coordinate bounds defining W_i, by Theorem 2.31.2. The sets are both open and closed in Y.

The norm-strict equalizer of Theorem 2.38.1 for this disjoint cover is the asserted product isomorphism: all pairwise intersections have zero algebra. Its factors are direct summands of the finite A_P-module D, so they are finite; their induced norms are canonical by Theorem 1.18.3. Each contains $t^{-1}(w_i)$ and is nonempty; Theorem 5.35.3 makes it pure of analytic dimension d. Proposition 5.35.4 gives the constants $\delta_i > 0$.

At s_0, the imposed equalities $Q \circ t = s_0$ leave only $w_1, \dots, w_m$ as possible moment values. Within W_i the remaining domain is exactly $t^{-1}(w_i)$. The rational universal property identifies its algebra with B_{w_i}, and identifies the base change of D_i to the exact-radius polytorus with that algebra. Laurent polynomial density identifies the completed residue fields of its Gauss point and η_{s_0}. The finite tensor comparison of Proposition 1.18.7 and Theorem 2.33.11 now identify the tensor in the statement with the actual fibre. If the joint moment image over another $s \in P$ is finite, apply Proposition 5.31.2 at s and retain the factors belonging to W_i. Finite products commute with these tensors, so their dimensions add, proving the last assertion. □

5.36 Gauss degrees at arbitrary real radii

Let K be complete for its specified real-valued non-Archimedean absolute value, which may be trivial. For $r \in \mathbb{R}^d_{>0}$ put

$$A_{K,r} = K\{r^{-1}T, rU\}/(T_iU_i - 1)_{i=1}^d.$$

The actual Laurent presentation of Theorem 1.17.2 identifies this algebra isometrically with the convergent Laurent series

$$\sum_{m\in\mathbb{Z}^d} a_m T^m, \qquad |a_m|r^m \longrightarrow 0 \quad \text{outside finite subsets},$$

$$\left\|\sum_m a_m T^m\right\|_r = \max_m |a_m| r^m.$$

By Proposition 1.2.2 and density of finite Laurent sums, this norm is multiplicative. Write $\xi_{K,r}$ for its spectrum point and $H_{K,r}$ for the completion of $\mathrm{Frac}(A_{K,r})$ for this norm. Thus $H_{K,r} = \mathcal{H}(\xi_{K,r})$. Empty tuples give $A_{K,r} = H_{K,r} = K$.

Proposition 5.36.1 (Monomial covers of Gauss fields)**.** *Let $C = (c_{ji}) \in M_d(\mathbb{Z})$ have nonzero determinant, put $s_j = \prod_i r_i^{c_{ji}}$, and set $e = |\det C|$. The substitution $S_j \mapsto \prod_i T_i^{c_{ji}}$ gives an isometric inclusion $A_{K,s} \hookrightarrow A_{K,r}$. If R is a set of representatives for $\mathbb{Z}^d/C^{\mathrm{t}}\mathbb{Z}^d$, then*

$$A_{K,r} = \bigoplus_{u\in R} A_{K,s}T^u, \qquad \left\|\sum_{u\in R} a_u T^u\right\|_r = \max_{u\in R} r^u \|a_u\|_s. \tag{5.36.1}$$

In particular the map is finite free of rank e, with the canonical finite-module Banach structure. Its actual fibre over $\xi_{K,s}$ is the field

$$A_{K,r}\widehat{\otimes}_{A_{K,s}} H_{K,s} = H_{K,r}, \qquad [H_{K,r} : H_{K,s}] = e.$$

The Gauss point is the only point of this fibre.

Proof. The substitution preserves each Laurent coefficient and its weighted size, since $s^v = r^{C^{\mathrm{t}}v}$. The exponent map is injective, so it preserves the coefficient norm and the finite-tail condition.

We first check the integer index. Integer row and column operations diagonalize a nonsingular integer matrix for this purpose. Move a nonzero entry to

the upper left. If an entry in its row or column is not divisible by it, division with remainder followed by a swap strictly decreases the positive absolute value of the pivot. After finitely many such reductions the pivot divides its entire row and column. Clear both by integer elementary operations and repeat on the remaining nonsingular square block. These operations are unimodular. A diagonal matrix has quotient index the product of the absolute values of its diagonal entries, which is its absolute determinant. Applying the same operations in transposed order also proves

$$[\mathbb{Z}^d : C\mathbb{Z}^d] = [\mathbb{Z}^d : C^{\mathsf{t}}\mathbb{Z}^d] = |\det C|.$$

Every exponent has a unique expression $u + C^{\mathsf{t}}v$ with $u \in R$ and $v \in \mathbb{Z}^d$. Grouping a convergent Laurent series by these finitely many cosets gives (5.36.1). Each grouped series converges: its weighted coefficients are those of the original series, divided by the fixed positive number r^u. Conversely a finite sum of such grouped series has a vanishing weighted tail. Disjoint exponents prove uniqueness and the norm equality. Since R is finite, its weighted maximum norm is equivalent to the usual maximum norm of a free $A_{K,s}$-module.

Put $F_s = \operatorname{Frac}(A_{K,s})$. The localization $A_{K,r} \otimes_{A_{K,s}} F_s$ is a finite-dimensional domain over F_s, hence a field: multiplication by a nonzero element is an injective linear endomorphism and is therefore surjective. It is thus $\operatorname{Frac}(A_{K,r})$, with the same coset basis. Clearing a common denominator in $A_{K,s}$ proves the weighted norm identity for coefficients in F_s as well.

Its completion is consequently $\bigoplus_{u \in R} H_{K,s} T^u$ with that weighted norm. Multiplication extends continuously, and its norm remains multiplicative by approximating two elements with elements of the dense valued field. It is a finite-dimensional domain over $H_{K,s}$, hence a field. By the definition of $H_{K,r}$ this completed field is $H_{K,r}$, of degree $|R| = e$. Proposition 2.33.19 identifies the algebraic tensor with the stated completed tensor; Theorem 2.33.11 identifies its spectrum with the actual analytic fibre.

Finally, a bounded multiplicative seminorm on the field $H_{K,r}$ is at most its given multiplicative norm, by applying its bound to successive powers. Applying the same inequality to the inverse of a nonzero element gives the reverse inequality. Its spectrum over $H_{K,s}$ is therefore a single point, with completed residue field $H_{K,r}$. □

For a finite $A_{K,r}$-algebra D whose given norm is equivalent to its canonical finite-module norm, define its Gauss fibre and degree by

$$E_{K,r}(D) = D\widehat{\otimes}_{A_{K,r}} H_{K,r}, \qquad \delta_{K,r}(D) = \dim_{H_{K,r}} E_{K,r}(D). \tag{5.36.2}$$

These are an actual finite analytic fibre algebra and a nonnegative integer by Proposition 2.33.19 and Theorem 2.33.11.

Proposition 5.36.2 (Scalar extension of a finite Gauss fibre)**.** *Let L/K be any complete isometric extension, and put $D_L = D\widehat{\otimes}_K L$. There are natural bounded algebra isomorphisms*

$$(A_{K,r})_L \simeq A_{L,r}, \qquad E_{L,r}(D_L) \simeq E_{K,r}(D) \otimes_{H_{K,r}} H_{L,r},$$

and the coefficient inclusion induces an isometric embedding $H_{K,r} \hookrightarrow H_{L,r}$. In particular

$$\delta_{L,r}(D_L) = \delta_{K,r}(D).$$

For either of these finite fibre algebras E over its indicated field H, its degree is

$$\dim_H E = \sum_{\mathfrak{p} \in \operatorname{Max} E} \operatorname{length}_{E_{\mathfrak{p}}}(E_{\mathfrak{p}})[\kappa(\mathfrak{p}) : H].$$

Proof. The actual relative pushout 2.33.8 extends the Laurent relation presentation coefficientwise. Its norm is the Laurent coefficient norm over L, by Theorem 1.17.2. The coefficient inclusion preserves the Gauss norm, so it extends first to the fraction fields and then to an isometric embedding $H_{K,r} \hookrightarrow H_{L,r}$.

The two bounded pushouts of D and L identify

$$D_L \simeq D\widehat{\otimes}_{A_{K,r}} A_{L,r}.$$

By Proposition 2.33.19, this is finite over $A_{L,r}$ with its canonical module norm. Applying Corollary 2.33.9 to the Gauss point, and then the same finite-base-change proposition, gives

$$\begin{aligned} D_L\widehat{\otimes}_{A_{L,r}} H_{L,r} &\simeq D\widehat{\otimes}_{A_{K,r}} H_{L,r} \\ &\simeq \left(D\widehat{\otimes}_{A_{K,r}} H_{K,r}\right) \otimes_{H_{K,r}} H_{L,r}. \end{aligned}$$

The tensors on the last line are already complete because the first factor is finite-dimensional over $H_{K,r}$. A basis over $H_{K,r}$ becomes a basis after this field extension, proving the degree equality, including degree zero.

A finite-dimensional algebra over a field is Artinian. Its local product decomposition is [StacksAlg, Tag 00JB]. In a composition series of $E_{\mathfrak{p}}$ every simple quotient is $\kappa(\mathfrak{p})$: the annihilator of a generator of a simple module is maximal, and this local ring has only one maximal ideal. Taking dimensions gives the displayed sum. Apply this argument to each of the two actual fibre algebras. □

Theorem 5.36.3 (Integral models computing an arbitrary-radius degree)**.** *Let D be as above. Let L/K be a complete nontrivially valued isometric extension, choose $b_j \in L^\times$ with $|b_j| = r_j$, and write $S_j = T_j/b_j$. Put*

$$O_L = L^\circ, \quad k_L = \widetilde{L}, \quad A_{L,0} = O_L\langle S_1^{\pm 1}, \dots, S_d^{\pm 1}\rangle.$$

For any finite list of power-bounded elements of D_L there is an admissible topologically finitely presented algebra $D_{L,0} \subset D_L$, finite over $A_{L,0}$, containing that list and having generic algebra D_L. For every such finite model put

$$C_{L,0} = (D_{L,0}/L^{\circ\circ}D_{L,0}) \otimes_{k_L[S^{\pm 1}]} k_L(S_1, \dots, S_d).$$

Then

$$\delta_{K,r}(D) = \sum_{\mathfrak{p} \in \operatorname{Max} C_{L,0}} \operatorname{length}_{(C_{L,0})_{\mathfrak{p}}}((C_{L,0})_{\mathfrak{p}})[\kappa(\mathfrak{p}) : k_L(S)]. \tag{5.36.3}$$

In particular this integer is independent of L, of the scalars b_j, and of the finite model. Such an extension L always exists.

If D is the actual full fibre at a weight w of analytic units $f_1, \dots, f_n$, and is finite with its canonical module norm over the polytorus of their monomials f^{q_j}, one may choose L realizing all $\exp(-w_i)$. For $a_i \in L^\times$ of these absolute values, the model may be chosen to contain all f_i/a_i and a_i/f_i. The target normalizers can be taken as $b_j = \prod_i a_i^{q_{ji}}$.

Proof. The coordinate change $S_j = T_j/b_j$ is an isometric isomorphism between $A_{L,r}$ and the unit-polytorus algebra over L; it sends their Gauss points to each other. Proposition 5.36.2 gives D_L its canonical finite-module Banach structure. Apply Theorem 5.32.1 over L. It constructs the required actual integral quotient model, with the prescribed elements, and computes its special-fibre length sum as $\delta_{L,r}(D_L)$. The same theorem gives this equality for every admissible finite model with that generic algebra. Proposition 5.36.2 identifies this number with $\delta_{K,r}(D)$, proving (5.36.3) and all the independence assertions.

To obtain an extension realizing any finite list of radii, append one radius $0 < \rho < 1$ and take the completion of the fraction field of its Laurent algebra for the multiplicative Gauss norm. Its coordinate elements realize the prescribed radii and ρ, so this is a complete nontrivially valued extension of K with the original absolute value on K.

In the last assertion the full fibre is the actual simultaneous Laurent domain $|f_i| = \exp(-w_i)$. The relative pushout 2.33.8 shows that its base change is the same actual Laurent domain over L. On every point of this domain both f_i/a_i and a_i/f_i have absolute value one. Theorem 1.20.2 makes these elements power bounded, also with the canonical equivalent norm. They may therefore be included in the finite prescribed list. The displayed choice of b_j makes the normalized target coordinates exactly the indicated monomials in these elements. □

Proposition 5.36.4 (Calibration under an isogeny of the target)**.** *Let $A_{K,r} \to D$ be finite with its canonical Banach structure, and let C and s be as in Proposition 5.36.1. Regard D also as an $A_{K,s}$-algebra by composition. It has the canonical finite-$A_{K,s}$-module Banach structure, and*

$$\delta_{K,s}(D) = |\det C|\, \delta_{K,r}(D).$$

More generally let D be an actual full moment-fibre algebra at $w \in \mathbb{R}^n$, and let $Q_0, Q_1 : \mathbb{Z}^n \to \mathbb{Z}^d$ have rank d and the same rational row space. Suppose the two monomial maps make D finite with its canonical module norms over their polytori at $Q_i w$. Let $N \subset \mathbb{Z}^n$ have rank d and suppose $Q_i|_N$ is injective. Writing δ_{Q_i} for the corresponding Gauss degree, one has

$$\frac{\delta_{Q_0}}{[\mathbb{Z}^d : Q_0(N)]} = \frac{\delta_{Q_1}}{[\mathbb{Z}^d : Q_1(N)]}.$$

Proof. Choose a finite free $A_{K,r}$-module surjecting onto D and give D its quotient norm. The finite weighted basis in (5.36.1) identifies that free module with a finite free $A_{K,s}$-module with an equivalent norm. The same quotient therefore gives the canonical finite-$A_{K,s}$-module topology on D.

Proposition 5.36.1 and associativity of the finite tensors identify

$$D \otimes_{A_{K,s}} H_{K,s} \simeq D \otimes_{A_{K,r}} \left(A_{K,r} \otimes_{A_{K,s}} H_{K,s}\right) \simeq D \otimes_{A_{K,r}} H_{K,r}.$$

Their completed versions are the same by Proposition 2.33.19. The algebra on the right has dimension $\delta_{K,r}(D)$ over $H_{K,r}$, and $[H_{K,r} : H_{K,s}] = |\det C|$, giving the first formula.

For the second assertion, equality of the rational row spaces gives an invertible rational matrix B with $Q_1 = BQ_0$. Choose a positive integer m clearing its denominators and set $C_0 = mB$, $C_1 = mI_d$. Then both C_i are nonsingular integer matrices and $C_0Q_0 = C_1Q_1$. These equal matrices define the same monomial map on the same actual algebra D, with the same target radii. Applying the first assertion twice gives

$$|\det C_0|\delta_{Q_0} = |\det C_1|\delta_{Q_1}.$$

For each i, the finite chain $C_iQ_i(N) \subset C_i\mathbb{Z}^d \subset \mathbb{Z}^d$ has index

$$[\mathbb{Z}^d : C_iQ_i(N)] = |\det C_i|[\mathbb{Z}^d : Q_i(N)].$$

Indeed representatives for the two successive quotients give representatives for the composite quotient, and C_i identifies the first quotient with $\mathbb{Z}^d/Q_i(N)$. The left sides for $i = 0, 1$ agree because $C_0Q_0 = C_1Q_1$. Dividing the two displayed identities proves the calibrated equality. □

5.37 Weights on interior flat tropical germs

Theorem 5.37.1 (Positive intrinsic weights at arbitrary real flat germs)**.** *Let $X = \mathcal{M}(B)$ be nonempty and pure of analytic dimension d over the original complete field K. Let $f_1, \dots, f_n \in B^\times$ and put $t(x) = (-\log|f_i(x)|)_i$. Fix $w \in t(X)$ and a saturated rank-d sublattice $N_0 \subset \mathbb{Z}^n$. Suppose that, for some open neighborhood W of w,*

$$t(X) \cap W \subset w + (N_0)_{\mathbb{R}}, \qquad F_w = t^{-1}(w) \subset \mathrm{Int}(X/K).$$

Let D_w be the actual affinoid algebra of the whole fibre F_w. For every integral map $Q : \mathbb{Z}^n \to \mathbb{Z}^d$ whose restriction to N_0 is injective, the monomials f^{q_j} make D_w finite, with its canonical module norm, over the exact-radius polytorus algebra at Qw. Its Gauss degree $\delta_Q(w)$ is positive, and

$$m_{X,f}(w) = \frac{\delta_Q(w)}{[\mathbb{Z}^d : Q(N_0)]} \in \mathbb{Z}_{>0}$$

is independent of Q. This assertion allows arbitrary real w and the trivial valuation. It uses the actual fibre algebra, including its nilpotents.

More precisely, after any complete nontrivial isometric extension L/K realizing the numbers e^{-w_i}, choose $a_i \in L^\times$ of these absolute values. Form

the residual moment cycle of $D_w \widehat{\otimes}_K L$ *with characters* f_i/a_i. *If* $\rho : \mathbb{T}_{\mathbb{Z}^n,\widetilde{L}} \to \mathbb{T}_{\mathbb{Z}^n/N_0,\widetilde{L}}$ *is the quotient, that cycle has the form* $\sum_s c_s[\rho^{-1}(s)]$, *and*

$$m_{X,f}(w) = \sum_s c_s[\kappa(s) : \widetilde{L}].$$

This integer is independent of the extension, normalizing elements, and compatible admissible model.

Proof. Transverse integral maps Q exist by the saturated-lattice splitting in Lemma 5.14.1. Choose a closed rectangular box P containing w in its interior and contained in W. Its inverse image $Y = t^{-1}(P)$ is the actual simultaneous Laurent domain, by Theorem 2.31.2. At every point of F_w, the finitely many coordinate inequalities defining Y are strict. Its relative presentation therefore puts $F_w \subset \mathrm{Int}(Y/X)$. Proposition 2.33.21 and the hypothesis give $F_w \subset \mathrm{Int}(Y/K)$.

The linear map Q is injective on $(N_0)_{\mathbb{R}}$. Since $t(Y) \subset w + (N_0)_{\mathbb{R}}$, the entire level of $Q \circ t|_Y$ at Qw is F_w. Theorem 5.31.1, applied to Y and its units f^{q_j}, makes its actual level algebra finite with the canonical module norm over the target polytorus. The level is the same affinoid domain as $F_w \subset X$: the rational universal property gives bounded inverse identifications of their algebras. Thus the finite algebra is precisely D_w.

Theorem 5.35.3 makes the nonempty domain F_w pure of analytic dimension d. Apply Proposition 5.35.4 to its finite map to the exact-radius polytorus, regarded as a polyannulus with degenerate intervals. Its Gauss degree is positive. This construction works for every indicated Q over K itself.

Choose a complete extension L as in Theorem 5.36.3, realizing all e^{-w_i} and one radius strictly between zero and one. The actual full fibre of X_L at w is $(F_w)_L$, by Theorem 2.36.9. Every point of X_L restricts to a point of X with the same character values, so $t(X_L) \cap W \subset w + (N_0)_{\mathbb{R}}$. Every point of $(F_w)_L$ is interior over L by the base-change assertion of Proposition 2.33.21. Proposition 5.36.2 preserves each finite map, its canonical module norm, and its Gauss degree.

Normalize by the a_i and apply Theorem 5.34.3 over L. Its hypotheses have just been verified for the same actual fibre algebra and for every Q. It identifies the residual supports with the indicated cosets and gives

$$\delta_{Q,L}(w) = [\mathbb{Z}^d : Q(N_0)] \sum_s c_s[\kappa(s) : \widetilde{L}].$$

Scalar extension preserves $\delta_Q(w)$, and its positivity has already been proved over K. This proves integrality, positivity, and independence of the projection. The left side divided by its fixed lattice index is defined over the original field and absolute value; it proves independence of L and the a_i. Independence of the compatible model also follows from Theorem 5.34.1. □

Theorem 5.37.2 (Local constancy on an interior flat germ)**.** *Under the hypotheses of Theorem 5.37.1, there is an open neighborhood V of w such that*

$$t(X) \cap V = (w + (N_0)_{\mathbb{R}}) \cap V.$$

Every v in this set has its whole fibre in $\mathrm{Int}(X/K)$, satisfies the same flat-germ hypotheses with lattice N_0, and has

$$m_{X,f}(v) = m_{X,f}(w).$$

The value at a weight is unchanged by restriction to an affinoid domain containing its whole moment fibre, whenever the two weighted germs satisfy these hypotheses.

Proof. The boundary $\partial_K X$ is compact, by openness of interior and compactness of X in Propositions 2.33.21 and 2.24.1. Its tropical image is compact and does not contain w. Choose the box P in the preceding proof also disjoint from that image. Then $Y = t^{-1}(P)$ lies in $\mathrm{Int}(X/K)$ and is pure of analytic dimension d, by Theorem 5.35.3.

Fix a transverse integral Q; one exists by choosing a basis of N_0 extending to a basis of $\mathbb{Z}^n$, using Lemma 5.14.1, and projecting onto the first d coordinates. The entire level of $Q \circ t|_Y$ at Qw is $F_w \subset \mathrm{Int}(Y/K)$, as above. Theorem 5.35.5 therefore supplies a closed rectangular neighborhood P' of Qw for which

$$Y' = (Q \circ t|_Y)^{-1}(P') \longrightarrow \mathbb{T}_{P'}$$

is finite and surjective, with a fixed positive Gauss degree δ at every $s \in P'$.

The affine restriction $Q : w + (N_0)_{\mathbb{R}} \to \mathbb{R}^d$ is an isomorphism. Its inverse sends P' exactly to $t(Y')$: inclusion in one direction follows from $t(Y) \subset w + (N_0)_{\mathbb{R}}$, and the other follows from surjectivity of $Y' \to \mathbb{T}_{P'}$. Take an open neighborhood

$$V \subset \mathrm{Int}(P) \cap Q^{-1}(\mathrm{Int}(P'))$$

of w. The preceding equality proves $t(X) \cap V = (w + (N_0)_{\mathbb{R}}) \cap V$. For v in this set, its whole fibre in X belongs to Y', since $v \in \mathrm{Int}(P)$ and $Qv \in P'$; in

particular it is interior over K. The local flat-germ condition at v follows by restricting to a sufficiently small neighborhood inside W, since $v + (N_0)_{\mathbb{R}} = w + (N_0)_{\mathbb{R}}$.

Restriction of the finite polyannulus map to its exact level at $s = Qv$ has algebra D_v, by Theorem 5.35.5 and injectivity of Q on the affine plane. Laurent polynomials are dense both in this target's exact-radius algebra and in the polyannulus algebra evaluated at η_s. Their completed Gauss residue fields are therefore the same completion of $K(T_1, \dots, T_d)$ with its weighted Gauss norm. Finite base change consequently identifies the Gauss fibre of D_v with that of Y' over η_s. Thus $\delta_Q(v) = \delta$ for every such v, including w. Theorem 5.37.1 gives

$$m_{X,f}(v) = \frac{\delta}{[\mathbb{Z}^d : Q(N_0)]} = m_{X,f}(w).$$

Finally an affinoid domain containing the whole fibre has the same actual fibre domain, with the same analytic structure. This follows from domain restriction and the two universal factorizations in Theorem 2.36.9. The local image equality just proved, applied to both domains, and inclusion of their moment images identify their tangent planes: both have dimension d. Their saturated tangent lattices are consequently equal. The fibre algebra and its monomial maps to each target polytorus are unchanged, so their Gauss degrees, and hence their calibrated weights, agree. □

Theorem 5.37.3 (Geometric pushforward under a finite locally free map)**.** *Let $p : X \to Y$ be a finite morphism of generalized K-affinoid spaces, both pure of analytic dimension d. Suppose its algebra is finite locally free of constant rank $\Delta > 0$ over the target algebra, with the canonical module Banach structure. Let unit moment tuples f_X and f_Y define $t_X : X \to \mathbb{R}^n$ and $t_Y : Y \to \mathbb{R}^{n'}$, and suppose that*

$$t_Y \circ p = a \circ t_X$$

comes from the corresponding identity of characters for an integral map $a : \mathbb{Z}^n \to \mathbb{Z}^{n'}$. Let $w' \in t_Y(Y)$ have its whole fibre in $\mathrm{Int}(Y/K)$, and suppose that the local tropical image at w' is contained in $w' + (N_Y)_{\mathbb{R}}$ for a saturated rank-d lattice $N_Y \subset \mathbb{Z}^{n'}$. Assume

$$a^{-1}(w') \cap t_X(X) = \{w_1, \dots, w_s\}$$

is finite and nonempty, and that the local tropical image at each w_i is contained in $w_i + (N_i)_{\mathbb{R}}$ for a saturated rank-d lattice $N_i \subset \mathbb{Z}^n$.

Then $a(N_i) \subset N_Y$ has finite index for every i, all the weights in Theorem 5.37.1 are defined, and

$$\Delta\, m_{Y,f_Y}(w') = \sum_{i=1}^{s} m_{X,f_X}(w_i)[N_Y : a(N_i)].$$

The locally free rank, the fibre algebras, and their lengths are taken before reduction. No restriction on the real weights or on the characteristic or value group of K is imposed.

Proof. Theorem 2.33.18 makes p everywhere interior relative to Y. The composition inclusion in Proposition 2.33.21 therefore gives

$$p^{-1}(t_Y^{-1}(w')) \subset \mathrm{Int}(X/K).$$

In particular the whole fibre at every w_i is interior. Theorem 5.37.1 defines its positive intrinsic weight and that at w'. Theorem 5.37.2 shows that the local images fill neighborhoods in their stated planes.

For v sufficiently near w_i in $w_i+(N_i)_{\mathbb{R}}$, one has $v \in t_X(X)$ and $a(v) \in t_Y(Y)$ sufficiently near w'. It follows that $a((N_i)_{\mathbb{R}}) \subset (N_Y)_{\mathbb{R}}$. Saturation of N_Y implies $a(N_i) \subset N_Y$. If the restriction of a to $(N_i)_{\mathbb{R}}$ had nonzero kernel, a small interval through w_i in that kernel would give infinitely many elements of $a^{-1}(w') \cap t_X(X)$. This contradicts the finite-set hypothesis. Hence this restriction is injective, and $a(N_i)$ has finite index in N_Y.

Choose an integral $Q : \mathbb{Z}^{n'} \to \mathbb{Z}^d$ transverse to N_Y. Take a small closed box in the target moment space, with w' in its interior and with its inverse image $Y_0 \subset Y$ contained in the specified flat-germ neighborhood. As in the proof of Theorem 5.37.1, the entire level of $Q \circ t_Y|_{Y_0}$ at Qw' is $t_Y^{-1}(w')$ and is interior over K in Y_0. Put $X_0 = p^{-1}(Y_0)$. Theorem 2.36.9 gives its actual affinoid algebra, and Proposition 2.33.19 preserves the finite canonical module structure. Ordinary base change of a locally free module preserves its rank: its local bases base change to local bases.

The entire level of $Qa \circ t_X|_{X_0}$ at Qw' is $p^{-1}(t_Y^{-1}(w'))$. Indeed, the target moment image in Y_0 lies in the plane on which Q is injective. This level is interior in X_0 by finite relative interior and composition. Its moment

values are exactly $w_1, \dots, w_s$. Proposition 5.31.2 therefore identifies its actual algebra with

$$\prod_{i=1}^{s} D_{w_i}.$$

Each factor is the original whole moment-fibre algebra on X, since that whole fibre already belongs to X_0.

Let $D'_{w'}$ be the actual whole target-fibre algebra, A the exact-radius target polytorus at Qw', and H its Gauss field. The algebra of the displayed source level is also the actual finite base change of the algebra of X along the algebra map from Y to $D'_{w'}$. It is consequently finite locally free of rank Δ over $D'_{w'}$. After tensoring over A with H, it is finite locally free of that rank over the Artinian algebra

$$E' = D'_{w'} \widehat{\otimes}_A H.$$

All these finite tensors are ordinary tensors with their complete canonical norms by Proposition 2.33.19.

By [StacksAlg, Tag 00JB], E' is a finite product of Artinian local algebras. On each factor, a local basis of the finite locally free module at its unique maximal ideal is a global basis: a principal open neighborhood of that ideal is the entire spectrum, and its defining element is a unit. Its H-dimension is therefore Δ times the H-dimension of that factor. Summing the dimensions and using the actual product of source fibres gives

$$\Delta\, \delta_Q(w') = \sum_{i=1}^{s} \delta_{Qa}(w_i).$$

Apply Theorem 5.37.1 to every term. Since Q is injective on N_Y, counting representatives in the subgroup chain $Qa(N_i) \subset Q(N_Y) \subset \mathbb{Z}^d$ gives

$$[\mathbb{Z}^d : Qa(N_i)] = [\mathbb{Z}^d : Q(N_Y)]\,[N_Y : a(N_i)].$$

Cancel the common positive first factor. This proves the stated geometric pushforward formula with all lengths and full field degrees already incorporated in the intrinsic weights. □

5.38 Local tropical geometry at interior fibres

Local polyhedrality of analytic moment images belongs to the theory developed by Berkovich and Ducros. For the compact-space and point-germ theorems, see A. Ducros, *Espaces de Berkovich, polytopes, squelettes et théorie*

des modèles, Confluentes Math. **4** (2012), 1250007, Theorems 3.2 and 3.4, DOI: 10.1142/S1793744212500077. The proof here reconstructs the local star at a whole interior fibre from the graded germ reductions and finite affinoid projections established earlier in the book.

For a tuple of invertible analytic functions $h = (h_1, \dots, h_n)$, write

$$t_h(y) = (-\log|h_1(y)|, \dots, -\log|h_n(y)|), \qquad h^m = \prod_{i=1}^{n} h_i^{m_i} \quad (m \in \mathbf{Z}^n).$$

The tropicalization of an algebraic torus subscheme over a trivially valued field is its actual analytic moment image, with the convention of Theorem 5.13.6.

Lemma 5.38.1 (Lifting strict sectors from a residue field)**.** *Let K be a complete non-Archimedean field with its specified absolute value, let (X, x) be a good K-analytic germ, and suppose that $x \in \mathrm{Int}(X/K)$. Let $h_1, \dots, h_n$ be invertible analytic functions near x such that $|h_i(x)| = 1$. Put $k = \widetilde{K}$, and let*

$$R = k[\widetilde{h}_1^{\pm 1}, \dots, \widetilde{h}_n^{\pm 1}] \subset \widetilde{\mathcal{H}(x)}, \qquad Z = \operatorname{Spec} R \subset \mathbf{G}^n_{m,k}.$$

If $u \in \mathrm{Trop}(Z)$ and $m_1, \dots, m_s \in \mathbf{Z}^n$ satisfy $\langle m_j, u\rangle > 0$ for every j, then every neighbourhood of x contains a point y for which

$$|h^{m_j}(y)| < 1 \qquad (1 \le j \le s).$$

In particular the corresponding strict rational sector contains moment values arbitrarily close to $0 = t_h(x)$.

Proof. Choose an analytic point of Z whose moment value is u. Its kernel is a prime $\mathfrak{p} \subset R$, and its absolute value induces a valuation ring $V_{\mathfrak{p}}$ in $\kappa(\mathfrak{p})$ containing the trivially valued field k. Let $B \subset R_{\mathfrak{p}}$ be the inverse image of $V_{\mathfrak{p}}$ under the residue map. This is a local subring of $\mathrm{Frac}(R) \subset \widetilde{\mathcal{H}(x)}$. Indeed, its maximal ideal is the inverse image of the maximal ideal of $V_{\mathfrak{p}}$, and an element outside that inverse image is a unit of $R_{\mathfrak{p}}$ whose inverse again lies in B. The character $\widetilde{h}^{m_j}$ is a unit of $R_{\mathfrak{p}}$, and its image in $\kappa(\mathfrak{p})$ has absolute value $e^{-\langle m_j, u\rangle} < 1$. It therefore belongs to the maximal ideal of B.

By [StacksAlg, Tag 00IA], there is a valuation ring $V \subset \widetilde{\mathcal{H}(x)}$ dominating B. It contains k, and each $\widetilde{h}^{m_j}$ belongs to its maximal ideal. Consequently $\widetilde{h}^{-m_j} \notin V$. Lemma 3.19.20 extends V to a graded valuation ring

$$W \subset F_x := \widetilde{\mathcal{H}(x)}^{\mathrm{gr}} \quad \text{containing } \widetilde{K}^{\mathrm{gr}}, \qquad W_1 = V.$$

No assertion about the rank of this valuation is needed.

Choose an ordinary affinoid neighbourhood of x on which the h_i are units. The ordinary local test preserves interiority over $\mathcal{M}(K)$ on this neighbourhood. The absolute evaluation clause makes the image of its graded algebra in F_x finite over $\widetilde{K}^{\mathrm{gr}}$. Every graded valuation ring containing $\widetilde{K}^{\mathrm{gr}}$ contains this image: apply the integral-closedness assertion of Lemma 3.19.1 to its homogeneous elements. Thus

$$\mathscr{R}(X,x) = \mathscr{P}_{\widetilde{K}^{\mathrm{gr}}}(F_x),$$

using the actual germ reduction of Proposition 3.19.4. In particular $W \in \mathscr{R}(X,x)$.

Suppose that a neighbourhood of x contains no point satisfying all the strict inequalities in the statement. Choose a smaller ordinary affinoid neighbourhood of x inside it on which all h_i are units. The finitely many Weierstrass domains

$$|h^{-m_j}| \leq 1 \qquad (1 \leq j \leq s)$$

cover this representative. They are a finite closed cover, hence admissible by Lemma 2.39.2, and all contain x. Each inequality is active at x. Proposition 3.19.6 says that their germ reductions cover $\mathscr{R}(X,x)$. By Lemma 3.19.5, the j-th reduction consists of the valuation rings containing $\widetilde{h}^{-m_j}$. None contains W, a contradiction. The case $s = 0$ is immediate. Finally continuity of t_h allows the neighbourhood to be chosen inside the inverse image of any prescribed neighbourhood of 0. □

Lemma 5.38.2 (A finite tropical basis over a trivially valued field)**.** *Let k be a field with the trivial absolute value, and let $J \subset k[T_1^{\pm 1}, \dots, T_n^{\pm 1}]$ be an ideal. There are finitely many nonzero $p_1, \dots, p_a \in J$ such that*

$$\mathrm{Trop}(\operatorname{Spec} k[T^{\pm 1}]/J) = \bigcap_{j=1}^{a} \mathrm{Trop}(V(p_j)).$$

For $J = 0$ the empty list is allowed. The set on either side is the support of a finite rational polyhedral fan. At every weight outside this set, some p_j has a unique term of least weight.

Proof. Form the homogeneous ideal $H \subset k[x_0, \dots, x_n]$ used in Theorem 5.16.5; localization in all variables followed by $x_0 = 1$ recovers J. Use

ordinary weight initials, taking terms of least weight. In the present trivial valuation, the hyperplane arrangement in that theorem is central. On each relatively open cone C its proof gives one fixed ordinary homogeneous ideal $H_C = \mathrm{in}_\omega(H)$ over k: the minimizing pivot sets and the surviving entries in their row bases are fixed on C, and these rows generate the ideal in the uniformly bounded degrees of Proposition 5.16.3. Restrict this finite arrangement to $\omega_0 = 0$.

For any cone C outside the tropicalization, localization of H_C in all variables is the unit ideal, by Theorem 5.13.6 and the localization argument in Theorem 5.16.5. Hence H_C contains a monomial x^{α_C}, of some degree e_C. In the finite-dimensional space H_{e_C}, choose a fixed row matrix and consider every column set B with a nonzero maximal minor. There are finitely many such sets. For every one include all members of its pivot row basis in a list $\mathcal{G}_C$.

Fix $\omega \in C$ and choose a minimizing pivot set B for this degree. Lemma 5.16.4 and Lemma 5.16.1 show that the initial rows form a basis of $(H_C)_{e_C}$ and have the identity matrix in the pivot columns. Since the single monomial vector x^{α_C} belongs to this space, its column must be a pivot: otherwise its pivot coordinates would all be zero, forcing the vector to be zero. Its pivot coordinates then show that the corresponding initial row is exactly x^{α_C}. Thus a member of the finite list $\mathcal{G}_C$ has a monomial initial at every $\omega \in C$.

Dehomogenize the lists for the finitely many excluded cones. These give nonzero Laurent polynomials in J. A homogeneous polynomial of fixed degree remains nonzero after $x_0 = 1$, since its remaining exponent vector determines the exponent of x_0. Every weight outside the tropicalization has a unique least term in one of the resulting Laurent polynomials. Such a weight is outside that polynomial's hypersurface tropicalization by the strong triangle inequality. Conversely, an actual analytic point of the subscheme is an analytic point of every one of these hypersurfaces, with the same moment value. This proves the equality. The fan assertion is the central arrangement already constructed. If J is the unit ideal, the polynomial 1 gives the assertion directly. □

Lemma 5.38.3 (The actual image of a finite affinoid map)**.** *Let $A \to D$ be a bounded homomorphism of generalized K-affinoid algebras, finite with*

its canonical module norm, and put $I = \ker(A \to D)$. *Its analytic image is exactly* $\mathcal{M}(A/I)$, *with the quotient affinoid structure, and*

$$\dim_K \mathcal{M}(D) = \dim_K \mathcal{M}(A/I) \leq \dim_K \mathcal{M}(A)$$

when $D \neq 0$. *If* D *is pure of analytic dimension* d, *so is* A/I.

Proof. The quotient is an actual affinoid algebra by Corollary 1.18.4. The injection $A/I \hookrightarrow D$ is integral by [StacksAlg, Tag 00GK]. For $z \in \mathcal{M}(A/I)$ with kernel $\mathfrak{p}$, lying over, [StacksAlg, Tag 00GQ], makes $D \otimes_{A/I} \kappa(\mathfrak{p})$ nonzero. It is a finite-dimensional vector space. Extending it to $\mathcal{H}(z)$ keeps it nonzero. Proposition 1.18.7 identifies this algebra with the actual completed fibre algebra, which has an analytic point by Theorem 1.20.1. The fibre identification of Theorem 2.33.11 therefore gives a point above z. This proves the image assertion.

At every point of $\mathcal{M}(D)$, the completed residue field is finite over that of its image, by Lemma 3.22.6. Taking the maxima in Theorem 3.22.7 on the two spaces gives equality of their analytic dimensions. The dimension inequality follows from the same maximum formula, since the quotient space has the same completed residue fields as its points in $\mathcal{M}(A)$.

Suppose D is pure of dimension d and let $\mathfrak{p}$ be a minimal prime of A/I. A prime of D above $\mathfrak{p}$ contains a minimal prime $\mathfrak{q}$ of D, by [StacksAlg, Tag 00E0(4)]. Its contraction equals $\mathfrak{p}$ by minimality. Thus $(A/I)/\mathfrak{p} \hookrightarrow D/\mathfrak{q}$ is a finite injection. These quotient algebras have the canonical finite module norms by Theorem 1.18.3. Apply the dimension equality just proved to this injection. The right-hand algebra has analytic dimension d, and hence so does the left-hand algebra. This holds for every minimal prime. □

Proposition 5.38.4 (A finite analytic image around a whole moment fibre)**.** *Let* $X = \mathcal{M}(B)$ *be a generalized affinoid space over a complete field* K *with its specified absolute value, let* $f_1, \dots, f_n \in B^\times$, *and put* $t = t_f$. *If* $w \in t(X)$ *and* $F_w = t^{-1}(w) \subset \mathrm{Int}(X/K)$, *there is a closed box* P *about* w, *with* w *in its interior, such that* $Y = t^{-1}(P)$ *lies in* $\mathrm{Int}(X/K)$ *and its moment map to the closed polyannulus* $\mathbb{T}_P$ *is finite. For* $A_P = \mathcal{O}(\mathbb{T}_P)$, $D_P = \mathcal{O}(Y)$, *and* $I_P = \ker(A_P \to D_P)$, *one has*

$$t(X) \cap P = t\big(\mathcal{M}(A_P/I_P)\big).$$

Every point of the right-hand analytic space has an actual lift to Y. *If* X *is pure of analytic dimension* d, *the closed analytic image* $\mathcal{M}(A_P/I_P)$ *is pure*

of dimension d. For every $v \in P$, restriction to the exact-radius polytorus at v gives the actual algebra of the whole fibre F_v.

Proof. Apply the first assertion of Theorem 5.35.5 to the complete tuple of n moment functions. That assertion places no equality between n and the dimension of X. It gives the stated domain, finite map, canonical module norm, and the exact-level identifications. Lemma 5.38.3 gives the actual image and the pointwise lifting assertion. In the pure case, Theorem 5.35.3 makes Y pure of dimension d, and the last assertion of the same lemma gives the purity of its finite image. □

Proposition 5.38.5 (A residual fan bounds and meets the actual germ)**.** *Let K be complete and nontrivially valued, put $O = K^\circ$ and $k = \widetilde{K}$, and let $X = \mathcal{M}(B)$ be a generalized affinoid space. Let $h_1, \dots, h_n \in B^\times$, and suppose the nonempty whole fibre $F_0 = t_h^{-1}(0)$ belongs to $\mathrm{Int}(X/K)$. Let D be its actual affinoid algebra, and let $D_0 \subset D$ be an actual admissible model, finite over*

$$O\langle T_1^{\pm 1}, \dots, T_n^{\pm 1}\rangle, \qquad T_i \longmapsto h_i.$$

Set

$$\overline{D}_0 = D_0/K^{\circ\circ}D_0, \quad J = \ker(k[T^{\pm 1}] \longrightarrow \overline{D}_0),$$
$$R = k[T^{\pm 1}]/J, \qquad Z = \operatorname{Spec} R.$$

Then $C = \mathrm{Trop}(Z)$ is the nonempty support of a finite rational polyhedral fan of dimension at most $\dim_K X$. There is a neighbourhood V of 0 such that

$$t_h(X) \cap V \subset C.$$

For every $u \in C$ and every finite list $m_j \in \mathbf{Z}^n$ with $\langle m_j, u\rangle > 0$, the strict sector $\{v : \langle m_j, v\rangle > 0 \text{ for all } j\}$ contains points of $t_h(X)$ arbitrarily close to 0.

Proof. The algebra $\overline{D}_0$ is finite over its subalgebra R. Thus $R \hookrightarrow \overline{D}_0$ is integral by [StacksAlg, Tag 00GK], and lying over, [StacksAlg, Tag 00GQ], applies to every prime of R. Formal specialization 3.16.15 is surjective on $\operatorname{Spec}\overline{D}_0$. If $\mathfrak{q}$ lies above $\mathfrak{p} \subset R$ and $x \in F_0$ specializes to $\mathfrak{q}$, evaluation gives injections

$$R/\mathfrak{p} \hookrightarrow \overline{D}_0/\mathfrak{q} \hookrightarrow \widetilde{\mathcal{H}(x)}.$$

Indeed a model element has zero residue at x exactly when its class belongs to $\mathfrak{q}$; every nonzero residue consequently has absolute value one before reduction. These injections extend to the fraction fields.

The finite-type algebra R is Noetherian, by [StacksAlg, Tag 00FO], and has finitely many minimal primes, by [StacksAlg, Tag 00FR]. For any such prime $\mathfrak{p}$, the preceding injection and Theorem 3.22.7 give

$$\dim(R/\mathfrak{p}) = \operatorname{trdeg}_k \operatorname{Frac}(R/\mathfrak{p}) \leq \operatorname{trdeg}_k \widetilde{\mathcal{H}(x)} \leq d_K(x) \leq \dim_K X,$$

where the equality is [StacksAlg, Tag 00P0]. Apply Theorem 5.19.5 to each reduced irreducible component of Z and take a common refinement of their finite fans. The tropicalization of their finite union is their union, since every analytic seminorm has a prime kernel containing one minimal prime by [StacksAlg, Tag 00E0(4)]. This proves the fan and dimension assertions. Nonemptiness also follows from specialization of any point of the nonempty fibre.

Take a finite tropical basis $p_1, \ldots, p_a$ for J from Lemma 5.38.2. Lift each nonzero coefficient to an element of O of absolute value one, and let $P_j(T) \in O[T^{\pm 1}]$ be the resulting polynomial. Its value $P_j(h)$ belongs to $K^{\circ\circ} D_0$. By the definition of this ideal it is a finite sum $\sum_\ell c_\ell d_\ell$, with $|c_\ell| < 1$ and $d_\ell \in D_0$. Model elements have absolute value at most one at every point of F_0, as in Theorem 3.16.15. It follows that

$$\max_{x \in F_0} |P_j(h)(x)| < 1.$$

Choose a real number $c_j < 1$ strictly larger than this maximum. The closed subset of X on which $|P_j(h)| \geq c_j$ is compact by Proposition 2.24.1 and has moment image avoiding 0. After shrinking a common neighbourhood V of 0, one therefore has $|P_j(h)(x)| < c_j$ whenever $t_h(x) \in V$. Shrink V again so that $e^{-\langle m, v\rangle} > c_j$ for every exponent m occurring in p_j and every $v \in V$. If $v \notin C$, the last assertion of Lemma 5.38.2 supplies an index j for which the least value of $\langle m, v\rangle$ among these exponents occurs exactly once. At a point x with $t_h(x) = v$, that term is the unique largest term of $P_j(h)(x)$, so $|P_j(h)(x)| = e^{-\langle m, v\rangle} > c_j$. This contradiction proves the asserted inclusion in C.

Finally let $u \in C$ and choose an actual analytic point of Z with moment value u, with kernel $\mathfrak{p}$. Choose $\mathfrak{q}$ above $\mathfrak{p}$ and $x \in F_0$ specializing to $\mathfrak{q}$, as in the first paragraph. The subalgebra generated by the residues of the $h_i^{\pm 1}$ in $\widetilde{\mathcal{H}(x)}$ is exactly $R/\mathfrak{p}$. The chosen analytic point factors through this algebra. If the list of inequalities is empty, the assertion is immediate. Otherwise the chosen point induces a valuation ring in $\operatorname{Frac}(R/\mathfrak{p})$. The residue injection already constructed identifies this ring with a local subring of $\widetilde{\mathcal{H}(x)}$. By

[StacksAlg, Tag 00IA], a valuation ring of that field dominates this local subring. Each residue of h^{m_j} lies in its maximal ideal, because its value at the chosen residual point is $e^{-\langle m_j,u\rangle} < 1$. Lemma 3.19.20 extends the dominating valuation ring to a graded valuation ring W containing $\widetilde{K}^{\mathrm{gr}}$ and with that ring as its degree-one part. Put $g_j = h^{-m_j}$, and let γ_j be its degree-one initial value at x. Thus no γ_j belongs to W.

For an arbitrary prescribed neighbourhood of x, choose an actual smaller rational neighbourhood N by Lemma 2.41.1, with all its defining inequalities strict at x. The strict inequalities give relative interior and Proposition 2.33.21 composes it with the original analytic interior. Thus $x \in \mathrm{Int}(N/K)$. Take the bounded coordinate maps from the actual rational presentations. The residue field at x is unchanged by Proposition 2.33.10. For an inner presentation of N/K, the finite-generation part of Theorem for the actual absolute admissible weighted Tate quotient makes the evaluated graded ring finite over $\widetilde{K}^{\mathrm{gr}}$: all new variables vanish at their assigned degrees. Every homogeneous element of that image therefore belongs to W. Indeed it satisfies a homogeneous monic equation, and dividing by its leading power would otherwise put 1 in the maximal homogeneous ideal of W.

Suppose the desired strict sector has no point in N. Then for each $y \in N$ one has $|g_j(y)| \le 1$ for at least one j. For each i form the actual domain

$$V_i = \{y \in N : |g_i/g_j(y)| \le 1 \text{ for every } j\}.$$

All ratios are units, so these are actual denominator-one radius-one domains containing x. Total comparability in the graded valuation ring orders the finitely many γ_i by divisibility. Choose i with $\gamma_i/\gamma_j \in W$ for all j. The graded reduction image of the actual V_i at x is finite over the image generated by the reduction of N and these degree-one ratios. For this use present N by an absolute weighted Tate algebra, append the ratios by the actual coefficientwise quotient of Proposition 1.17.3, and invoke only the admissible Tate-presentation clause of Theorem . Any surviving class of an original coordinate comes from its class in N by spectral contraction, and any surviving appended class is the stated ratio. The residue identification along $V_i \to N$ is the rational Proposition 2.33.10. Graded integral closedness (Lemma 3.19.1) puts the image of V_i in W. On V_i, however, $|g_i(y)| \le |g_j(y)| \le 1$ for some j at each point. Thus g_i has spectral seminorm at most one on V_i, by the spectral maximum formula 1.20.3. Its class at x is $\gamma_i \in W$, a contradiction. This proves realization of the strict signs in every neighbourhood of x. Continuity of t_h proves the assertion about values approaching 0. The choice of

x used the whole fibre; it did not restrict to the fibre above one target Gauss point. □

Strict sectors at a normalized interior point. Let x be an interior point of an affinoid over the complete ground field, and let analytic units h_i have absolute value one at x. Let $R \subset \widetilde{\mathcal{H}(x)}$ be the Laurent algebra generated over the residue field by their degree-one initial units. Suppose a residual analytic point of R, over the trivially valued residue field, satisfies the prescribed finitely many signs $|\widetilde{h}^{m_j}| < 1$. Every ordinary neighborhood of x then contains a point with $|h^{m_j}| < 1$ for every j.

To apply the preceding minimum-ratio argument at this fixed point, let $\mathfrak{q}$ be the kernel of the residual point. Its valuation ring lies in $\mathrm{Frac}(R/\mathfrak{q})$. Take the inverse image of that ring under the residue map $R_{\mathfrak{q}} \to \mathrm{Frac}(R/\mathfrak{q})$. The inverse image is local. An element whose residue is a unit of the valuation ring is a unit of $R_{\mathfrak{q}}$ and its inverse also belongs to the inverse image. This gives an actual local subring of $\widetilde{\mathcal{H}(x)}$ with all the prescribed monomial residues in its maximal ideal. A dominating valuation ring exists by [StacksAlg, Tag 00IA]. By Lemma 3.19.20 it extends to a graded valuation ring W containing the graded ground field. For $g_j = h^{-m_j}$, each initial value γ_j is outside W.

Take a strict rational neighborhood N inside the prescribed neighborhood. Strict inequalities and forward interior composition make x inner in N over the ground field. In an inner weighted presentation all added coordinate classes evaluate to zero at the assigned degrees. The fixed absolute presentation result therefore puts the evaluated graded ring of N inside W by graded integral closedness. If the desired signs fail everywhere on N, some $|g_j| \leq 1$ at each point there. Choose i with all γ_i/γ_j in W using total homogeneous divisibility. On the actual radius-one quotient domain where all $|g_i/g_j| \leq 1$, append those ratios to the same absolute weighted presentation. The surviving old coordinate classes come from N by spectral contraction. The new ones evaluate to the stated ratios. The same fixed absolute result and graded integral closedness put the evaluated graded ring of the quotient inside W. But on that domain $|g_i| \leq 1$ everywhere, so the spectral maximum formula puts γ_i in W, a contradiction.

Theorem 5.38.6 (The local tropical star of a whole interior fibre)**.** *Let $X = \mathcal{M}(B)$ be nonempty and pure of analytic dimension d over a complete non-Archimedean field K with its specified absolute value. Let $f_1, \dots, f_n \in B^\times$, put $t = t_f$, and suppose*

$$w \in t(X), \qquad F_w = t^{-1}(w) \subset \operatorname{Int}(X/K).$$

Choose a complete nontrivially valued isometric extension L/K and elements $a_i \in L^\times$ with $|a_i| = e^{-w_i}$. Let D_w be the actual algebra of F_w, put $D = (D_w)_L$, and set $h_i = f_i/a_i$. There is an actual admissible model $D_0 \subset D$, finite over $L^\circ\langle T_1^{\pm 1}, \dots, T_n^{\pm 1}\rangle$ by $T_i \mapsto h_i$. For any such model set

$$Z = \operatorname{Spec} \operatorname{im}\left(\widetilde{L}[T^{\pm 1}] \longrightarrow D_0/L^{\circ\circ}D_0\right).$$

Then $C = \operatorname{Trop}(Z)$ is the support of a finite pure d-dimensional rational polyhedral fan, and there is an open neighbourhood V of w such that

$$t(X) \cap V = (w + C) \cap V.$$

Its support C is independent of the extension, normalizing elements, and compatible model. The theorem allows the trivial absolute value on K, arbitrary real w, and nonreduced B.

Proof. Proposition 5.38.4, restricted to the exact level at w, makes D_w finite with its canonical norm over the n-dimensional exact-radius polytorus. Theorem 5.36.3 constructs an extension realizing all the radii, and gives the indicated actual finite model over every such L. The actual domain base-change theorem 2.36.9 identifies $\mathcal{M}(D)$ with the whole normalized zero fibre in X_L. It is contained in $\operatorname{Int}(X_L/L)$ by the base-change assertion of Proposition 2.33.21. Moreover

$$t_h(X_L) = t(X) - w, \qquad \dim_L X_L = \dim_K X = d,$$

by Theorems 2.33.13 and 3.21.8. No purity assertion after this scalar extension is used.

Apply Proposition 5.38.5 to X_L. It gives a nonempty finite rational fan C of dimension at most d, an inclusion of $t(X) - w$ in C near 0, and actual moment values approaching w in every strict rational sector meeting C. The last assertion means sectors containing a specified point of C with all their

defining inequalities strict. The boundary $\partial_K X$ is compact, by Propositions 2.33.21 and 2.24.1. Its moment image is compact and avoids w. Choose $\varepsilon > 0$ such that in the open Euclidean ball $B_\varepsilon(w)$ one has

$$t(X) \cap B_\varepsilon(w) \subset w + C, \qquad t(\partial_K X) \cap B_\varepsilon(w) = \varnothing.$$

Fix a maximal cone σ of this fan and put $r = \dim \sigma$. The set

$$E_\sigma = t(X) \cap \big(w + \operatorname{relint} \sigma\big) \cap B_\varepsilon(w)$$

is nonempty. If $\sigma = \{0\}$ this follows from $w \in t(X)$. Otherwise choose a nonzero rational vector $u \in \operatorname{relint} \sigma$. There is a strict rational sector containing u which meets C only in $\operatorname{relint} \sigma$. To see this, choose an integral linear form ℓ with $\ell(u) > 0$ and use the slice $\ell(v) = 1$. In this slice a sufficiently small rational open box around $u/\ell(u)$ avoids the finitely many other cones and the proper faces of σ. Its defining inequalities, after multiplication by the positive $\ell(v)$ and clearing denominators, together with $\ell(v) > 0$, define the required strict sector. Sector lifting from the preceding proposition, followed by $t_h(X_L) = t(X) - w$, gives points of E_σ arbitrarily close to w.

Take $v \in E_\sigma$ and put $N_\sigma = \mathbf{Z}^n \cap \operatorname{span}_{\mathbf{R}} \sigma$. This is saturated of rank r: a rational basis of the span becomes integral after clearing denominators. Since the fan is finite and $v - w$ belongs to the relative interior of a maximal cone, the moment image in a sufficiently small neighbourhood of v lies in $v + (N_\sigma)_{\mathbf{R}}$. Choose a closed rectangular box P_v in that neighbourhood, with v in its interior, and put $Y_v = t^{-1}(P_v)$. Choose an integral projection $Q : \mathbf{Z}^n \to \mathbf{Z}^r$ that is injective on N_σ, using Lemma 5.14.1. Its monomials are analytic units on Y_v. The entire level of $Q \circ t|_{Y_v}$ at Qv is exactly $F_v = t^{-1}(v)$, since Q is injective on this affine plane.

Every point of F_v is interior over K, because the chosen ball avoids $t(\partial_K X)$. The defining inequalities of Y_v are strict on F_v, so its actual rational presentation puts $F_v \subset \operatorname{Int}(Y_v/X)$. Composition in Proposition 2.33.21 therefore gives $F_v \subset \operatorname{Int}(Y_v/K)$. Theorem 5.31.1 now makes the actual algebra of F_v finite over the r-dimensional exact-radius polytorus at Qv. The rational universal property 2.31.2 identifies this level algebra with the original full fibre algebra in X. By Theorem 5.35.3 its analytic dimension is d. Lemma 5.38.3 and Proposition 5.35.4 give

$$d \le r.$$

The residual fan bound gives $r \le d$. Thus every maximal cone has dimension d.

At every point of E_σ, the hypotheses of Theorem 5.37.2 are now satisfied over the original field: X is pure of analytic dimension d, the whole fibre is interior, and the local image lies in the rank-d saturated tangent plane. That theorem makes E_σ relatively open in

$$U_\sigma = \big(w + \operatorname{relint}\sigma\big) \cap B_\varepsilon(w).$$

It is relatively closed there because $t(X)$ is compact. The set U_σ is convex and nonempty. Starting at a point of E_σ, join it to any point of U_σ by its line segment. The inverse image of E_σ on $[0,1]$ is open and closed and contains 0. If it were not all of $[0,1]$, the supremum of the initial interval it contains would contradict either its closedness or its openness. Thus $E_\sigma = U_\sigma$. This applies also to the zero-dimensional case, where $U_\sigma = \{w\}$. The relative interiors of the maximal cones are dense in their union. Closedness of $t(X)$ therefore fills all their faces inside the ball. Together with the opposite inclusion already proved, this yields

$$t(X) \cap B_\varepsilon(w) = (w + C) \cap B_\varepsilon(w).$$

Finally, two choices of normalizers, extension, or model give conical supports with the same germ at 0 by this equality. Multiplying any vector by a sufficiently small positive real number puts it in that common neighbourhood. Homogeneity of the two supports then makes them equal everywhere. □

Corollary 5.38.7 (Local polyhedrality without a purity assumption)**.** *Let $X = \mathcal{M}(B)$ be a generalized affinoid space over any complete non-Archimedean field with its specified absolute value, and let $t = t_f$ be the moment map of finitely many analytic units. If $w \in t(X)$ and the whole fibre F_w is interior over K, there is a finite rational polyhedral fan C and a neighbourhood V of w such that*

$$t(X) \cap V = (w + |C|) \cap V.$$

More precisely, $|C|$ is the union of the pure fans supplied by Theorem 5.38.6 for the irreducible components of X meeting F_w, using their analytic dimensions.

Proof. The generalized affinoid algebra B is Noetherian by Theorem 1.18.3, applied to the ideals of the finite module B over itself, and has finitely many minimal primes $\mathfrak{p}_i$, by [StacksAlg, Tag 00FR]. The closed analytic subspaces $X_i = \mathcal{M}(B/\mathfrak{p}_i)$ cover X: the prime kernel of every analytic point contains a

minimal prime by [StacksAlg, Tag 00E0(4)], and the point factors boundedly through that quotient. The quotient affinoid structure is again given by Corollary 1.18.4. Each nonempty X_i is pure of its analytic dimension, since its algebra is a domain.

The closed immersion $X_i \to X$ is finite, hence everywhere inner by Theorem 2.33.18. Composition in Proposition 2.33.21 therefore makes every point of $X_i \cap F_w$ interior over K. For those i for which this intersection is nonempty, apply Theorem 5.38.6 to X_i. For every other i, Proposition 2.24.1 makes $t(X_i)$ compact. It avoids w and can be removed by shrinking the neighbourhood of w. Intersect the finitely many resulting neighbourhoods. The equality for X follows by taking their union. Subdividing by the finitely many rational hyperplanes used to define all the cones gives a common rational polyhedral refinement, and hence C with the stated support. □

5.39 Finite polyhedrality of actual analytic moment images

Throughout this section K is complete for its specified real-valued non-Archimedean absolute value. It may be trivially valued, and affinoid presentation radii may be arbitrary positive real numbers. The dimension is analytic dimension. The polyhedral inequality descriptions have integral linear parts and arbitrary real constants.

Theorem 5.39.1 (A finite Gauss-fibre cover of the analytic boundary)**.** *Let $X = \mathcal{M}(A)$ be a nonempty generalized affinoid space of analytic dimension d. There are finitely many elements $a_j \in A$, with positive spectral radii $r_j = \rho_A(a_j)$, and bounded maps*

$$K\{r_j^{-1}T\} \longrightarrow A, \qquad T \longmapsto a_j,$$

with the following property. Let η_j be the radius-r_j Gauss point, let $H_j = \mathcal{H}(\eta_j)$ with its specified absolute value, and put

$$X_j = \mathcal{M}_{H_j}\big(A \widehat{\otimes}_{K\{r_j^{-1}T\}} H_j\big).$$

The natural maps identify these actual analytic fibres with compact subsets of X, preserve completed residue fields, and satisfy

$$\partial_K X = \bigcup_j X_j, \qquad \dim_{H_j} X_j \le d - 1$$

for every nonempty X_j. The empty list is allowed. In particular an affinoid of analytic dimension zero has empty absolute boundary.

Proof. Choose homogeneous algebra generators $\bar{a}_j$ of $\widetilde{A}^{\mathrm{gr}}$ over $\widetilde{K}^{\mathrm{gr}}$ by Theorem 3.18.7, and discard zero generators. If $\bar{a}_j$ has degree r_j, choose a lift a_j in the spectral filtration. Nonvanishing of its initial form means exactly that $\rho_A(a_j) = r_j > 0$. Theorem 1.20.2, together with the spectral formula 1.20.3, gives a constant C_j with $\|a_j^m\| \le C_j r_j^m$ for every $m \ge 0$. Proposition 1.9.3 therefore gives the displayed bounded substitution map. This uses the original admissible norm on A; it does not require $\|a_j\| \le r_j$.

Fix $x \in X$ and let S_x be the image of $\widetilde{A}^{\mathrm{gr}}$ in $\widetilde{\mathcal{H}(x)}^{\mathrm{gr}}$. Write u_j for the image of $\bar{a}_j$. The graded innerness criterion 3.18.10, applied to evaluation $A \to \mathcal{H}(x)$ over K, says that x is interior precisely when S_x is finite over $\widetilde{K}^{\mathrm{gr}}$.

A homogeneous element u of degree r satisfying any nonzero polynomial relation over the graded base satisfies a monic homogeneous relation. Indeed, take a nonzero homogeneous component of that polynomial relation, for the grading with $\deg T = r$. Its highest nonzero coefficient is a nonzero homogeneous element of the graded field $\widetilde{K}^{\mathrm{gr}}$, and is therefore invertible. Divide by that coefficient. Thus every such u is integral. If all the u_j are integral, their finitely many monic relations express S_x as a finite module, generated by monomials with bounded exponents. Conversely, in a finite algebra every element is integral: expressing multiplication by it on a finite generating family and applying the adjugate to the resulting square matrix gives a monic annihilating polynomial, which annihilates 1 as well. Consequently

$$x \in \partial_K X \iff \text{some } u_j \text{ satisfies no nonzero homogeneous polynomial relation over } \widetilde{K}^{\mathrm{gr}}.$$

For a fixed j, this last condition is equivalent to the image of x in the radius-r_j disc being η_j. To prove one direction, let $P(T) = \sum_i c_i T^i$ be a nonzero polynomial over K, and put $R = \max_i |c_i| r_j^i$. The terms attaining this maximum give a nonzero homogeneous polynomial in the initial variable. If u_j has no relation, its value is nonzero. Hence

$$|P(a_j(x))| = R.$$

Weighted polynomials are dense in $K\{r_j^{-1}T\}$, so these equalities identify the bounded seminorm on the whole disc algebra with the Gauss seminorm. Conversely, at that Gauss seminorm one has $|a_j(x)| = r_j$. Lift the finitely many

coefficients of a proposed nonzero homogeneous relation for u_j to elements of K with their exact prescribed sizes. All its terms have one common weighted size. A relation of initial forms would make the evaluated polynomial have strictly smaller size, contrary to the Gauss equality. This proves the equivalence and the asserted equality of boundary sets.

Theorem 2.33.11 constructs X_j as the actual generalized H_j-affinoid fibre. It gives its homeomorphism onto the full inverse image of η_j and the isometric identification of its completed residue field at a point z with $\mathcal{H}_A(x)$ at the corresponding point $x \in X$. The field H_j is the completion of $K(T)$ for the radius-r_j Gauss absolute value: weighted polynomial density also gives density of their fractions. Lemma 3.22.4 gives $d(H_j/K) = 1$. The tower formula of Lemma 3.22.2 therefore gives

$$d_{H_j}(z) = d(\mathcal{H}_A(x)/H_j) = d_K(x) - 1 \leq d - 1.$$

Taking the maximum on the nonempty affinoid X_j and using Theorem 3.22.7 proves the dimension bound. If $d = 0$, a nonempty fibre would have a point with negative relative invariant, which is impossible. Thus the boundary is empty in that case. Compactness of the fibres is Proposition 2.24.1. □

Theorem 5.39.2 (Finite polyhedral upper bounds without an interior hypothesis)**.** *Let $X = \mathcal{M}(A)$ be a nonempty generalized affinoid space of analytic dimension d, and let analytic units $f_1, \dots, f_n$ define $t : X \to \mathbb{R}^n$. For every $w \in t(X)$ there are a finite rational polyhedral fan C of dimension at most d and a neighbourhood V of w such that*

$$t(X) \cap V \subset (w + |C|) \cap V.$$

Consequently $t(X)$ is contained in the support of a finite integral affine polyhedral complex of dimension at most d.

Proof. Choose a complete isometric extension L/K containing elements with sizes equal to every radius in a fixed presentation of A, and elements c_i with $|c_i| = e^{-w_i}$; require also that L be nontrivially valued. Such a field is explicit: take the completion of a rational function field with weighted Gauss norms assigning these finitely many positive radii to its variables, and add a variable of size strictly between zero and one. The Gauss construction is Proposition 1.2.2; its valued completion is the one in Lemma 3.22.4. The actual scalar presentation 2.33.5, followed by rescaling the finitely many presentation variables, makes X_L strict. Its dimension is d by Theorem 3.21.8.

Put $h_i = f_i/c_i$. Scalar spectral surjectivity 2.33.13 gives

$$t_h(X_L) = t(X) - w.$$

It suffices to prove the upper bound at zero for this actual strict space. Its whole fibre $F = t_h^{-1}(0)$ is a nonempty strict affinoid domain by Theorem 2.31.2. Let D be its algebra. It has an admissible integral model D_0 by Proposition 3.14.7. The elements $h_i^{\pm 1}$ are power-bounded in D, since their values on F are one and Theorem 1.20.2 applies. Adjoin them to D_0 by Theorem 3.16.8. The resulting algebra is still an actual admissible model of the same D, and contains all these elements. Use this enlarged model in what follows.

Write $k = \widetilde{L}$, $\mathfrak{m} = L^{\circ\circ}$, and

$$J = \ker\bigl(k[T_1^{\pm 1}, \dots, T_n^{\pm 1}] \longrightarrow D_0/\mathfrak{m}D_0\bigr), \qquad R = k[T^{\pm 1}]/J.$$

Thus R injects into the actual special-fibre algebra. For every minimal prime $\mathfrak{p}$ of R, localization preserves this injection, by [StacksAlg, Tag 00HT]. The algebra $(D_0/\mathfrak{m}D_0) \otimes_R R_{\mathfrak{p}}$ is nonzero, so it has a prime by [StacksAlg, Tag 00E0(1)]. Its contraction is the unique prime of $R_{\mathfrak{p}}$. It therefore gives a prime $\mathfrak{q}$ of the special fibre lying above $\mathfrak{p}$; no finiteness of the injection $R \to D_0/\mathfrak{m}D_0$ is required here. Actual specialization surjectivity, Theorem 3.16.15, supplies $x \in F$ specializing to $\mathfrak{q}$. The induced injections give

$$\operatorname{Frac}(R/\mathfrak{p}) \hookrightarrow \widetilde{\mathcal{H}(x)}.$$

By [StacksAlg, Tag 00P0] and Theorem 3.22.7,

$$\dim(R/\mathfrak{p}) = \operatorname{trdeg}_k \operatorname{Frac}(R/\mathfrak{p}) \leq d_L(x) \leq d.$$

The residue field here is the same as for $x \in X_L$, by Corollary 2.33.15.

The finite-type k-algebra R is Noetherian by [StacksAlg, Tag 00FO], and has finitely many minimal primes, by [StacksAlg, Tag 00FR]. Its tropical support is the union of the supports of the corresponding integral quotients: every analytic prime kernel contains a minimal prime by [StacksAlg, Tag 00E0(4)]. Theorem 5.19.5 bounds the dimension of each of these algebraic tropicalizations by d. Lemma 5.38.2 gives a finite rational fan C with support $\operatorname{Trop}(\operatorname{Spec} R)$ and finitely many nonzero $p_j \in J$ cutting out that support tropically. Its dimension is therefore at most d.

Lift every nonzero coefficient of each p_j to an element of L° of absolute value one, obtaining a Laurent polynomial P_j. Since $p_j \in J$, $P_j(h) \in \mathfrak{m}D_0$.

Express this membership as a finite sum $\sum_\ell b_{j\ell} d_{j\ell}$ with $|b_{j\ell}| < 1$ and $d_{j\ell} \in D_0$. Every $d_{j\ell}$ has absolute value at most one on F, by the actual model presentation. Hence there is a real $c_j < 1$ with $|P_j(h)| < c_j$ throughout F. The compact subset of X_L where $|P_j(h)| \geq c_j$ has compact moment image missing zero. Avoiding these finitely many images gives a neighbourhood V_0 of zero where all these strict inequalities hold on the entire inverse image. This uses the compact spectrum of Proposition 2.24.1.

Shrink V_0 further so that, for every monomial of every P_j, its norm at a weight $v \in V_0$ is greater than c_j. At zero all these finitely many norms equal one, so continuity permits the simultaneous choice. If an actual moment value $v \in V_0$ lay outside $|C|$, some p_j would have a unique least-weight term there. The same term of $P_j(h)$ would have strictly largest absolute value at any point over v, and that value would exceed c_j. The non-Archimedean triangle equality would give $|P_j(h)| > c_j$, a contradiction. Thus $t_h(X_L) \cap V_0 \subset |C|$. Translating back proves the local assertion over the original field and norm.

Finally, at every $w \in t(X)$ choose a closed rectangular box centred at w inside its upper-bound neighbourhood. Finitely many box interiors cover the compact set $t(X)$. The union of the intersections of these boxes with the corresponding translated finite fans contains $t(X)$. It is a finite union of integral affine polytopes, all of dimension at most d. Cutting by their finitely many defining hyperplanes gives a finite common complex, as in Lemma 5.14.2. This proves the final assertion. □

Theorem 5.39.3 (Global polyhedrality and the tropicalized boundary)**.** *Let X be a nonempty generalized affinoid space of analytic dimension d over K, and let t be the moment map of any finite tuple of analytic units. The actual image $t(X)$ is the support of a finite integral affine polyhedral complex of dimension at most d. The actual boundary image $t(\partial_K X)$ is likewise finite polyhedral, of dimension at most $d-1$; it is empty when $d = 0$.*

If X is pure of analytic dimension d, every point of $t(X) \setminus t(\partial_K X)$ has the pure d-dimensional local fan of Theorem 5.38.6.

Proof. We induct on the analytic dimension, simultaneously for all complete specified ground fields, all positive real radii, and all unit tuples. Theorem 5.39.2 gives a finite polyhedral upper bound of dimension zero when $d = 0$, hence a finite set containing $t(X)$. Any subset of a finite set is a finite zero-dimensional complex. Theorem 5.39.1 makes the boundary empty. This establishes the induction base.

Assume the assertion for every analytic dimension less than d. First suppose X is pure of dimension d. Use Theorem 5.39.1 to cover its actual boundary by the finitely many actual affinoid fibres X_j over their specified fields H_j, each of dimension at most $d-1$. The restrictions of all original moment functions remain analytic units there. The homeomorphisms and residue-field identifications in that theorem preserve their absolute values. By induction,

$$B = t(\partial_K X) = \bigcup_j t(X_j)$$

is a finite union of integral affine polytopes of dimension at most $d-1$. In particular it admits a finite complex structure of that dimension.

Put $S = t(X)$. By Theorem 5.39.2, choose a finite complex $\mathcal{P}$ of dimension at most d whose support contains S. The upper-bound construction uses bounded boxes, so all its cells may be taken to be polytopes. Since $B \subset S$, cutting by the defining hyperplanes of both complexes gives a common refinement of $\mathcal{P}$ in which B is a subcomplex.

For a d-cell σ of this refinement, its relative interior misses B. The set $S \cap \operatorname{relint}(\sigma)$ is relatively closed because S is compact. It is also relatively open. Indeed, near one of its points no other cell of the finite complex meets that point, so the actual moment image is contained in the affine span of σ. The whole moment fibre is interior, since its value does not belong to B. Theorem 5.37.2, with the saturated rank-d tangent lattice of σ, fills a neighbourhood in that affine plane. This proves relative openness. The relative interior of σ is convex and therefore connected, by the line-segment open-and-closed argument used in Theorem 5.38.6. Thus the intersection is either empty or all of $\operatorname{relint}(\sigma)$.

Select the cells for which it is nonempty and let T be their union with all their faces. Closedness of S shows $T \subset S$. We claim $S = B \cup T$. If $v \in S \setminus (B \cup T)$, choose a neighbourhood missing the closed sets B and T. The whole fibre at v is interior, so Theorem 5.38.6 presents S there by a pure d-dimensional translated fan. A relatively open part of a d-cone in this fan cannot lie in the finitely many affine spans of the lower-dimensional cells of $\mathcal{P}$. To check this, choose a line direction in its span outside the finitely many proper direction subspaces; each remaining proper affine span meets a line in that direction at at most one point. Such a direction exists: in a basis of the d-plane, the vectors $(1, b, \dots, b^{d-1})$, for integers b, avoid each fixed proper linear subspace except at finitely many b, by applying a nonzero

linear equation for that subspace. Consequently arbitrarily close to v there is a point of S in the relative interior of a d-cell of $\mathcal{P}$. That cell is selected, contradicting the chosen neighbourhood's disjointness from T. This proves the claim. The finite union $B \cup T$ is polyhedral of dimension at most d.

For a general $X = \mathcal{M}(A)$ of dimension d, the Noetherian algebra A has finitely many minimal primes, by Theorem 1.18.3 and [StacksAlg, Tag 00FR]. The actual quotient affinoids of Corollary 1.18.4 $\mathcal{M}(A/\mathfrak{p})$ cover X, because every analytic prime kernel contains a minimal prime, [StacksAlg, Tag 00E0(4)]. Each quotient is a domain, and is pure of its analytic dimension. This dimension is at most d: its points have the same completed residue fields as their images in X, so apply Theorem 3.22.7. The pure case just proved handles the components of dimension d, and induction handles the others. Their finite union of moment images proves the assertion for $t(X)$. The boundary assertion for this general X follows directly from its own finite Gauss-fibre cover and the induction hypothesis, exactly as in the pure case. No purity after a coefficient extension is used.

Finally, the stated local purity off the boundary image is precisely Theorem 5.38.6, whose full-fibre hypothesis holds at every such value. □

5.40 Generic cycles in actual analytic Gauss fibres

Throughout, K is complete for its specified real-valued non-Archimedean absolute value. The valuation may be trivial. All affinoid algebras may be generalized, and finite algebra maps carry their canonical finite-module Banach structures. For a positive real polyradius r, write $R = A_{K,r}$ and $H = H_{K,r}$ for the actual Laurent algebra and its Gauss field in Section 5.36.

Proposition 5.40.1 (A Gauss fibre sees the generic component lengths)**.** *Let A be a generalized K-affinoid algebra, and let $A \to D$ represent an affinoid domain of $\mathcal{M}(A)$. Suppose that a bounded map $R \to D$ is finite, and put*

$$E = D\widehat{\otimes}_R H.$$

Then $E = D \otimes_R H$ is a finite-dimensional H-algebra and is flat as an ordinary A-module. Every prime of E contracts to a minimal prime of A.

For a finite A-module M and $\mathfrak{p} \in \operatorname{Min}(A)$, put

$$\beta_{\mathfrak{p}}(M) = \operatorname{length}_{A_{\mathfrak{p}}}(M_{\mathfrak{p}}), \qquad \lambda_{\mathfrak{p}}(E) = \dim_H(E/\mathfrak{p}E).$$

These are finite nonnegative integers, and

$$\dim_H(M \otimes_A E) = \sum_{\mathfrak{p} \in \operatorname{Min}(A)} \beta_{\mathfrak{p}}(M)\lambda_{\mathfrak{p}}(E). \tag{5.40.1}$$

The term $\lambda_{\mathfrak{p}}(E)$ is positive exactly when a prime of E contracts to $\mathfrak{p}$.

If an ideal $I \subset A$ is contained in no minimal prime, then $IE = E$. If $M_{\mathfrak{p}} = 0$ at every minimal prime, then $M \otimes_A E = 0$.

Proof. The Laurent Gauss norm is multiplicative and has zero kernel, by the actual presentation and norm calculation in Theorem 1.17.2 and Proposition 1.2.2. Hence R is a domain and $R \to H$ factors through $\operatorname{Frac}(R)$. Localization is flat by [StacksAlg, Tag 00HT(1)]. A module over a field is flat by the ideal criterion [StacksAlg, Tag 00HD], since that field has only the zero and unit ideals. It follows that H is flat over R.

Proposition 2.33.19 identifies E with the displayed ordinary tensor, with its complete canonical finite-dimensional norm. The homomorphism $D \to E$ is flat: tensoring a D-module with E is tensoring its underlying R-module with H. The domain map $A \to D$ is flat by Proposition 2.38.2. Composing these two exact tensor functors proves that $A \to E$ is flat.

The algebra E is Artinian and is a finite product of its local factors E_j, by [StacksAlg, Tag 00JB]. This includes the empty product when $E = 0$. Let $\mathfrak{q}_j$ be the maximal ideal of a nonzero factor, and let $\mathfrak{p}_j$ be its contraction in A. A strictly smaller prime of A would, by flat going down [StacksAlg, Tag 00HS], lift to a strictly smaller prime under the corresponding prime of E. Every prime of an Artinian ring is minimal. Thus $\mathfrak{p}_j$ is minimal in A.

The ring A is Noetherian by Theorem 1.18.3, and has finitely many minimal primes by [StacksAlg, Tag 00FR]. For any such prime $\mathfrak{p}$, the local ring $A_{\mathfrak{p}}$ is Noetherian of dimension zero, by [StacksAlg, Tag 00FN] and the minimality of $\mathfrak{p}$. It is Artinian by [StacksAlg, Tag 00KH]. Therefore every finite module over it has finite length.

Fix j and put $\mathfrak{p} = \mathfrak{p}_j$. Every element of $A \setminus \mathfrak{p}$ maps to a unit of E_j, so $A \to E_j$ factors through $A_{\mathfrak{p}}$. The factor E_j is flat over A, being a direct summand of E, and hence is flat over $A_{\mathfrak{p}}$ by [StacksAlg, Tag 00HT(2)]. Take a composition series of $M_{\mathfrak{p}}$. Every simple quotient is $\kappa(\mathfrak{p})$: a simple module over a commutative local ring is its residue field. Tensoring this series with E_j remains exact and gives

$$\dim_H(M \otimes_A E_j) = \beta_{\mathfrak{p}}(M)\, \dim_H(E_j/\mathfrak{p}E_j).$$

The quotient on the right is nonzero, since $\mathfrak{p}E_j \subset \mathfrak{q}_j$.

For a different minimal prime $\mathfrak{p}' \neq \mathfrak{p}_j$, choose an element of $\mathfrak{p}'$ outside $\mathfrak{p}_j$. Its image is a unit of E_j, so $E_j/\mathfrak{p}'E_j = 0$. Consequently $E/\mathfrak{p}E$ is exactly the product of $E_j/\mathfrak{p}E_j$ over the factors with contraction $\mathfrak{p}$. Summing the preceding dimension identity proves (5.40.1) and the positivity assertion.

Finally, if I is contained in no minimal prime, then for each j it contains an element outside $\mathfrak{p}_j$. Thus $IE_j = E_j$, and hence $IE = E$. The last assertion follows from the displayed length formula. □

Theorem 5.40.2 (Weights of finite modules on an interior flat germ)**.** *Let $Y = \mathcal{M}(A)$ be nonempty and pure of analytic dimension d. Let a unit moment tuple f define $t : Y \to \mathbb{R}^n$, and let $w \in t(Y)$. Suppose that the entire fibre $F_w = t^{-1}(w)$ lies in $\mathrm{Int}(Y/K)$ and that, for some neighborhood W of w and a saturated rank-d lattice $N \subset \mathbb{Z}^n$,*

$$t(Y) \cap W \subset w + N_{\mathbb{R}}.$$

For $\mathfrak{p} \in \mathrm{Min}(A)$, put $Y_{\mathfrak{p}} = \mathcal{M}(A/\mathfrak{p})$. Set $m_{\mathfrak{p}}(w) = 0$ if its moment fibre at w is empty; otherwise this fibre satisfies the same flat-germ hypotheses, and let $m_{\mathfrak{p}}(w)$ be its positive intrinsic weight.

Let M be a finite A-module. For any integral $Q : \mathbb{Z}^n \to \mathbb{Z}^d$ injective on N, let D_w be the actual algebra of F_w, let R_Q be the polytorus algebra at Qw, and let H_Q be its Gauss field. Put

$$E_Q = D_w \widehat{\otimes}_{R_Q} H_Q, \qquad e_Q = [\mathbb{Z}^d : Q(N)], \qquad \delta_Q(M, w) = \dim_{H_Q}(M \otimes_A E_Q).$$

Then

$$\frac{\delta_Q(M, w)}{e_Q} = \sum_{\mathfrak{p} \in \mathrm{Min}(A)} \beta_{\mathfrak{p}}(M) m_{\mathfrak{p}}(w) \in \mathbb{Z}_{\geq 0}. \tag{5.40.2}$$

In particular this integer, denoted $m_{M,f}(w)$, is independent of Q and is additive in short exact sequences of finite A-modules. For $M = A$ it is the intrinsic weight of Y:

$$m_{Y,f}(w) = \sum_{\mathfrak{p} \in \mathrm{Min}(A)} \mathrm{length}(A_{\mathfrak{p}}) m_{\mathfrak{p}}(w).$$

These module weights are unchanged by restriction to an affinoid domain containing the whole fibre, whenever the two underlying pure-dimensional germs satisfy the stated flat-germ hypotheses.

Proof. Theorem 5.37.1 gives every finite map $R_Q \to D_w$, with its canonical norm and actual Gauss fibre. Apply Proposition 5.40.1 to the domain $F_w \subset Y$.

The quotient $A \to A/\mathfrak{p}$ is finite with its canonical norm. Its spectral map is everywhere interior relative to Y by Theorem 2.33.18. The composition inclusion in Proposition 2.33.21 therefore makes every point over F_w interior over K. The affinoid $Y_{\mathfrak{p}}$ is pure of analytic dimension d by the assumed purity of A, and its moment image is contained in that of Y. If its fibre at w is nonempty, Theorem 5.37.1 applies with the same lattice N.

The actual domain base-change theorem 2.36.9 and finite tensor comparison 2.33.19 identify its full fibre algebra with $D_w/\mathfrak{p}D_w$. This is finite over R_Q. Its actual Gauss algebra is

$$(D_w/\mathfrak{p}D_w)\widehat{\otimes}_{R_Q} H_Q = E_Q/\mathfrak{p}E_Q.$$

For a nonempty fibre its dimension is $e_Q m_{\mathfrak{p}}(w)$ by the flat-germ weight theorem. For an empty fibre the actual algebra is zero, by Theorem 1.20.1, and the same identity holds with $m_{\mathfrak{p}}(w) = 0$. Substitution in (5.40.1) proves (5.40.2).

All tensors in this argument also have their canonical analytic meaning for M. The finite module $M \otimes_A D_w$ has its complete canonical norm by Proposition 1.18.7. A quotient of a finite sum of copies of the finite canonical R_Q-module D_w gives its canonical finite-R_Q-module topology: compose the two finite free quotient presentations. Applying the same tensor comparison over R_Q shows that $M \otimes_A E_Q$ is already complete. Thus no separated completion discards a submodule in the length calculation.

Flatness of $A \to E_Q$ makes its tensor functor exact, proving additivity. For $M = A$ the numerator is the ordinary Gauss degree of D_w, so the formula gives exactly $m_{Y,f}(w)$.

Finally let $A \to A_V$ represent a domain containing F_w, and replace M by $M \otimes_A A_V$. The actual full fibre algebra is still D_w, by Theorem 2.36.9. The saturated tangent lattice is unchanged by Theorem 5.37.2. For a common Q, associativity gives

$$(M \otimes_A A_V) \otimes_{A_V} E_Q = M \otimes_A E_Q.$$

Both the Gauss dimension and its lattice divisor are the same, which proves the restriction assertion. □

5.41 Finite analytic pushforward with generic cycle degrees

Theorem 5.41.1 (Finite pushforward with full generic lengths)**.** *Let $p : X = \mathcal{M}(B) \to Y = \mathcal{M}(A)$ be finite, with the canonical finite-A-module norm on B. Suppose that X and Y are pure of analytic dimension d. Let unit moment tuples define $t_X : X \to \mathbb{R}^n$ and $t_Y : Y \to \mathbb{R}^{n'}$, and let $a : \mathbb{Z}^n \to \mathbb{Z}^{n'}$ be integral. Assume the corresponding identity of characters, so that $t_Y \circ p = a \circ t_X$.*

Let $w' \in t_Y(Y)$ have its whole fibre in $\mathrm{Int}(Y/K)$, and suppose that the local target image is contained in $w' + (N_Y)_{\mathbb{R}}$ for a saturated rank-d lattice N_Y. Assume that

$$a^{-1}(w') \cap t_X(X) = \{w_1, \dots, w_s\}$$

is finite and nonempty and that the local image at each w_i is contained in $w_i + (N_i)_{\mathbb{R}}$ for a saturated rank-d lattice N_i.

For every i, the lattice $a(N_i)$ is contained in N_Y with finite index. Write $m_{\mathfrak{p}}(w')$ for the component weights of Y in Theorem 5.40.2. Then

$$\sum_{i=1}^{s} m_{X,f_X}(w_i)[N_Y : a(N_i)] = m_{B,f_Y}(w') = \sum_{\mathfrak{p} \in \mathrm{Min}(A)} \beta_{\mathfrak{p}}(B) m_{\mathfrak{p}}(w'). \quad (5.41.1)$$

The coefficients are the full generic pushforward lengths:

$$\beta_{\mathfrak{p}}(B) = \sum_{\substack{\mathfrak{q} \in \mathrm{Min}(B) \\ \mathfrak{q} \cap A = \mathfrak{p}}} \mathrm{length}_{B_{\mathfrak{q}}}(B_{\mathfrak{q}})[\kappa(\mathfrak{q}) : \kappa(\mathfrak{p})].$$

Consequently, if a positive rational number Δ satisfies

$$\beta_{\mathfrak{p}}(B) = \Delta \ \mathrm{length}(A_{\mathfrak{p}})$$

for every component with nonempty moment fibre at w', then

$$\Delta \, m_{Y,f_Y}(w') = \sum_{i=1}^{s} m_{X,f_X}(w_i)[N_Y : a(N_i)].$$

For a reduced integral target, Δ is the positive integer $\dim_{\mathrm{Frac}(A)}(B \otimes_A \mathrm{Frac}(A))$. If B is also integral, it is $[\mathrm{Frac}(B) : \mathrm{Frac}(A)]$.

Proof. Finite relative interior, Theorem 2.33.18, and the composition inclusion 2.33.21 put every whole source fibre over w' in $\mathrm{Int}(X/K)$. Theorem 5.37.1 therefore defines all source and target weights. Their local images fill relative neighborhoods in the specified planes by Theorem 5.37.2. The equality of moment maps then gives $a((N_i)_{\mathbb{R}}) \subset (N_Y)_{\mathbb{R}}$. Saturation gives $a(N_i) \subset N_Y$. A nonzero vector in the kernel of $a|_{(N_i)_{\mathbb{R}}}$ would produce a small interval of source moment weights above w', contrary to the stated finite set. Thus $a|_{N_i}$ is injective, and its image has finite index in N_Y.

Choose an integral $Q : \mathbf{Z}^{n'} \to \mathbf{Z}^d$ injective on N_Y by Lemma 5.14.1. Inside the target flat-germ neighbourhood choose a closed box $P = \prod_j [\alpha_j, \beta_j]$ with w' in its interior. Write $g_j = f_{Y,j}$ and $Y_0 = t_Y^{-1}(P)$. The inequalities

$$|g_j| \le e^{-\alpha_j}, \qquad |g_j^{-1}| \le e^{\beta_j}$$

give a single rational presentation over A with denominator 1. Theorems 2.31.1 and 2.31.2 identify its quotient, with its quotient norm, as the affinoid domain algebra of Y_0. At every y in the full fibre $F' = t_Y^{-1}(w')$, the two coordinates for each j are strictly below their displayed presentation radii. Thus $y \in \mathrm{Int}(Y_0/Y)$ by Definition 2.7.1. Since $F' \subset \mathrm{Int}(Y/K)$ by hypothesis, Proposition 2.33.21 gives $F' \subset \mathrm{Int}(Y_0/K)$.

The image of Y_0 lies in $w' + (N_Y)_{\mathbf{R}}$, on which Q is injective. Its entire projected level at Qw' is therefore F'. For every norm-admissible affinoid test over Y, mapping into F' is equivalent to mapping into Y_0 and then into this projected level. The rational domain universal property gives inverse bounded maps between the two representing algebras. Denote this algebra by $D'_{w'}$ with its original characters.

By Theorem 2.36.9, $X_0 = p^{-1}(Y_0)$ and $p^{-1}(F')$ are the actual pullbacks of the two target domains. Proposition 2.33.19 preserves the finite canonical module structure of $X_0 \to Y_0$. Theorem 2.33.18 and the composition inclusion put every point above F' in $\mathrm{Int}(X_0/K)$. By the character identities, the whole Qa-level on X_0 at Qw' is $p^{-1}(F')$. Its source moment values are precisely the w_i: every original source point with $t_X = w_i$ already maps into F'. The same universal property identifies the projected source level with the pulled-back domain over X, and each exact w_i-domain in X_0 with the original whole domain in X. Proposition 5.31.2 now splits the projected level algebra into the product of their actual algebras. Consequently there are bounded algebra isomorphisms

$$\prod_i D_{w_i} \;\simeq\; B \widehat{\otimes}_A D'_{w'} \;\simeq\; B \otimes_A D'_{w'}.$$

The last isomorphism uses the given finite canonical norm and Proposition 2.33.19. The maps respect the projected target characters, since they come from restriction and pullback of the specified character identity.

Let R_Q be the exact-radius target at Qw' and H_Q its Gauss field. All finite tensors are ordinary complete canonical tensors by Proposition 2.33.19. Tensoring the preceding product with H_Q and taking dimensions gives

$$\dim_{H_Q}(B \otimes_A E_Q) = \sum_i \delta_{Qa}(w_i).$$

Theorem 5.40.2 evaluates the left side as $[\mathbb{Z}^d : Q(N_Y)]m_{B,f_Y}(w')$. Theorem 5.37.1 evaluates each right-hand term as $[\mathbb{Z}^d : Qa(N_i)]m_{X,f_X}(w_i)$. Counting representatives in $Qa(N_i) \subset Q(N_Y) \subset \mathbb{Z}^d$ gives

$$[\mathbb{Z}^d : Qa(N_i)] = [\mathbb{Z}^d : Q(N_Y)]\,[N_Y : a(N_i)].$$

Cancellation proves (5.41.1).

For the coefficient formula, fix a minimal prime $\mathfrak{p}$ of A. The ring $A_{\mathfrak{p}}$ is Artinian by the first proposition. Its finite algebra $B_{\mathfrak{p}} = B \otimes_A A_{\mathfrak{p}}$ has finite length as an $A_{\mathfrak{p}}$-module, and hence is Artinian as a ring. Decompose it into its local factors by [StacksAlg, Tag 00JB]. They are $B_{\mathfrak{q}}$ for primes $\mathfrak{q}$ of B over $\mathfrak{p}$. Such primes are minimal in B: a smaller prime would have the same contraction, contradicting incomparability [StacksAlg, Tag 00GT] for the finite, hence integral, map [StacksAlg, Tag 00GK]. Every simple quotient in a composition series of $B_{\mathfrak{q}}$ is $\kappa(\mathfrak{q})$, whose length over $A_{\mathfrak{p}}$ is its full finite dimension over $\kappa(\mathfrak{p})$. Adding these lengths gives the asserted coefficient formula.

The target formula in Theorem 5.40.2 now proves the assertion with Δ. If A is an integral domain, its unique generic local ring is $\mathrm{Frac}(A)$ and has length one. Thus $\beta_{(0)}(B)$ is the displayed vector-space dimension. It is positive because (5.41.1) has a positive left side. If B is integral, this positivity first makes $A \to B$ injective: a nonzero element of its kernel would become invertible and annihilate the generic algebra. Localizing the domain B at the nonzero elements of A is therefore injective. The resulting finite-dimensional domain is a field and hence is precisely $\mathrm{Frac}(B)$. This proves the last assertion. □

Proposition 5.41.2 (The free locus of a finite analytic module)**.** *Let A be a generalized K-affinoid algebra and let M be a finite A-module. The set*

$$U_M = \{\mathfrak{p} \in \operatorname{Spec}(A) : M_{\mathfrak{p}} \text{ is free over } A_{\mathfrak{p}}\}$$

is open. It is a finite union of principal opens $D(g_j)$ on each of which M_{g_j} is finite free. If M is free at all minimal primes, then the ideal $I = (g_1, \dots, g_t)$ is contained in no minimal prime. This condition holds for every finite M when A is reduced.

Let

$$U_M^{\mathrm{an}} = \{y \in \mathcal{M}(A) : \ker(y) \in U_M\}.$$

For every affinoid domain $V \subset U_M^{\mathrm{an}}$, its restriction $M \otimes_A A_V$ is finite locally free as an ordinary A_V-module. Its local bases give bounded isomorphisms with the canonical free-module norms on affinoid domains where the corresponding g_j is a unit.

Suppose M is free at all minimal primes, and let E be any actual Gauss algebra in Proposition 5.40.1. Then $IE = E$. On a local factor E_j whose residue prime contracts to $\mathfrak{p}$, the module $M \otimes_A E_j$ is free of rank $\operatorname{rank}_{A_{\mathfrak{p}}} M_{\mathfrak{p}}$.

Proof. The ring A is Noetherian and every finite module is finitely presented, by Theorem 1.18.3. Suppose $M_{\mathfrak{p}}$ is free of rank r. A basis can be represented by elements of M: multiply its finitely many members by their respective denominators, which are units in $A_{\mathfrak{p}}$. They give a map $A^r \to M$ whose localization at $\mathfrak{p}$ is an isomorphism. Its kernel and cokernel are finite and become zero at $\mathfrak{p}$ by exactness of localization, [StacksAlg, Tag 00HT]. For each member of finite generating lists, vanishing after localization supplies an annihilator outside $\mathfrak{p}$. The product of these finitely many annihilators is an element $g \notin \mathfrak{p}$ for which $M_g \simeq A_g^r$. This proves openness and gives a principal free neighborhood of every point of U_M.

Let I be the ideal generated by all these elements g. It is generated by finitely many of them, since A is Noetherian: express a finite generating set of I using finitely many of the original g's. Thus $U_M = D(I) = \bigcup_j D(g_j)$ with the asserted free bases. If every minimal prime belongs to U_M, none contains I. When A is reduced, each $A_{\mathfrak{p}}$ at a minimal prime is a reduced Artinian local ring, by Proposition 5.40.1. Its maximal ideal is nilpotent by [StacksAlg, Tag 00JB] and hence zero; it is a field. The finite module $M_{\mathfrak{p}}$ is therefore free.

Empty domains are immediate. Let $V = \mathcal{M}(A_V) \subset U_M^{\mathrm{an}}$ be nonempty. There is no point of V where all g_j vanish. The quotient A_V/IA_V is an actual affinoid algebra with its canonical norm, by Theorem 2.33.18, and has empty spectrum. Theorem 1.20.1 makes it zero. Hence $IA_V = A_V$ and the principal opens $D(g_j)$ cover $\mathrm{Spec}(A_V)$. The given algebraic bases base change on these opens and prove that $M \otimes_A A_V$ is finite locally free. If $W \subset V$ is an affinoid domain on which g_j is a unit, its corresponding basis gives an algebraic isomorphism

$$M \otimes_A A_W \simeq A_W^{r_j}.$$

Both maps are bounded for the canonical norms by Theorem 1.18.3. Such domains cover V: compactness, Proposition 2.24.1, gives a positive lower bound for $\max_j |g_j(y)|$, and the resulting finitely many Laurent domains $|g_j| \geq \varepsilon$ cover. Their actual algebras are given by Theorem 2.31.2.

Finally, $IE = E$ follows from Proposition 5.40.1. For a local factor over $\mathfrak{p}$, the map $A \to E_j$ factors through $A_{\mathfrak{p}}$. Tensor its prescribed free basis with E_j to obtain the stated rank. □

Theorem 5.41.3 (Finite neighborhoods of a relative interior level)**.** *Let $p : X = \mathcal{M}(B) \to Y = \mathcal{M}(A)$ be any affinoid morphism, and let a unit moment tuple on Y define $t_Y : Y \to \mathbb{R}^{n'}$. Fix $w' \in t_Y(Y)$ and suppose*

$$p^{-1}(t_Y^{-1}(w')) \subset \mathrm{Int}(X/Y).$$

There is a closed rectangular box P about w', with w' in its interior, for which

$$Y_0 = t_Y^{-1}(P), \qquad X_0 = p^{-1}(Y_0), \qquad p_0 : X_0 \longrightarrow Y_0$$

are actual affinoid domains and a finite morphism with the canonical module Banach structure. The box may be chosen inside any prescribed neighborhood of w'.

Suppose in addition that X and Y are pure of analytic dimension d, that w' is a whole interior flat germ of t_Y with saturated lattice N_Y, and that unit moment coordinates on X and an integral lattice map a satisfy the character identity $t_Y \circ p = a \circ t_X$. Suppose

$$a^{-1}(w') \cap t_X(X) = \{w_1, \ldots, w_s\}$$

is finite and nonempty, and that the local source image at each w_i lies in $w_i + (N_i)_{\mathbb{R}}$ for a saturated rank-d lattice N_i. Write A_0 and B_0 for the actual

algebras of Y_0 and X_0. For a sufficiently small box as above, all the original source weights are defined and

$$\sum_i m_{X,f_X}(w_i)[N_Y : a(N_i)] = m_{B_0,f_Y}(w') = \sum_{\mathfrak{p}\in \mathrm{Min}(A_0)} \mathrm{length}_{(A_0)_{\mathfrak{p}}}((B_0)_{\mathfrak{p}}) m_{(Y_0)_{\mathfrak{p}},f_Y}(w').$$

The component weight is zero for an empty fibre. The resulting integer is independent of the chosen box. If the displayed generic module lengths are Δ times those of A_0 on all components meeting the fibre, then the middle term is $\Delta m_{Y,f_Y}(w')$.

Proof. By Proposition 2.33.21, the relative boundary $Z = X \setminus \mathrm{Int}(X/Y)$ is closed. It is compact by Proposition 2.24.1. The compact set $(t_Y \circ p)(Z)$ does not contain w', so choose a closed box P about w' avoiding it and inside the prescribed neighborhood. The simultaneous coordinate bounds give the actual domain Y_0 by Theorem 2.31.2. Theorem 2.36.9 gives the actual domain X_0, with algebra $B\widehat{\otimes}_A A_0$.

Every point of X_0 comes from $\mathrm{Int}(X/Y)$. Base change of relative interior in Proposition 2.33.21 makes p_0 everywhere interior. Theorem 2.43.8 proves that B_0 is finite over A_0 and has its canonical module norm. This proves the first assertion over the original field and absolute value.

For the remaining assertions choose P also inside the target flat-germ neighborhood. Purity of X_0 and Y_0 follows from Theorem 5.35.3. The whole target fibre is contained in Y_0; all its defining inequalities are strict at that fibre. The relative domain presentation and the composition inclusion 2.33.21 therefore make it interior over K in Y_0. Its weight is the original one by Theorem 5.37.2.

Each entire original source fibre at w_i is contained in X_0, because $a(w_i) = w'$. It is interior over K in X by the assumed relative interior and the target absolute interior. It is also interior in X_0 by the finite relative interior of p_0 and composition. The local flat containment persists under restriction. Theorem 5.37.1 defines these weights; Theorem 5.37.2 identifies their values before and after restriction. The complete set of source moment values over w' is unchanged. Theorem 5.41.1, applied to the actual finite map p_0, now gives the displayed formula and the assertion involving Δ.

For independence of the box, intersect any two sufficiently small boxes. Their intersection is again a closed box with w' in its interior. The asso-

ciated finite maps restrict to the same actual map on this intersection, by Theorem 2.36.9 and Proposition 2.33.19. The finite module over either target restricts to this same module, and the intersection contains the whole target moment fibre. The restriction assertion in Theorem 5.40.2 proves equality of the two middle terms. This proves the claimed independence. □

5.42 Cycles of finite analytic modules

Theorem 5.42.1 (Module cycles and finite geometric pushforward)**.** *Let $Y = \mathcal{M}(A)$ be pure of analytic dimension d, with a unit moment tuple f_Y and moment map t_Y. Let $\Omega \subset \mathbb{R}^{n'}$ be open and convex, with $\Omega \cap t_Y(\partial_K Y) = \varnothing$. Suppose a finite pure d-dimensional integral affine polyhedral complex $\mathcal{C}_Y$ has*

$$t_Y(Y) \cap \Omega = |\mathcal{C}_Y| \cap \Omega.$$

For every finite A-module M, the values $m_{M,f_Y}(v)$ are constant on $\operatorname{relint}(\sigma) \cap \Omega$ for each d-cell σ. They define a nonnegative integral balanced d-cycle, denoted $\operatorname{Trop}_{f_Y,\Omega}(M)$. These cycles are additive in short exact sequences and independent of the chosen polyhedral subdivision. For $M = A$ this is the analytic cycle of Theorem 5.43.2.

Let $p : X = \mathcal{M}(B) \to Y$ be finite, with X pure of analytic dimension d. Suppose unit moment coordinates on X and an integral map $a : \mathbb{Z}^n \to \mathbb{Z}^{n'}$ satisfy the corresponding character identity $t_Y \circ p = a \circ t_X$. Suppose also that a finite pure d-dimensional integral affine complex $\mathcal{C}_X$ satisfies

$$t_X(X) \cap a^{-1}(\Omega) = |\mathcal{C}_X| \cap a^{-1}(\Omega).$$

Then lattice-index pushforward on these open sets gives

$$a_* \operatorname{Trop}_{f_X, a^{-1}(\Omega)}(B) = \operatorname{Trop}_{f_Y,\Omega}(B). \tag{5.42.1}$$

On the left B is the structure module of X; on the right it is its finite A-module. If $\Delta \in \mathbb{Q}_{\geq 0}$ satisfies

$$\beta_{\mathfrak{p}}(B) = \Delta \operatorname{length}(A_{\mathfrak{p}}) \qquad (\mathfrak{p} \in \operatorname{Min}(A)),$$

then the right side is $\Delta \operatorname{Trop}_{f_Y,\Omega}(A)$. The same statement allows a positive rational Δ for a nonreduced target.

Proof. Form the finite A-algebra

$$A \oplus M, \qquad (a,m)(a',m') = (aa', am' + a'm),$$

with its canonical Banach structure from Theorem 2.33.18. The ideal $0 \oplus M$ has square zero. Every multiplicative seminorm annihilates it, so projection and the coefficient inclusion identify its spectrum with that of A. Its minimal primes are $\mathfrak{p} \oplus M$, and the corresponding integral quotients are $A/\mathfrak{p}$. Consequently $Y_M = \mathcal{M}(A \oplus M)$ is pure of analytic dimension d and has the same moment image under the units $(f_{Y,j}, 0)$.

Every point of Y_M above a fibre over Ω is interior over K: the map $Y_M \to Y$ is finite and hence relatively interior, and all points of Y with moment value in Ω are interior by hypothesis. Apply the composition inclusion 2.33.21. Theorem 5.43.2 therefore gives positive balanced analytic cycles for both Y and Y_M on the same complex over Ω.

At an interior point v of a d-cell, let E_Q be the actual target Gauss algebra for a transverse projection.

For the domain comparison at v, use $f_i = f_{Y,i}$ and $r_i = \exp(-v_i)$ in the following exact-level calculation.

Let A be a generalized affinoid over the fixed complete non-Archimedean field K, let M be finite over A, and give the idealization $A_M = A \oplus M$ its canonical finite-algebra Banach structure from Theorem 2.33.18. For units $f_i \in A^\times$ and positive radii r_i, put

$$D = A\{r^{-1}T, rS\}/(T_i - f_i, S_i - f_i^{-1})_i, \qquad D_M = A_M\{r^{-1}T, rS\}/(T_i - (f_i,0), S_i - (f_i^{-1},0))_i$$

These use actual ideals and the displayed quotient norms. The rational point and geometric factorization clauses of Theorems 2.31.1 and 2.31.2, with denominator 1 and the simultaneous upper bounds r_i, r_i^{-1}, identify the algebras with the whole exact-radius domains below and above, respectively. The lifted unit has inverse $(f_i^{-1}, 0)$. Thus the inequalities upstairs describe exactly the inverse image of the whole domain. The same descriptions include the empty domain.

There is a canonical bounded isomorphism, with bounded inverse,

$$D_M \simeq D \widehat{\otimes}_A A_M.$$

Indeed, for a commutative Banach K-algebra C with a bounded unital map $\phi : A_M \to C$, the bounded factorization clause of Theorem 2.31.2 says that extending ϕ across D_M requires exactly the estimates

$$\|\phi((f_i, 0))^m\| \le c_i^+ r_i^m, \qquad \|\phi((f_i^{-1}, 0))^m\| \le c_i^- r_i^{-m} \quad (m \ge 0)$$

for some constants $c_i^{\pm}$. The factorization is unique. These are precisely the estimates for extending $\phi|_A$ across D. Thus D_M represents the pairs of bounded maps from A_M and D agreeing on A. Their balanced product on finite sums $\sum_j d_j \otimes b_j$ has norm bounded by the product of the two operator bounds times $\max_j \|d_j\|\|b_j\|$. Taking the projective infimum and passing through separation and completion gives the unique bounded map from $D\widehat{\otimes}_A A_M$. The two universal factorizations are inverse because their composites fix both structural maps. This comparison preserves the actual algebras over A_M, hence also the maps from the exact-radius target torus defined by the common projecting monomials in the units.

Proposition 2.33.19 gives the Gauss algebra of Y_M as

$$(A \oplus M) \otimes_A E_Q = E_Q \oplus (M \otimes_A E_Q).$$

Thus its dimension is the sum of the two dimensions. Theorem 5.40.2 and the common lattice divisor give

$$m_{Y_M}(v) = m_Y(v) + m_{M,f_Y}(v).$$

Subtracting the two balanced cycles proves constancy and balancing for the module weights. Their nonnegativity and integrality are (5.40.2). Additivity follows from the exact-sequence assertion of that theorem, and common-refinement invariance follows from the same property of the two analytic cycles. This proves the first part.

For the finite map p, every point of X whose moment value lies in $a^{-1}(\Omega)$ is interior over K, again by finite relative interior and composition. Thus the stated source analytic cycle is defined. Exclude from the target the lower-dimensional cells of $\mathcal{C}_Y$, the images of all cells of $\mathcal{C}_X$ of dimension less than d, and the images of those d-cells on whose tangent space a has rank less than d. Linear images of the finitely many polyhedra are polyhedra, by the finite elimination and refinement construction in Theorem 5.17.2. Each excluded set has dimension at most $d-1$. For $d = 0$ the nonempty cells are points and every restriction has rank zero. The exclusions therefore remove no point, so every target point in the support is already in the complement. For $d > 0$ the

complement is dense in the relative interior of every target d-cell: a line in its affine span with direction outside the finitely many excluded proper direction subspaces meets those affine subspaces in at most finitely many points. Such a line direction exists by the finite-polynomial argument in Theorem 5.43.1.

Fix a target point v in this complement and in the target support. Every source moment value above it lies in the relative interior of a d-cell on which a is injective. There is at most one such point per cell, so the full inverse image in $t_X(X)$ is finite. If it is nonempty, all the hypotheses of Theorem 5.41.1 hold: the target and source germs are flat at cell interiors, and the target whole fibre is interior. The theorem identifies the lattice-index sum of source weights with $m_{B,f_Y}(v)$.

If this finite inverse image is empty, the actual inverse image of the entire target moment fibre is empty. Its algebra is $B \otimes_A D_v$, by finite base change and Theorem 2.36.9. Theorem 1.20.1 makes this algebra zero. Hence $B \otimes_A E_Q = 0$ and $m_{B,f_Y}(v) = 0$, which is also the empty lattice-index sum.

The map a on the actual source support over Ω is proper. For a compact subset $C \subset \Omega$, its inverse image is the closed subset $t_X(X) \cap a^{-1}(C)$ of the compact set $t_X(X)$. Refine the target along the finitely many cell images and pull the defining hyperplanes back to the source, as in Theorem 5.17.2. The lattice-index sum then defines the local pushforward; facets with smaller-dimensional image contribute zero. On the generic part of every resulting target d-cell, this sum equals the module weight just computed. Both are constant there, so the cycles agree. This proves (5.42.1). The last assertion follows on every such cell from Theorem 5.40.2 and its formula for the structure module A. □

Theorem 5.42.2 (Finite-module pushforward and composition)**.** *Keep the finite morphism $p : X = \mathcal{M}(B) \to Y = \mathcal{M}(A)$, the moment tuples, the lattice map a, and the given complexes over Ω in Theorem 5.42.1. For every finite B-module M, regarded also as a finite A-module, one has*

$$a_* \operatorname{Trop}_{f_X, a^{-1}(\Omega)}(M) = \operatorname{Trop}_{f_Y,\Omega}(M).$$

Its target generic coefficients are

$$\operatorname{length}_{A_{\mathfrak{p}}}(M_{\mathfrak{p}}) = \sum_{\substack{\mathfrak{q} \in \operatorname{Min}(B) \\ \mathfrak{q} \cap A = \mathfrak{p}}} \operatorname{length}_{B_{\mathfrak{q}}}(M_{\mathfrak{q}})[\kappa(\mathfrak{q}) : \kappa(\mathfrak{p})] \qquad (\mathfrak{p} \in \operatorname{Min}(A)).$$

These pushforwards respect finite composition. More precisely, let $Z = \mathcal{M}(C) \to X$ also be finite with Z pure of analytic dimension d, and let a unit tuple f_Z and an integral map b satisfy the corresponding character identity. Assume a finite pure integral complex presents the actual f_Z-image on $(ab)^{-1}(\Omega)$. For every finite C-module L,

$$(ab)_* \operatorname{Trop}_{f_Z,(ab)^{-1}(\Omega)}(L) = a_* b_* \operatorname{Trop}_{f_Z,(ab)^{-1}(\Omega)}(L) = \operatorname{Trop}_{f_Y,\Omega}(L).$$

Here ab means $a \circ b$, and the middle pushforwards use the indicated inverse open sets.

If P is a finite locally free A-module of constant rank r, then the tensor projection formula is

$$a_* \operatorname{Trop}_{f_X,a^{-1}(\Omega)}(M \otimes_A P) = \operatorname{Trop}_{f_Y,\Omega}(M \otimes_A P) = r \operatorname{Trop}_{f_Y,\Omega}(M).$$

Proof. The square-zero algebra $B \oplus M$ is finite over B and over A, with the canonical finite-module norm, by Theorem 2.33.18. It has the same analytic points, moment image, and pure analytic dimension as B, as proved in Theorem 5.42.1. Apply that theorem to its finite map to Y. Its source cycle is the sum of the structure cycle of X and the module cycle of M. Its target module cycle is the sum of the cycles of B and M as A-modules. The theorem for $B \to A$ and subtraction give the asserted equality. Subtraction is valid on a common finite refinement because each lattice-index coefficient is a finite linear sum of source coefficients. The same compact actual support gives properness for the square-zero source, including modules with zero generic weight.

For a minimal prime $\mathfrak{p}$ of A, decompose the finite Artinian algebra $B_{\mathfrak{p}}$ into its local factors $B_{\mathfrak{q}}$, as in the proof of Theorem 5.41.1. The finite module $M_{\mathfrak{p}}$ decomposes into the corresponding $M_{\mathfrak{q}}$. A composition series of each factor as a $B_{\mathfrak{q}}$-module has residue field $\kappa(\mathfrak{q})$ as every simple quotient. Its length over $A_{\mathfrak{p}}$ is the full field degree $[\kappa(\mathfrak{q}) : \kappa(\mathfrak{p})]$. Adding these lengths proves the displayed coefficient formula.

The composite of two finite canonical affinoid maps is finite and canonical: finite module generators compose, and composing their finite free quotient presentations gives the same Banach topology. Apply the first assertion to $C \to B$, then to $B \to A$ with L as a finite B-module, and finally to $C \to A$. All source support above the stated open sets is interior by finite relative interior and Proposition 2.33.21. The given complexes therefore meet the

same hypotheses at each step. The three equalities give the composition formula.

Finally, tensor P with an actual Artinian Gauss algebra E_Q used to compute any of the target module weights. On a local factor E_j, the map from A factors through the local ring at the contracted prime. A local free basis of P of rank r therefore gives $P \otimes_A E_j \simeq E_j^r$. Consequently

$$\dim_{H_Q}\big((M \otimes_A P) \otimes_A E_Q\big) = r \, \dim_{H_Q}(M \otimes_A E_Q).$$

Divide by the common lattice index and apply Theorem 5.40.2. This proves the target tensor equality on every generic cell. The first assertion, applied to the finite B-module $M \otimes_A P$, gives its pushforward equality. All these tensors have their canonical complete finite-module norms by Proposition 1.18.7. □

Theorem 5.42.3 (Pushforward on a relative interior weight domain)**.** *Let $p : X = \mathcal{M}(B) \to Y = \mathcal{M}(A)$ be an affinoid morphism, with X and Y pure of analytic dimension d. Let a unit tuple f_Y define $t_Y : Y \to \mathbb{R}^{n'}$. Write $\partial(X/Y) = X \setminus \mathrm{Int}(X/Y)$ and put*

$$U_p = \mathbb{R}^{n'} \setminus \big(t_Y(\partial_K Y) \cup (t_Y \circ p)(\partial(X/Y))\big).$$

This is open. There is a canonical local nonnegative integral balanced d-cycle $\mathcal{C}_{p,f_Y}$ on U_p, with support $(t_Y \circ p)(X) \cap U_p$. It is the local analytic cycle

$$\mathcal{C}_{p,f_Y} = \mathrm{Trop}_{p^* f_Y}(X)|_{U_p}.$$

Every $w \in U_p \cap t_Y(Y)$ has a closed target moment box P about w, with w in its interior, such that

$$Y_0 = t_Y^{-1}(P), \qquad X_0 = p^{-1}(Y_0), \qquad p_0 : X_0 \longrightarrow Y_0$$

is an actual finite canonical affinoid map. Writing $A_0 = \mathcal{O}(Y_0)$ and $B_0 = \mathcal{O}(X_0)$, there is an open neighbourhood $W \subset \mathrm{int}(P)$ of w on which

$$\mathcal{C}_{p,f_Y}|_W = \mathrm{Trop}_{f_Y|Y_0}(B_0)|_W.$$

These finite-module descriptions agree on overlaps and under further target-box restriction. At a flat target germ $v \in W \cap t_Y(Y)$ their weight is

$$m_{\mathcal{C}_{p,f_Y}}(v) = \sum_{\mathfrak{p} \in \mathrm{Min}(A_0)} \mathrm{length}_{(A_0)_{\mathfrak{p}}}((B_0)_{\mathfrak{p}}) m_{(Y_0)_{\mathfrak{p}},f_Y}(v),$$

where an empty component fibre has weight zero.

Suppose a unit tuple f_X and an integral map $a : \mathbb{Z}^n \to \mathbb{Z}^{n'}$ satisfy the character identity $p^* f_Y = f_X^{a^*}$. All source weights in $a^{-1}(U_p) \cap t_X(X)$ have whole interior fibres, and

$$a_*\big(\mathrm{Trop}_{f_X}(X)|_{a^{-1}(U_p)}\big) = \mathcal{C}_{p,f_Y}.$$

The pushforward uses the entire actual source support and is proper over U_p.

Proof. The absolute boundary of Y and the relative boundary of X are closed, by Proposition 2.33.21, and compact, by Proposition 2.24.1. Their moment images are compact, so U_p is open. If $(t_Y \circ p)(x) \in U_p$, then x is interior relative to Y and $p(x)$ is interior over K. The composition inclusion in Proposition 2.33.21 makes x interior over K. Consequently

$$U_p \cap (t_Y \circ p)(\partial_K X) = \varnothing.$$

Theorem 5.45.3, applied on X to the pullback unit tuple $p^* f_Y$, defines the asserted local cycle and its support.

Fix $w \in U_p \cap t_Y(Y)$. The entire inverse image of its target moment fibre is relatively interior by definition of U_p. Theorem 5.41.3 therefore supplies the stated actual finite map, and permits P to be chosen inside U_p. Choose an open box $W \subset \mathrm{int}(P)$ about w. The whole target fibre at every $v \in W$ satisfies the box inequalities strictly. It is interior in Y_0 relative to Y, by the actual rational presentation, and interior in Y over K, by $P \subset U_p$. Composition makes it interior in Y_0 over K. Thus W belongs to the whole interior weight domain of Y_0. Theorem 5.35.3 gives purity of Y_0 and of every nonempty X_0.

The finite-map assertion of Theorem 5.45.3, with the same moment tuple on source and target and the identity lattice map, now gives

$$\mathrm{Trop}_{p_0^*(f_Y|Y_0)}(X_0)|_W = \mathrm{Trop}_{f_Y|Y_0}(B_0)|_W.$$

The whole pullback moment fibre at every $v \in W$ is the same in X_0 and X, and it is absolute interior in both. For X_0 this follows from finite relative interior and the target interior just checked. The flat-germ restriction assertion of Theorem 5.37.2 identifies their weights on every local generic cell. Hence the source cycle in this display is $\mathcal{C}_{p,f_Y}|_W$. If X_0 is empty, its algebra and module cycle are zero by Theorem 1.20.1, and the same identity holds.

For completeness, the finite-module descriptions also compare directly. Intersect two boxes at a weight in the overlap of their open interiors. The intersection has that weight in its interior and retains the whole target fibre and its entire inverse image. The actual domain and finite tensor comparisons, Theorem 2.36.9 and Proposition 2.33.19, identify both restricted finite algebras with the algebra of this same inverse-image domain. The whole-fibre restriction assertion of Theorem 5.40.2 gives equal module weights on all generic cells of a common local refinement. This proves the overlap and restriction statements. The generic-length expression is the formula of that theorem for the actual finite A_0-module B_0.

Finally, the equality $t_Y \circ p = a \circ t_X$ and the first paragraph show that every whole f_X-fibre above U_p is absolute interior. Apply the finite-map theorem 5.45.3 to the identity map of X, with source tuple f_X, target tuple $p^* f_Y$, and lattice map a, and restrict its equality to U_p. Its target module is the structure module of X, so the result is exactly the asserted pushforward. For a compact subset $C \subset U_p$, the complete inverse image $t_X(X) \cap a^{-1}(C)$ is closed in the compact set $t_X(X)$. This proves the stated properness on the actual support. □

Theorem 5.42.4 (The exceptional image of a generically free module)**.** *Let $Y = \mathcal{M}(A)$ be nonempty and pure of analytic dimension d, and let $I \subset A$ be an ideal contained in no minimal prime. Put $Z = \mathcal{M}(A/I)$, with its actual closed-subspace structure. If $d = 0$, then Z is empty. If Z is nonempty, then*

$$\dim_K Z \leq d - 1.$$

For any unit tuple f defining $t : Y \to \mathbb{R}^n$, the entire actual image $t(Z)$ is the support of a finite integral affine polyhedral complex of dimension at most $d-1$; for $d = 0$ it is empty. Put $U_Y = \mathbb{R}^n \setminus t(\partial_K Y)$. The intersection $t(Z) \cap U_Y$ is relatively closed in $t(Y) \cap U_Y$, and its complement is relatively open and dense there.

In particular, let M be a finite A-module which is free at every minimal prime, and let I_M define its nonfree locus as in Proposition 5.41.2. For every

$$w \in \big(t(Y) \cap U_Y\big) \setminus t(\mathcal{M}(A/I_M)),$$

there is a closed moment box P about w such that the whole domain $Y_P = t^{-1}(P)$ is in the analytic free locus and $M \otimes_A \mathcal{O}(Y_P)$ is finite locally free. If A is integral and the generic rank of M is r, this local rank is constantly r

on $\operatorname{Spec}\mathcal{O}(Y_P)$. *These conclusions apply to every finite module over reduced* A. *For a finite algebra* $M = B$, *the corresponding actual finite map over* Y_P *is finite locally free, with the same constant rank in the integral-target case.*

Proof. The finite quotient A/I has its actual generalized affinoid structure by Theorem 2.33.18. Choose a free-radius extension $L = K_s$ making A and A/I strict, by Theorem 1.17.6. The quotient comparison of Theorem 1.18.8 gives

$$(A/I)_L = A_L/IA_L.$$

Lemma 5.35.1 identifies the minimal primes of A_L with $\mathfrak{p}A_L$ for $\mathfrak{p} \in \operatorname{Min}(A)$, and their contractions are $\mathfrak{p}$. Thus IA_L is contained in no minimal prime of A_L. The analytic-dimension theorem 3.21.8 gives $\dim A_L = d$, since A_L is strict.

Every chain of primes of A_L/IA_L lifts to a chain $\mathfrak{q}_0 \subsetneq \cdots \subsetneq \mathfrak{q}_\ell$ of primes of A_L containing IA_L. By [StacksAlg, Tag 00E0(4)] applied to the zero ideal in A_L and the prime $\mathfrak{q}_0$, there is a minimal prime $\mathfrak{p}_L \subseteq \mathfrak{q}_0$ of A_L. The inclusion $\mathfrak{p}_L \subset \mathfrak{q}_0$ is strict, because IA_L is not contained in $\mathfrak{p}_L$. Prepending $\mathfrak{p}_L$ therefore gives a chain of length $\ell + 1$ in A_L. Hence $\ell + 1 \leq d$. Put $R = A_L/IA_L$. If $R \neq 0$, then [StacksAlg, Tag 00E0(2)] gives a maximal ideal $\mathfrak{m}$ of R. The quotient $R/\mathfrak{m}$ is a field, so $\mathfrak{m}$ is prime. There is thus a chain of length zero in this case, and the bound on all chains gives $\dim R \leq d - 1$. The quotient is zero when $d = 0$. The faithful quotient comparison detects zero before extension, and Theorem 3.21.8 identifies the dimension of every nonzero quotient with that of $\mathcal{M}(A/I)$ over the original K.

If Z is empty, its image has the empty complex. Otherwise apply Theorem 5.39.3 to Z and the restrictions of the original units. The dimension inequality just proved gives the asserted finite complex of dimension at most $d - 1$ for the entire actual image. Compactness of Z and its image, Proposition 2.24.1, proves relative closedness on U_Y.

At every point of $t(Y) \cap U_Y$, Theorem 5.38.6 presents the ambient actual image by a finite pure d-dimensional fan. The exceptional complex is contained in a finite union of affine subspaces of dimension at most $d - 1$. No such finite union contains a relatively open part of a d-cell. For example, choose a line direction in its tangent plane outside the finitely many proper direction subspaces; the finite-polynomial construction in Theorem 5.43.1 supplies one. Every short line segment in that direction meets each excluded affine subspace at most once. Since a pure finite complex is the closure of

the union of its maximal-cell interiors, this proves density of the complement at every point. Openness follows from the relative closedness already proved. For $d = 0$ the exceptional set is empty and the assertion is immediate.

For the module M, Proposition 5.41.2 makes I_M an ideal avoiding every minimal prime, and identifies its analytic zero set with the nonfree locus. Its image under t is compact. Choose a closed box P about the given w, with w in its interior, contained in U_Y and disjoint from that compact image. The actual domain Y_P is given by Theorem 2.31.2. It lies entirely in the analytic free locus, so the analytic restriction assertion of Proposition 5.41.2 makes the restricted module finite locally free.

If A is integral, a free basis of $M_{\mathfrak{p}}$ at any prime of the free locus becomes a basis over $\operatorname{Frac}(A)$ after further localization. Its rank is therefore the same integer r at every such prime. The principal free bases in the proof of that proposition consequently all have rank r. They base change to the indicated cover of $\operatorname{Spec}\mathcal{O}(Y_P)$, proving the constant-rank assertion. Reduced A has the required generic freeness by the same proposition. For a finite algebra B, finite base change and its canonical complete norm, Proposition 2.33.19, identify the restricted algebra with $B \otimes_A \mathcal{O}(Y_P)$. The module assertion is exactly finite local freeness of this actual morphism. □

5.43 Balancing from finite analytic degrees

Fix a complete real-valued non-Archimedean field K, with its specified absolute value. The valuation may be trivial. Let $X = \mathcal{M}(B)$ be a generalized K-affinoid space, pure of analytic dimension d, and let $f_1, \dots, f_n \in B^\times$. Write

$$t : X \longrightarrow N_{\mathbb{R}}, \qquad t(x) = (-\log|f_1(x)|, \dots, -\log|f_n(x)|), \qquad N = \mathbb{Z}^n.$$

At a whole interior flat d-dimensional germ, use the positive integer $m_{X,f}$ of Theorem 5.37.1. All tangent lattices are saturated in the ambient lattice.

Theorem 5.43.1 (The normal equation at a polyhedral wall)**.** *Suppose $d \geq 1$, $w \in t(X)$, and $t^{-1}(w) \subset \operatorname{Int}(X/K)$. Let $N_\tau \subset N$ be saturated of rank $d-1$. For $1 \leq i \leq r$, let $N_i \subset N$ be saturated of rank d and contain N_τ, and let $u_i \in N_i$ lift a primitive generator of N_i/N_τ. Suppose the half-planes*

$$C_i = (N_\tau)_{\mathbb{R}} + \mathbb{R}_{\geq 0} u_i$$

are distinct, and that on an open neighborhood W of w the actual moment image is

$$t(X) \cap W = \left(w + \bigcup_{i=1}^{r} C_i \right) \cap W.$$

For each i, the weight $m_{X,f}$ is a fixed positive integer m_i on the relative interior of $w + C_i$ sufficiently near w. These integers satisfy

$$\sum_{i=1}^{r} m_i u_i = 0 \quad \text{in } N/N_\tau.$$

Proof. The boundary of X is compact, by Propositions 2.33.21 and 2.24.1. Its moment image is compact and misses w. Shrink W to avoid that image. Away from the common wall, distinct half-planes have disjoint relative interiors. Near such a point the image is an open part of its affine d-plane, and its whole fibre is interior. Theorems 5.37.1 and 5.37.2 give a positive locally constant integer there. Intersecting the relative interior with a sufficiently small open box about w gives a convex set. A locally constant function is constant on each segment in that set: otherwise the supremum of the initial interval of constancy contradicts local constancy. This gives the integers m_i.

By Lemma 5.14.1, choose a homomorphism $q : N \to \mathbb{Z}^{d-1}$ whose restriction to N_τ is an isomorphism. Subtracting from each u_i its unique element of N_τ with the same q-image gives representatives satisfying $q(u_i) = 0$, without changing the half-planes or the asserted normal equation. Let $\lambda : N \to \mathbb{Z}$ vanish on N_τ and satisfy $\lambda(u_i) \neq 0$ for every i. Put

$$Q = (q, \lambda) : N \longrightarrow \mathbb{Z}^d.$$

Since N_i/N_τ is generated by the class of u_i, the chosen basis of N_τ, followed by u_i, is a basis of N_i. In these bases $Q|_{N_i}$ has matrix $\operatorname{diag}(I_{d-1}, \lambda(u_i))$. Consequently

$$Q|_{(N_i)_{\mathbb{R}}} \text{ is injective}, \qquad [\mathbb{Z}^d : Q(N_i)] = |\lambda(u_i)|. \tag{5.43.1}$$

Take a small closed rectangular box $P \subset W$ with w in its interior, and let $Y = t^{-1}(P)$ be the actual affinoid domain given by Theorem 2.31.2. It is pure of analytic dimension d by Theorem 5.35.3. At each point of $t^{-1}(w)$ all inequalities defining Y are strict. Thus that fibre is interior in Y over X, and composition in Proposition 2.33.21 makes it interior in Y over K.

The whole level of $Q \circ t|_Y$ at $s_0 = Qw$ is $t^{-1}(w)$. Indeed, for $v - w = b + au_i \in C_i$, with $b \in (N_\tau)_{\mathbb{R}}$ and $a \geq 0$, the equation $Q(v-w) = 0$ first gives $a\lambda(u_i) = 0$ and then $q(b) = 0$. Thus $a = b = 0$. Theorem 5.35.5, applied to the monomial units with exponent matrix Q on Y, gives a closed box P' about s_0 and an actual finite map

$$Z = (Q \circ t|_Y)^{-1}(P') \longrightarrow \mathbb{T}_{P'}.$$

Its Gauss-fibre dimension is a fixed positive integer δ on P'. Every point of Z is interior in Y over K.

For a sufficiently small $\varepsilon > 0$, both $s_\pm = s_0 \pm \varepsilon e_d$ lie in the interior of P'. The moment values in Y over s_+ are exactly

$$v_i^+ = w + \frac{\varepsilon}{\lambda(u_i)} u_i, \qquad \lambda(u_i) > 0,$$

and those over s_- are exactly

$$v_i^- = w - \frac{\varepsilon}{\lambda(u_i)} u_i, \qquad \lambda(u_i) < 0.$$

To see this, the first $d-1$ coordinate equations give $b = 0$, and the last gives the displayed coefficient of u_i. Choose ε so that all these finitely many points belong to the interior of P; the local image hypothesis then also proves their existence. Distinct half-planes give distinct points on each side.

Every whole moment fibre at these values in X belongs to Y. The projected levels avoid the absolute boundary of Y, since they belong to $Z \subset \mathrm{Int}(Y/K)$. Proposition 5.31.2 therefore decomposes each actual level algebra into the product of its whole moment fibre algebras, before reduction. Theorem 5.35.5 identifies these level algebras with the exact-radius restrictions of the same finite algebra over $\mathbb{T}_{P'}$. Their Gauss fields are the same weighted completions of the target Laurent rational function field. Consequently their Gauss dimensions are both δ, and the product decompositions give

$$\delta = \sum_{\lambda(u_i)>0} \delta_Q(v_i^+), \qquad \delta = \sum_{\lambda(u_i)<0} \delta_Q(v_i^-).$$

By Theorem 5.37.1 and (5.43.1), these identities read

$$\sum_{\lambda(u_i)>0} m_i \lambda(u_i) = \sum_{\lambda(u_i)<0} m_i(-\lambda(u_i)).$$

Hence $\lambda(\sum_i m_i u_i) = 0$ for every such λ.

These integral covectors separate points of the free quotient N/N_τ. Explicitly, in a basis of that quotient use covectors with coordinates $(1, a, a^2, \dots, a^{h-1})$, where $h = \operatorname{rank}(N/N_\tau)$ and $a \in \mathbb{Z}$. Their values on any fixed nonzero vector are a nonzero polynomial in a, with finitely many roots. If $\sum_i m_i u_i$ had nonzero class, choose an integer a avoiding the roots for that class and for all the nonzero classes of the u_i. The resulting covector would contradict the preceding equality. Thus the normal equation holds in N/N_τ. □

Theorem 5.43.2 (The analytic weights on a given polyhedral image)**.** *Let $\Omega \subset N_{\mathbb{R}}$ be open and convex, with $\Omega \cap t(\partial_K X) = \varnothing$. Suppose a finite pure d-dimensional integral affine polyhedral complex $\mathcal{C}$ satisfies*

$$t(X) \cap \Omega = |\mathcal{C}| \cap \Omega.$$

Discard cells not meeting Ω. Each d-cell σ has a well-defined positive integer m_σ: it is $m_{X,f}(v)$ for any $v \in \operatorname{relint}(\sigma) \cap \Omega$. For every $(d-1)$-cell τ meeting Ω these integers obey

$$\sum_{\sigma \supset \tau} m_\sigma u_{\sigma/\tau} = 0 \quad \text{in } N/N_\tau.$$

Thus they define a positive integral balanced d-cycle on Ω. It is unchanged by a common polyhedral refinement or by an affinoid restriction containing all moment fibres over Ω and satisfying the same hypotheses.

Proof. At an interior point of a d-cell, the finiteness and face intersection property of the complex give a neighborhood in which its support is an open part of that cell's affine span. The whole fibre is interior by the condition on Ω. Theorems 5.37.1 and 5.37.2 therefore give a positive locally constant integer on $\operatorname{relint}(\sigma) \cap \Omega$. This intersection is convex, so the segment argument in the preceding proof makes the integer constant.

Choose $w \in \operatorname{relint}(\tau) \cap \Omega$. Such a point exists whenever τ meets the open set Ω: points of its relative interior approach every point of the polyhedron. Only cells containing τ occur sufficiently near w. In a finite inequality presentation of an incident d-cell, inequalities strict at w remain strict in a small neighborhood; the remaining inequality in its affine span cuts out the half-space pointing into that cell from τ. Its direction is $(N_\tau)_{\mathbb{R}} + \mathbb{R}_{\geq 0} u_{\sigma/\tau}$. Distinct incident cells give distinct half-spaces, since otherwise their relative

interiors would intersect. Theorem 5.43.1 now gives the displayed equation. For $d = 0$ there is no normal equation to check.

On a subdivision, the generic interior of each new d-cell has the same whole fibres and tangent lattice as its old cell, so its weight is the old weight. Lemma 5.14.2 identifies the resulting cycles under common refinement. For an affinoid restriction as in the statement, Theorem 5.37.2 identifies the actual fibre algebras, tangent lattices and weights. The same argument on a common refinement proves the asserted equality of cycles. □

5.44 Adding moment coordinates

Theorem 5.44.1 (Pushforward after adding analytic unit coordinates)**.** *In the setting above let $g_1, \dots, g_m \in B^\times$ and put*

$$\widehat{t} = (t, (-\log|g_j|)_j) : X \longrightarrow \mathbb{R}^{n+m}, \qquad \pi : \mathbb{Z}^{n+m} \longrightarrow \mathbb{Z}^n.$$

Let $\Omega \subset \mathbb{R}^n$ be open and convex and avoid $t(\partial_K X)$. Suppose finite pure d-dimensional integral affine complexes $\mathcal{C}$ and $\widehat{\mathcal{C}}$ satisfy

$$t(X) \cap \Omega = |\mathcal{C}| \cap \Omega,$$
$$\widehat{t}(X) \cap \pi^{-1}(\Omega) = |\widehat{\mathcal{C}}| \cap \pi^{-1}(\Omega).$$

Equip both with their analytic weights from Theorem 5.43.2. Then on Ω

$$\pi_*[\widehat{\mathcal{C}}] = [\mathcal{C}].$$

More explicitly, outside a finite union of polyhedra of dimension at most $d-1$, each $v \in |\mathcal{C}| \cap \Omega$ lies in the relative interior of a d-cell σ, its full inverse image in $\widehat{t}(X)$ is finite, and

$$m_\sigma = \sum_{\substack{u \in \widehat{t}(X) \\ \pi(u) = v}} m_{\widehat{\sigma}(u)} [N_\sigma : \pi(N_{\widehat{\sigma}(u)})]. \tag{5.44.1}$$

Here u lies in the relative interior of a unique d-cell $\widehat{\sigma}(u)$, and π is injective on its tangent space. The equality uses all source moment fibres over v.

Proof. The set $\pi^{-1}(\Omega)$ is open and convex and misses $\widehat{t}(\partial_K X)$. Thus the indicated weights exist on both complexes and are balanced by Theorem 5.43.2.

Remove from Ω the cells of $\mathcal{C}$ of dimension less than d, the images of all cells of $\widehat{\mathcal{C}}$ of dimension less than d, and the images of those d-cells on whose

tangent space π has rank less than d. Each removed set is contained in a finite union of affine subspaces of dimension at most $d-1$. The images are polyhedra: eliminating one real coordinate from a finite list of linear inequalities replaces the upper and lower bounds for that coordinate by their pairwise comparisons, and preserves the inequalities not involving it; iterating gives a finite inequality presentation of a linear image. Rational coefficients remain rational. This also supplies a finite polyhedral refinement adapted to all these images, by cutting along the finitely many resulting supporting hyperplanes.

The complement is dense in the relative interior of every d-cell meeting Ω. To verify this directly, in its affine span choose a line direction outside the finitely many proper linear subspaces parallel to the excluded affine subspaces. A line in that direction meets each of them at at most one point. Arbitrarily short segments therefore contain points of the complement. Such a direction exists, for example by the finite-polynomial argument in the proof of Theorem 5.43.1.

Fix v in this complement and in the target support. Every $u \in \widehat{t}(X)$ above v is in $\pi^{-1}(\Omega)$, so it lies in the relative interior of a unique d-cell of $\widehat{\mathcal{C}}$, and π has full rank on that cell. The affine restriction is injective, so there is at most one such point for each of the finitely many cells. There is at least one, since $t = \pi \circ \widehat{t}$. This proves finiteness and nonemptiness of the full inverse image.

Near v the target image is contained in its affine d-plane, and near every u the joint image is contained in its affine d-plane. The whole target fibre is interior because $v \notin t(\partial_K X)$; the whole source fibres are contained in it. Apply Theorem 5.37.3 to the identity morphism $X \to X$, with source moment tuple (f, g), target moment tuple f, and lattice map π. Its algebra is finite free of rank one over itself, with its original Banach structure. All its full-fibre hypotheses have just been checked. The resulting formula is exactly (5.44.1).

The restriction of π to the actual joint support over Ω is proper: above a compact subset of Ω its inverse image is a closed subset of the compact set $\widehat{t}(X)$. On the finite refinement constructed above, the weight defining π_* at a generic point of a target d-cell is the finite sum in (5.44.1); cells with smaller-dimensional image contribute no d-weight. The formula agrees with the analytic target weight on a dense subset of every such cell. Both are constant there, so the weighted cycles are equal. □

5.45 Local analytic tropical cycles

Lemma 5.45.1 (A finite presentation near a compact projected fibre)**.** *Let $S \subset \mathbb{R}^n$ be compact, let $a : \mathbb{R}^n \to \mathbb{R}^m$ be an integral linear map, and let $w \in \mathbb{R}^m$. Suppose that, at each $u \in S \cap a^{-1}(w)$, there are a neighbourhood V_u and a finite pure d-dimensional rational polyhedral fan C_u such that*

$$S \cap V_u = (u + |C_u|) \cap V_u.$$

There are an open convex neighbourhood W of w and a finite pure d-dimensional integral affine polyhedral complex $\mathcal{D}$ such that

$$|\mathcal{D}| \subset S, \qquad S \cap a^{-1}(W) = |\mathcal{D}| \cap a^{-1}(W).$$

If the fibre is empty, $\mathcal{D}$ may be empty. The neighbourhood W may be required to lie in any prescribed neighbourhood of w.

Proof. For each u in the compact fibre, take a closed rectangular box P_u centred at u, contained in V_u, and with u in its interior. The interiors of finitely many such boxes $P_{u_1}, \dots, P_{u_s}$ cover the fibre. Put

$$T = \bigcup_{j=1}^{s} \big((u_j + |C_{u_j}|) \cap P_{u_j}\big) = \bigcup_{j=1}^{s} (S \cap P_{u_j}).$$

For every d-cone σ of C_{u_j}, the polytope $(u_j + \sigma) \cap P_{u_j}$ has dimension d: the box contains a neighbourhood of its cone vertex. Every smaller-dimensional cone is a face of a d-cone. Thus T is a finite union of d-dimensional integral affine polytopes and their faces. Cut these polytopes by all the finitely many hyperplanes in their inequality and affine-hull presentations. Their cells and faces form a finite common refinement $\mathcal{D}$ with support T. Each cell is contained in the closure of a d-cell. Indeed, in any original d-polytope its relative interior is dense, and the finitely many proper cutting hyperplanes have empty relative interior. Hence this complex is pure of dimension d. This is also the explicit refinement construction of Lemma 5.14.2.

The set

$$E = S \setminus \bigcup_{j=1}^{s} \operatorname{int}(P_{u_j})$$

is compact and has no point over w. Its image $a(E)$ is compact and misses w. Choose a sufficiently small open convex neighbourhood W of w disjoint from

that image. Every point of $S \cap a^{-1}(W)$ belongs to one of the box interiors, hence to T. Conversely $T \subset S$, proving both asserted inclusions. If the fibre is empty, apply the same compactness argument to $E = S$ and take the empty complex. Shrinking W proves the last assertion. □

Definition 5.45.2 (A local weighted polyhedral cycle)**.** A local integral d-cycle on an open subset U of a real lattice space is a collection of finite weighted integral affine polyhedral complexes on an open cover of U, with integer weights on their d-cells, which agree after common refinement on every overlap. It is balanced if each local complex satisfies the primitive-normal balancing equations. Complexes with all weights zero represent the zero cycle. Lattice-index pushforward is computed on such local presentations when the map on their support is proper and the required source presentations are finite near each target point.

Theorem 5.45.3 (Analytic cycles on whole interior weight domains)**.** *Let $Y = \mathcal{M}(A)$ be a generalized affinoid space, pure of analytic dimension d, over any complete non-Archimedean field with its specified absolute value. Let f_Y be a finite tuple of analytic units, let $t_Y : Y \to \mathbb{R}^{n'}$ be its moment map, and put*

$$U_Y = \mathbb{R}^{n'} \setminus t_Y(\partial_K Y).$$

There is a unique local positive integral balanced d-cycle

$$\mathrm{Trop}_{f_Y}(Y)|_{U_Y}$$

whose support is $t_Y(Y) \cap U_Y$ and whose weights at flat d-dimensional germs are the actual Gauss-degree weights. For every finite A-module M there is a local nonnegative integral balanced cycle $\mathrm{Trop}_{f_Y}(M)|_{U_Y}$ with the module weights of Theorem 5.40.2. It is additive in short exact sequences and is unchanged by common subdivision. The structure module gives the preceding positive cycle.

Let $p : X = \mathcal{M}(B) \to Y$ be finite, with X pure of analytic dimension d. Let f_X be a unit tuple and let $a : \mathbb{Z}^n \to \mathbb{Z}^{n'}$ satisfy the actual character identities $p^* f_{Y,j} = \prod_i f_{X,i}^{a_{ji}}$, so that $t_Y \circ p = a \circ t_X$. The entire source support over U_Y lies in its whole interior weight domain, and

$$a_*\big(\mathrm{Trop}_{f_X}(X)|_{a^{-1}(U_Y)}\big) = \mathrm{Trop}_{f_Y}(B)|_{U_Y}. \tag{5.45.1}$$

In particular, adjoining any finite list of analytic unit coordinates to a moment tuple and projecting back to that tuple preserves its local analytic cycle.

Proof. The set U_Y is open: the absolute boundary is closed in the compact affinoid spectrum by Propositions 2.33.21 and 2.24.1. At a point of $t_Y(Y) \cap U_Y$, Theorem 5.38.6 gives a translated finite pure rational fan presenting the actual image on a sufficiently small open convex neighbourhood $W \subset U_Y$. Theorem 5.43.2 gives its positive integral balanced weights. At a point of $U_Y \setminus t_Y(Y)$ take a neighbourhood disjoint from the compact image and use the zero cycle.

These local presentations agree on overlaps. Cut along the finitely many defining hyperplanes of two presentations. On the relative interior of every resulting d-cell meeting the overlap, the actual image has the same flat germ and saturated tangent lattice. Both weights are therefore m_{Y,f_Y} of that same whole fibre. The common refinement has equal weights, which is the required agreement. This also proves uniqueness. Theorem 5.42.1 on each of these neighbourhoods gives the module cycles. Their weights agree on overlaps by Theorem 5.40.2; its exact-sequence formula proves the stated additivity.

For the finite morphism, any point x with $a(t_X(x)) \in U_Y$ maps to an absolute interior point of Y. Finite morphisms are everywhere relatively inner by Theorem 2.33.18. Composition in Proposition 2.33.21 makes x an absolute interior point of X. Thus

$$a^{-1}(U_Y) \cap t_X(\partial_K X) = \varnothing.$$

Every whole source moment fibre above this set is interior. Theorem 5.38.6 therefore applies at each of its weights.

Fix $w \in U_Y$. Apply Lemma 5.45.1 to the compact set $S = t_X(X)$ and its complete inverse image over w. It supplies a finite pure source complex on $a^{-1}(W)$ for some open convex neighbourhood $W \subset U_Y$ of w. If $w \in t_Y(Y)$, shrink W inside one target fan neighbourhood already constructed. The two finite complexes then satisfy exactly the hypotheses of Theorem 5.42.1. Its equality proves (5.45.1) over W. If the source inverse image over w is empty, the compactness part of the lemma allows W to miss $a(t_X(X))$; the empty-fibre argument in that same theorem makes the module cycle zero there. If $w \notin t_Y(Y)$, both sides are zero on a smaller neighbourhood disjoint from $t_Y(Y)$.

The map on the actual source support is proper over U_Y: the inverse image of a compact subset of U_Y is closed in the compact set $t_X(X)$. These finite local presentations therefore define the lattice-index pushforward, and their equalities glue to the displayed identity. Finally take $p = \mathrm{id}_Y$, $B = A$, and

the coordinate projection from the enlarged moment tuple. Its finite module is the structure module, giving the last assertion. □

5.46 Integration on analytic moment cycles

Definition 5.46.1 (Lattice normalization for real superforms)**.** On an open subset of $N_{\mathbb{R}}$, a real superform of bidegree (p, q) is a smooth function with values in $\bigwedge^p N'^*_{\mathbb{R}} \otimes \bigwedge^q N''^*_{\mathbb{R}}$. All one-form generators anticommute. The operators d' and d'' differentiate coefficients and wedge the corresponding primed or double-primed differential on the left. The involution J exchanges the two copies and fixes functions. In particular $d'' = Jd'J$, as is checked on a coefficient and on the constant one-form generators.

For an affine d-plane with tangent lattice M, choose an integral basis and its affine coordinates $x_1, \dots, x_d$. Use the positive top generator

$$\omega_M = d'x_1 \wedge d''x_1 \wedge \cdots \wedge d'x_d \wedge d''x_d.$$

The lattice-normalized integral of $c\omega_M$ on a polyhedron is the ordinary real integral of c in these coordinates. A form is restricted to a polyhedron by restricting both cotangent factors to its affine span. Its support on a weighted complex is the closure, in that complex, of the points in the relative interiors of its maximal cells where this restriction is nonzero, after discarding cells of weight zero. Compact support below refers to this support.

Lemma 5.46.2 (The real polyhedral integration calculation)**.** *Lattice-normalized integration of smooth top superforms with compact support is well-defined and additive under finite polyhedral subdivision. Let $F : \sigma \to \tau$ be an affine isomorphism of d-dimensional polyhedra whose linear part maps the tangent lattice N_σ into N_τ. If that lattice map is injective, then*

$$\int_\sigma F^*\alpha = [N_\tau : F(N_\sigma)] \int_\tau \alpha.$$

A linear map of rank less than d has zero pullback in bidegree (d, d).

Suppose $d \geq 1$, and let β have bidegree $(d-1, d)$ near a d-polyhedron σ, with compact tangential support on σ. For each facet τ choose a basis $v_1, \dots, v_{d-1}$ of N_τ and a primitive lift $u_{\sigma/\tau} \in N_\sigma$ pointing into σ. Write $d\mu_\tau$ for the real measure giving this basis covolume one. Then

$$\int_\sigma d'\beta = (-1)^{d(d+1)/2} \sum_{\tau \prec \sigma} \int_\tau \beta(v'_1, \dots, v'_{d-1}; v''_1, \dots, v''_{d-1}, u''_{\sigma/\tau})\, d\mu_\tau. \quad (5.46.1)$$

The facet expression is independent of the chosen basis and of the lift modulo N_τ.

Proof. We first give the elementary real integration facts used in the calculation. A closed bounded box in $\mathbb{R}^r$ is sequentially compact: repeatedly bisect its sides, retain a closed subbox containing infinitely many terms of a sequence, and choose terms with increasing indices in the nested boxes. Their diameters tend to zero, so completeness of the real coordinates gives a convergent subsequence in the original box. A continuous function on a compact subset is bounded and uniformly continuous. Otherwise a sequence witnessing failure of either assertion has a convergent subsequence; in the second case take pairs at distance tending to zero. Continuity at the common limit is a contradiction.

Let P be a bounded polytope in $\mathbb{R}^r$, and let c be continuous on a neighbourhood of P. In a fixed bounding box use a cubical grid of side length h. The grid boxes meeting a given affine hyperplane have total volume at most Ch. To see this, choose a nonzero coordinate coefficient in an equation for the hyperplane. For each box in the other $r-1$ coordinates, the possible remaining coordinate ranges over an interval of length at most a constant times h, so only boundedly many of the remaining grid intervals are met. There are at most $C'h^{-(r-1)}$ such boxes in the fixed bounding region. The boundary of P is contained in finitely many such hyperplanes. Its grid boxes therefore have total volume tending to zero.

The upper and lower grid sums for c on the boxes wholly inside P differ by at most the bounding volume times the modulus of continuity of c at distance $\sqrt{r}h$. The boundary boxes add an error bounded by $Ch\sup|c|$. Both errors tend to zero. Refining two grids gives the same limit, which defines the integral. The same bounds allow signed functions and prove additivity under a finite polyhedral dissection: its additional faces lie in finitely many hyperplanes and contribute zero. They also prove that lower-dimensional polyhedra have zero r-dimensional integral. For unbounded polyhedra, intersect with a box containing the compact support in its interior; a larger box gives the same value.

We will use iterated integration in these coordinates. The same construction proves it for the functions just considered. On each line parallel to a coordinate axis, the characteristic function of a polytope times a continuous function is piecewise continuous on finitely many intervals. The upper and lower step functions of a rectangular grid bound its one-dimensional integrals.

Integrating these step functions in the remaining variables gives exactly their rectangular grid sums. Their difference tends to zero by the preceding estimates. Thus both orders of integration have the same limit. This argument also proves existence of the required outer integrals; it does not assume an interchange theorem.

One-dimensional translation and scaling follow directly by translating or scaling interval subdivisions. Interchanging coordinates follows from the equality of iterated integrals. A shear $x_i \mapsto x_i + cx_j$ preserves the integral, because after fixing all other coordinates it is a translation in x_i. Every invertible real matrix is a product of shears, coordinate interchanges and nonzero diagonal scalings, by Gaussian elimination. Hence ordinary real change of variables for an invertible affine map with linear matrix L has factor $|\det L|$. All the intermediate regions are polyhedra, so the preceding integral constructions apply at every step.

In integral bases, pullback of a top superform contributes $(\det L)^2$, one determinant from each exterior factor. The scalar change of variables contributes $|\det L|^{-1}$. Their product is $|\det L|$. For a full-rank integral lattice map this is $[N_\tau : F(N_\sigma)]$, by the integer basis calculation in Lemma 5.14.1. A change of integral basis has determinant ± 1, proving independence of the normalization. If the rank is less than d, the pullback on $\bigwedge^d$ is zero. This proves the first assertions.

For completeness, the one-dimensional derivative formula also follows from the same integral. If g is continuous, the difference quotient of $G(t) = \int_a^t g(s)\,ds$ lies between the minimum and maximum of g on the intervening interval; hence $G' = g$. A function with zero derivative is constant by the mean value argument: a continuous function on a closed interval attains its extrema by the compactness just proved, an interior extremum of a differentiable function has derivative zero, and subtraction of the line through the endpoint values gives Rolle's argument. Applying this to a C^1 function minus the primitive of its derivative gives

$$\int_a^b h'(s)\,ds = h(b) - h(a).$$

Apply this identity on the coordinate lines through a polyhedron, followed by the established iterated integration. For a coordinate x_j, almost every such line meets a bounded convex polytope in an interval. Its endpoints lie on facets; the projections of intersections of distinct facets have dimension

at most $r-2$ and have zero $(r-1)$-dimensional integral by the grid estimate. On a facet written $x_j = \ell(\widehat{x}_j)$ the endpoint sign is the sign of the j-th outward normal component. Give the facet its Euclidean measure in orthonormal affine coordinates; the proved linear change of variables computes this measure in any other affine parametrization. The graph's Euclidean area factor is $\sqrt{1+|\nabla\ell|^2}$, obtained by taking the determinant of the Gram matrix $I+\nabla\ell\,\nabla\ell^{\mathsf{t}}$. The absolute value of the corresponding unit-normal component is its reciprocal. Thus the endpoint integral is exactly the facet integral of that normal component times the coefficient. Facets parallel to these lines have zero normal component and give no term. Summing over j proves the divergence formula on a polytope for a C^1 vector field. The argument applies to an unbounded polyhedron with compact support by cutting with a box outside the support; all the new facet terms vanish.

We now apply this coefficient formula to β. Put $s_d = (-1)^{d(d-1)/2}$. In coordinates for any integral basis of N_σ, write its tangential restriction uniquely as

$$\beta = s_d \sum_{j=1}^{d} (-1)^{j-1} b_j \, d'x_1 \wedge \cdots \widehat{d'x_j} \cdots \wedge d'x_d \wedge d''x_1 \wedge \cdots \wedge d''x_d.$$

Direct differentiation gives $d'\beta = (\sum_j \partial_j b_j)\omega_{N_\sigma}$. At a facet, the chosen basis of N_τ followed by $u_{\sigma/\tau}$ is an integral basis of N_σ: the quotient is free of rank one and its indicated element is primitive. This is again Lemma 5.14.1. Use its affine coordinates $(t_1,\dots,t_{d-1},s)$, with the facet in $s=0$ and the polyhedron locally in $s\ge 0$. The divergence contribution of this facet is $-b_d(t,0)\,dt_1\cdots dt_{d-1}$. On the other hand,

$$\beta(v'_1,\dots,v'_{d-1};v''_1,\dots,v''_{d-1},u''_{\sigma/\tau}) = s_d(-1)^{d-1}b_d(t,0).$$

The ratio of these two expressions is $(-1)^d s_d = (-1)^{d(d+1)/2}$. A unimodular change of cell coordinates has absolute determinant one; the two exterior factors and the scalar change of variables above therefore preserve this facet calculation. This proves (5.46.1) for all facets with one common sign. A basis change in N_τ contributes its determinant twice, and a change of the lift by a tangent vector gives a repeated vector in the double-primed alternating factor. These observations prove the last assertion. □

Theorem 5.46.3 (Integration and closedness of a local balanced cycle)**.** *Let C be a local weighted integral d-cycle on an open subset $U \subset N_{\mathbb{R}}$ in the sense of Definition 5.45.2. For smooth superforms with compact support on C, the cell formula*

$$I_C(\alpha) = \sum_{\sigma} m_\sigma \int_\sigma \alpha$$

defines a linear functional in bidegree (d,d), independent of finite local presentations and subdivisions. It is nonnegative on forms whose tangential top coefficients are nonnegative whenever all weights are nonnegative. If C is balanced, then

$$I_C(d'\beta) = 0, \qquad I_C(d''\gamma) = 0$$

for compactly supported forms of bidegrees $(d-1,d)$ and $(d,d-1)$, respectively. For $d = 0$ the functional is the weighted sum of values and both differential assertions are empty.

If an integral affine map a is proper on the support of C, has finite source presentations near the target support, and defines the lattice-index pushforward a_*C, then

$$I_C(a^*\alpha) = I_{a_*C}(\alpha)$$

for every smooth α with compact ambient support in the target open set.

Proof. Let K be the support of the form on C. Around each point of this compact set choose a finite presentation and a smaller closed rectangular box contained in its open domain. Finitely many box interiors cover K. Intersect the finitely many presented cells with these boxes and take a common hyperplane refinement. On overlaps their weights agree by the definition of a local cycle. Count each resulting cell once with that weight. This gives a finite polyhedral description on an open neighbourhood of K in the support. Cells or artificial faces outside that neighbourhood meet no nonzero tangential coefficient of the form. The integral may therefore be computed on this finite description.

Two such descriptions have a common refinement near K. The first assertion of Lemma 5.46.2 proves that the two sums coincide. Linearity and nonnegativity follow from the corresponding inequalities for real grid sums.

For β, use such a finite description around its support. Any artificial exterior facet lies outside that support; all the adjacent tangential coefficients of β vanish in a relative neighbourhood, so their boundary contractions vanish

there as well. On a genuine $(d-1)$-face τ, formula (5.46.1) adds the normal lifts with their weights. Its contribution is

$$(-1)^{d(d+1)/2}\int_{\tau}\beta(v'_1,\dots,v'_{d-1};v''_1,\dots,v''_{d-1},(\sum_{\sigma\supset\tau}m_\sigma u_{\sigma/\tau})'')\,d\mu_\tau.$$

Balancing puts the vector in the last slot in $(N_\tau)_{\mathbb{R}}$. The double-primed factor alternates, so this expression is zero. Summing the finitely many faces gives $I_C(d'\beta)=0$. The identities $d''=Jd'J$ and $J\omega_{N_\sigma}=(-1)^d\omega_{N_\sigma}$ give the assertion for γ by exchanging the two exterior factors. This verifies both closedness statements with the stated normalization.

For the projection formula, properness makes the support of the pullback on C compact. Choose finite source and target presentations near these compact sets and refine along all cell images. On a source d-cell of full rank, the affine map is injective on its affine span. The change-of-variables formula of Lemma 5.46.2 multiplies its contribution by $[N_\tau : a(N_\sigma)]$. On a source cell of rank less than d the pullback vanishes. Grouping the remaining finitely many contributions over each target cell gives exactly its lattice-index pushforward weight. This is the asserted identity. □

Theorem 5.46.4 (Analytic moment integrals and finite change of charts)**.** *Let $X=\mathcal{M}(B)$ be a generalized affinoid space, pure of analytic dimension d, over a complete non-Archimedean field with its specified absolute value. For a unit tuple f write $t_f : X\to\mathbb{R}^n$ and $U_f=\mathbb{R}^n\setminus t_f(\partial_K X)$. For every finite B-module M, the formula*

$$I_{M,f}(\alpha)=I_{\mathrm{Trop}_f(M)|_{U_f}}(\alpha)$$

defines a linear functional on smooth top forms whose tangential support is compact in U_f. It is nonnegative when their tangential top coefficients are nonnegative. It is additive in short exact sequences of modules and satisfies

$$I_{M,f}(d'\beta)=0,\qquad I_{M,f}(d''\gamma)=0$$

for smooth compactly supported tests of the indicated complementary bidegrees in U_f.

Let $p : X=\mathcal{M}(B)\to Y=\mathcal{M}(A)$ be finite, with Y also pure of analytic dimension d. Suppose unit tuples f_X, f_Y and an integral map a satisfy $t_{f_Y}\circ p = a\circ t_{f_X}$. For every finite B-module M, regarded also as a finite A-module, and every smooth top form α with compact ambient support in U_{f_Y},

$$I_{M,f_X}(a^*\alpha)=I_{M,f_Y}(\alpha). \tag{5.46.2}$$

The support of the left-hand test on its actual source cycle is compact and lies in its whole interior weight domain; there α is understood to be extended by zero outside U_{f_Y}.

In particular, let f, g be two unit tuples on the same X, let π_f, π_g be the projections from the joint tuple (f, g), and let α, β be top forms with compact ambient support in U_f, U_g, respectively. Extend them by zero outside these open sets. If

$$\pi_f^* \alpha = \pi_g^* \beta$$

on every tangential d-plane of the actual joint local moment image over $\pi_f^{-1}(U_f) \cup \pi_g^{-1}(U_g)$, then $I_{B,f}(\alpha) = I_{B,g}(\beta)$.

Adjoining unit coordinates is faithful on tangential superforms in every bidegree: on $t_f(X) \cap U_f$, a smooth superform is zero on all tangential faces if and only if its pullback is zero on all tangential faces of the actual joint image over U_f.

Proof. Theorem 5.45.3 constructs the local balanced module cycles with non-negative integral weights. Their definition uses the actual Gauss algebras and generic local lengths of Theorem 5.40.2. The functional, its positivity, and both differential identities are therefore Theorem 5.46.3. The exact-sequence equality of module weights gives the corresponding equality of these finite cell integrals.

First assume that the target units pull back to the actual monomials in the source units prescribed by a. For this finite map, every point whose target weight belongs to U_{f_Y} is interior in X, by finite relative interior and composition, as proved in Theorem 5.45.3. The complete source moment support over a compact subset of U_{f_Y} is compact. Near each target weight, Lemma 5.45.1 supplies a finite source presentation retaining the entire inverse support; the target has the local fan presentation of Theorem 5.38.6. Theorem 5.42.2 on these finite presentations gives

$$a_*\big(\mathrm{Trop}_{f_X}(M)|_{a^{-1}(U_{f_Y})}\big) = \mathrm{Trop}_{f_Y}(M)|_{U_{f_Y}}.$$

The local identities agree after refinement because the module weights refer to the same actual fibres. The projection formula of Theorem 5.46.3 proves (5.46.2). Notice that its real factor is the lattice index, whereas the target coefficients are the full finite-module generic lengths. Both appear in the proved cycle formula.

For a general equality of moment maps as in the statement, use the joint source tuple $(f_X, p^* f_Y)$. Its actual image is the graph of a. The case just proved applies both to its projection onto f_X with the identity morphism and to its projection onto f_Y with the morphism p. The first graph projection is an integral isomorphism, with inverse $u \mapsto (u, a(u))$. It identifies saturated tangent lattices and has index one on every cell. The second projection is a after this identification. The corresponding finite lattice-index sums therefore give the same cycle formula for the stated moment-map equality, and its integral follows from the same real projection formula. All these comparisons are over U_{f_Y}; finite relative interior and composition give the required absolute interior on the whole source fibres.

Apply this result to $p = \mathrm{id}_X$ with source tuple (f, g) and target tuple f, and then with target tuple g. The source structure module is B in both cases. A compactly supported smooth form on U_f extends smoothly by zero to $\mathbb{R}^n$: near the complement of U_f its support is absent. The support of its pullback on the joint actual image is a closed subset of the compact set $t_{(f,g)}(X) \cap \pi_f^{-1}(\operatorname{supp} \alpha)$. Every point of that set lies over a whole interior f-fibre, so the joint cycle is defined there. The same holds for β. Their tangential equality gives equal cell integrals on a common finite presentation. The two identity projection formulas now give the asserted equality of original integrals.

Finally consider a form η of any bidegree on the target moment image over U_f. If its tangential restrictions vanish, refine the joint and target local presentations so that every source cell maps into one target cell. Pullback on tangent spaces then gives zero on the source. Conversely suppose the joint pullback vanishes. Near any target point take the finite presentations supplied above, and remove the lower-dimensional target cells and the images of lower-dimensional or rank-dropping source cells, exactly as in Theorem 5.44.1. On the dense remaining part of every target d-cell, the positive target weight is the sum of the positive source weights times their lattice indices. Hence at least one full-rank source cell lies above every such point. Its tangent map is a real linear isomorphism onto the target tangent plane, so pullback is injective on both exterior factors. The tangential value of η is zero there. Continuity of its smooth coefficients extends this vanishing over the entire target d-cell. Every smaller face is contained in such a cell, and restriction to its tangent space preserves zero. This proves the converse, including the bidegrees above d, where all these restrictions are already zero. □

5.47 Weights on partial affinoid domains

Throughout this section K is complete for its specified real-valued non-Archimedean absolute value. Trivial valuation and arbitrary positive affinoid radii are allowed. Purity means analytic purity as in Section 5.35. All fibre algebras are the actual affinoid algebras, with their nilpotents.

Lemma 5.47.1 (Finite affinoid domains and idempotents)**.** *Let $A \to B$ represent a generalized affinoid domain $U \subseteq \mathcal{M}(A)$. Suppose that B is finite over A and that its given norm is equivalent to its canonical finite-module norm. There is a unique idempotent $e \in A$ such that the restriction map identifies B with $eA = A/(1-e)A$, boundedly in both directions. Moreover,*

$$U = \{x : |e(x)| = 1\}, \qquad A \simeq eA \times (1-e)A.$$

The set U is open and closed, and the displayed product is a bounded isomorphism with bounded inverse. These assertions include the empty domain, for which $e = 0$.

Proof. The self-intersection of the domain has actual algebra $B\widehat{\otimes}_A B \simeq B$, and the isomorphism is multiplication, by Theorem 2.36.9. Proposition 1.18.7 identifies this tensor with $B \otimes_A B$. Thus the two tensor arrows from B agree, and $A \to B$ is an epimorphism of ordinary rings. The finite epimorphism theorem, [StacksAlg, Tag 04VT], makes it surjective.

Put $J = \ker(A \to B)$. It is finitely generated by Theorem 1.18.3. The domain restriction is flat by Proposition 2.38.2. Tensoring $J \hookrightarrow A$ with A/J is therefore injective. Its source is J/J^2 and its map to A/J is zero, so $J = J^2$. By [StacksAlg, Tag 00EH], $J = (1-e)A$ for an idempotent e. Multiplication by e identifies A/J with eA. If another idempotent e' has the same kernel, then $e(1-e') = e'(1-e) = 0$, so $e = ee' = e'$. This proves uniqueness.

Every point takes an idempotent to 0 or 1. The points killing $(1-e)A$ are exactly those with $|e| = 1$. The quotient norm is canonical, so they are precisely the points of B. The two level sets of $|e|$ are open and closed. The algebraic maps in the product decomposition and their inverses are maps between finite canonical A-modules, hence bounded by Theorem 1.18.3. The factors are actual affinoid quotients by Corollary 1.18.4. Finally the empty-domain algebra is zero by Theorem 1.20.1, giving $e = 0$. □

Theorem 5.47.2 (Inclusion–exclusion on interior fibre covers)**.** *Let $X = \mathcal{M}(A)$ be pure of analytic dimension d, let $f_1, \dots, f_n \in A^\times$, and put $t = (-\log|f_1|, \dots, -\log|f_n|)$. Fix $w \in t(X)$ and a saturated rank-d lattice $N \subset \mathbb{Z}^n$. Suppose that*

$$F_w = t^{-1}(w) \subset \mathrm{Int}(X/K), \qquad t(X) \cap W \subset w + N_{\mathbb{R}}$$

for an open neighborhood W of w. Let $V_1, \dots, V_q \subseteq X$ be affinoid domains such that

$$F_w \subseteq \bigcup_{i=1}^{q} V_i, \qquad F_w \cap V_i \subseteq \mathrm{Int}(V_i/K) \quad (1 \le i \le q).$$

For nonempty $I \subseteq \{1, \dots, q\}$, write $V_I = \bigcap_{i \in I} V_i$, $A_I = \mathcal{O}(V_I)$ and $F_I = F_w \cap V_I$. Let D and D_I be the actual algebras of F_w and F_I.

Each F_I is an open and closed affinoid domain of F_w. There are unique idempotents $e_i \in D$ such that, with $e_I = \prod_{i \in I} e_i$, restriction gives bounded isomorphisms

$$D_I \simeq e_I D, \qquad \prod_{i=1}^{q} (1 - e_i) = 0. \tag{5.47.1}$$

For every integral $Q : \mathbb{Z}^n \to \mathbb{Z}^d$ injective on N, let R_Q be the exact-radius polytorus algebra at Qw, let H_Q be its Gauss field, and put

$$E_Q = D \widehat{\otimes}_{R_Q} H_Q, \qquad E_{Q,I} = D_I \widehat{\otimes}_{R_Q} H_Q, \qquad c_Q = [\mathbb{Z}^d : Q(N)].$$

Then $E_{Q,I} = e_I E_Q$. For every finite D-module P,

$$\dim_{H_Q}(P \otimes_D E_Q) = \sum_{\varnothing \neq I \subseteq \{1,\dots,q\}} (-1)^{|I|+1} \dim_{H_Q}(P \otimes_D E_{Q,I}). \tag{5.47.2}$$

All these tensors also agree with their completed tensors for the canonical finite-module norms.

In particular, let M be a finite A-module and set $M_I = M \otimes_A A_I$. Write $m_{M_I,f}(w) = 0$ if F_I is empty. For a nonempty F_I, its whole fibre is interior in V_I and its module weight is defined by Theorem 5.40.2. Then

$$m_{M,f}(w) = \sum_{\varnothing \neq I \subseteq \{1,\dots,q\}} (-1)^{|I|+1} m_{M_I,f}(w). \tag{5.47.3}$$

For $M = A$ this is the same identity for the intrinsic weights $m_{X,f}$ and $m_{V_I,f}$. If the selected parts $F_w \cap V_i$ are pairwise disjoint, it reduces to the sum of their weights.

There is an open neighborhood W' of w on which the same domains cover every whole fibre. For every $v \in t(X) \cap W' = (w + N_{\mathbb{R}}) \cap W'$, all the preceding assertions apply at v. The empty intersections remain empty, and each module weight in (5.47.3) is constant on this neighborhood in the indicated plane.

Proof. Finite intersections are actual affinoid domains by Corollary 2.36.10. Every nonempty one is pure of analytic dimension d by Theorem 5.35.3. If $x \in F_w \cap V_i$, the composition equality 2.44.1 makes x interior in V_i/X. The domain interior theorem 2.44.3 says that it is an ordinary interior point of V_i in X. Consequently, if $x \in F_I$, the intersection of these finitely many neighborhoods is a neighborhood of x contained in V_I. The same domain theorem, followed by the composition inclusion in Proposition 2.33.21, gives

$$F_I \subset \operatorname{Int}(V_I/K).$$

Thus no extra boundary condition on the intersections is required.

The whole flat-germ theorem 5.37.1 makes D and every nonzero D_I finite canonical modules over the same R_Q. It applies to V_I because its moment image is contained in that of X, and hence in the same affine plane near w. An empty F_I has zero algebra by Theorem 1.20.1. The domain base-change theorem 2.36.9 identifies $D \to D_I$ with the actual domain restriction to $F_I \subset F_w$.

This restriction is also finite with its canonical D-module norm. Indeed, any finite R_Q-generating family of D_I also generates it over D. Controlled lifts through its canonical R_Q-presentation, followed by the bounded map $R_Q \to D$, bound the quotient norm from the corresponding D-presentation by a constant times the given norm of D_I. Conversely the bounded D-action bounds its given norm by that quotient norm. These are exactly the two finite-generator norm comparisons of Theorem 1.18.3.

Lemma 5.47.1, first for each singleton I, supplies the unique e_i. Domain intersections and their completed tensor presentations identify

$$D_I \simeq \widehat{\bigotimes}_{i \in I, D} e_i D \simeq e_I D.$$

Here completion changes nothing by Proposition 1.18.7; multiplication gives the last algebraic identification. If $h = \prod_i (1 - e_i)$ were nonzero, the nonzero affinoid quotient hD would have a point by Theorem 1.20.1. Its image in F_w

would belong to none of the V_i, a contradiction. This proves (5.47.1) with the actual algebras, including their nilpotents.

Finite base change, Proposition 2.33.19, gives $E_{Q,I} = e_I E_Q$. Put $L = P \otimes_D E_Q$, a finite-dimensional H_Q-vector space. For each $J \subseteq \{1, \dots, q\}$ set

$$a_J = \prod_{j \in J} e_j \prod_{j \notin J} (1 - e_j).$$

These are pairwise orthogonal idempotents with sum 1, and $a_\varnothing = 0$. Therefore $L = \bigoplus_{J \neq \varnothing} a_J L$. On the summand $a_J L$, e_I acts as 1 precisely when $I \subseteq J$, and otherwise as 0. Its coefficient in the right side of (5.47.2) is

$$\sum_{\varnothing \neq I \subseteq J} (-1)^{|I|+1} = 1,$$

as follows by expanding $\prod_{j \in J}(1 - 1) = 0$. This proves that formula.

The finite D-module P is finite over R_Q. Composing finite free quotient presentations gives equivalent canonical norms for this restriction of scalars. Proposition 1.18.7 consequently identifies every tensor just used with its complete canonical finite-dimensional tensor. In particular, if $P = M \otimes_A D$, associativity identifies its factor $P \otimes_D E_{Q,I}$ with $M_I \otimes_{A_I} E_{Q,I}$. Dividing (5.47.2) by c_Q and applying Theorem 5.40.2 to X and the nonempty V_I proves (5.47.3), independently of Q. The structure-module case agrees with Theorem 5.37.1. Pairwise disjoint parts make every intersection of size at least two empty.

We finally choose the neighborhood uniformly. The ordinary interiors of the V_i cover F_w, as proved above. The complement of their union in compact X is compact, and its moment image misses w. Also the compact sets $\partial_K X$ and $\partial_K V_i$ have moment images missing w. Shrink W to avoid all these images. Compactness and openness of interior are Propositions 2.24.1 and 2.33.21. The resulting neighborhood has whole fibres covered by the same V_i, and each selected fibre is interior in its own domain. The intersection argument above applies unchanged. Every V_I whose fibre at w is empty has compact moment image missing w; shrinking again keeps it empty throughout the neighborhood.

Theorem 5.37.2 makes the image of X equal to the indicated plane nearby. For each fixed V_I, apply the finite generic-component formula in Theorem 5.40.2 to M_I. A component with empty fibre at w remains absent nearby by compactness. Every other component has a whole interior flat fibre, as verified in that theorem's proof, and its intrinsic weight is locally constant

by Theorem 5.37.2. There are only finitely many components and intersections. One final shrinking gives their simultaneous local constancy and all the stated assertions. □

References. The algebraic inputs concerning finite epimorphisms and idempotent ideals are the cited Stacks lemmas. The contribution here is their application to the actual generalized analytic fibre algebras and the resulting boundary-sensitive localization of Gauss and tropical module weights. This is a foundational reconstruction; no claim of novelty in the literature is made.

5.48 Global additivity over affinoid covers

Use the global top-dimensional chains $\mathcal{T}_f(M)$ and their lattice-normalized integrals $\mathcal{I}_{M,f}$ from the finite-module chain and weights and the finite-cell functional. The original complete field and absolute value are fixed; trivial valuation and arbitrary positive presentation radii are allowed.

Theorem 5.48.1 (Global additivity for a finite affinoid cover)**.** *Let $X = \mathcal{M}(A)$ be nonempty and pure of analytic dimension d, let M be a finite A-module, and let a finite tuple of analytic units f define $t : X \to \mathbb{R}^n$. Suppose that $V_1, \dots, V_q$ is a finite affinoid-domain cover of X. For nonempty $I \subseteq \{1, \dots, q\}$ put*

$$V_I = \bigcap_{i \in I} V_i, \qquad A_I = \mathcal{O}(V_I), \qquad M_I = M \otimes_A A_I, \qquad f_I = f|_{V_I}.$$

An empty intersection contributes the zero chain and zero integral. Then, as integral weighted d-chains in the same $\mathbb{R}^n$,

$$\mathcal{T}_f(M) = \sum_{\varnothing \neq I \subseteq \{1,\dots,q\}} (-1)^{|I|+1} \mathcal{T}_{f_I}(M_I). \tag{5.48.1}$$

In particular, for every smooth real superform α of bidegree (d,d) defined on a neighborhood of the actual compact image $t(X)$,

$$\mathcal{I}_{M,f}(\alpha) = \sum_{\varnothing \neq I \subseteq \{1,\dots,q\}} (-1)^{|I|+1} \mathcal{I}_{M_I,f_I}(\alpha). \tag{5.48.2}$$

The identities are unchanged by finite refinements of the cover or of the polyhedral complexes used to represent the chains.

Proof. Corollary 2.36.10 makes every V_I an actual affinoid domain of X, with its compatible restriction algebra. Every nonempty V_I is pure of analytic dimension d by Theorem 5.35.3. The finite module M_I has its canonical complete norm by Theorem 1.18.3. Thus all the nonzero terms in the claimed identity have the stated analytic meaning.

Theorem 5.39.3 makes the actual images $t(X)$ and $t(V_I)$ finite integral affine polyhedral sets. It also makes

$$E = t(\partial_K X) \cup \bigcup_{\varnothing \neq I \subseteq \{1,\dots,q\}} t(\partial_K V_I)$$

a finite polyhedral subset of $t(X)$ of dimension at most $d-1$; for $d=0$ it is empty. By Lemma 5.14.2, choose one finite common subdivision of $t(X)$ in which every $t(V_I)$ and E is a subcomplex, and which also refines the representatives of all the finitely many chains under consideration.

Fix a d-cell σ of this subdivision and a point $w \in \operatorname{relint}(\sigma)$. Its relative interior misses E. Since the whole image has dimension at most d, near w no cell other than σ is present. Hence the local moment image is contained in the affine d-plane $w + (N_\sigma)_{\mathbb{R}}$, where N_σ is its saturated tangent lattice. The whole fibre F_w is interior in X, and each $F_w \cap V_i$ is interior in V_i, by the definition of E. The domains cover F_w because they cover X.

Apply Theorem 5.47.2 to this fibre and the finite module M. It gives

$$m_{M,f}(w) = \sum_{\varnothing \neq I \subseteq \{1,\dots,q\}} (-1)^{|I|+1} m_{M_I, f_I}(w),$$

with zero for the empty selected fibres. The common subdivision ensures that $\operatorname{relint}(\sigma)$ is either contained in $t(V_I)$ or disjoint from it. By the finite-module chain and weights, the terms in this identity are exactly the coefficients of the corresponding global chains on σ. Thus these coefficients agree on every d-cell. Lower-dimensional cells carry no coefficient in a d-chain. This proves (5.48.1); it also covers the case $\dim t(X) < d$, when there are no d-cells.

All these chains have compact polyhedral support contained in $t(X)$. Apply the finite-cell functional to the same smooth form on each term. Their common representatives have finitely many cells, and the integral is the sum of the cell integrals times their integer coefficients. The coefficient identity proves (5.48.2). Subdivision invariance is part of the finite-cell functional. Repeating the argument for any finite refinement of the affinoid cover gives the same global chain $\mathcal{T}_f(M)$ and the same integral, which proves the final assertion. □

5.49 Global moment chains and finite analytic chart data

Theorem 5.49.1 (Global finite-module tropical chains)**.** *Let $X = \mathcal{M}(A)$ be pure of analytic dimension d over a complete non-Archimedean field with its specified absolute value, and let a unit tuple f define $t_f : X \to \mathbb{R}^n$. For every finite A-module M there is a canonical finite nonnegative integral d-dimensional polyhedral chain*

$$\mathcal{T}_f(M).$$

Its support is contained in $t_f(X)$. On any common finite subdivision of the actual image and $t_f(\partial_K X)$, the weight of a d-cell is the module weight $m_{M,f}(v)$ at any point of its relative interior. Cells of dimension less than d give no d-chain term. The chain is additive in short exact sequences, independent of subdivision, and balanced off $t_f(\partial_K X)$. For $M = A$ every occurring d-cell has positive weight.

For a smooth (d,d)-superform α on an open neighbourhood of the actual compact image, define

$$\mathcal{I}_{M,f}(\alpha) = \sum_{\sigma} m_\sigma \int_\sigma \alpha.$$

This is independent of subdivision and is nonnegative when the tangential top coefficients of α are nonnegative. It agrees with $I_{M,f}$ of Theorem 5.46.4 for tests supported in the whole interior weight domain.

Let $p : \mathcal{M}(B) \to \mathcal{M}(A)$ be finite, with both spaces pure of analytic dimension d, and suppose moment tuples satisfy $t_{f_A} \circ p = a \circ t_{f_B}$ for an integral map a. For every finite B-module M,

$$a_* \mathcal{T}_{f_B}(M) = \mathcal{T}_{f_A}(M), \qquad \mathcal{I}_{M,f_B}(a^*\alpha) = \mathcal{I}_{M,f_A}(\alpha).$$

On the right M is its finite A-module. In particular, adjoining analytic unit coordinates preserves these chains under projection and preserves the corresponding integrals.

Proof. Theorem 5.39.3 gives a finite polyhedral image of dimension at most d and a finite boundary image of dimension at most $d-1$. Choose one finite common subdivision with the boundary image as a subcomplex. At a point in the relative interior of a d-cell, the whole moment fibre is therefore interior, and the local image is contained in that cell's affine d-plane. Theorem 5.40.2 defines the nonnegative integer weight there. It is locally constant,

by Theorem 5.42.1 on small convex neighbourhoods with the actual local fan presentations of Theorem 5.38.6. The relative interior of the cell is convex, so the weight is constant there. For the structure module it is positive by Theorem 5.37.1.

On a common subdivision of two choices, the generic weights compute the same whole-fibre module invariant. Thus their chains agree. Additivity follows from the exact-sequence formula of Theorem 5.40.2. On the complement of the boundary image the chain is the local balanced module cycle of Theorem 5.45.3. All cells with nonzero weights are compact polytopes: the actual moment image is compact, and the complex is finite. Consequently the integral is a finite sum of the integrals constructed in Lemma 5.46.2. That lemma gives subdivision independence and positivity. Restriction to the whole interior weight domain gives exactly the previously defined local integral.

First suppose that the compatibility is an identity of analytic characters: each target unit pulls back to the monomial in the source units prescribed by a. For this finite morphism, take finite global subdivisions of the two actual images and their boundary images. Refine along the images of all source cells, using the finite linear elimination and hyperplane construction in Theorem 5.17.2. Outside a finite union of polyhedra of dimension at most $d-1$ in each target d-cell, the target whole fibre is interior, and every source weight above it lies in a full-rank d-cell. The entire inverse weight set is finite, with at most one point per such source cell. Finite relative interior and composition imply absolute interior for every point of those source fibres.

Near such a target weight, Lemma 5.45.1 retains the complete source inverse support in a finite pure presentation. Theorem 5.42.2 then identifies the finite lattice-index sum with the target weight of M as an A-module. Its empty-inverse- image case gives zero on both sides. Thus the generic weight of every target d-cell is exactly its pushforward weight. The resulting equality of finite chains is $a_*\mathcal{T}_{f_B}(M) = \mathcal{T}_{f_A}(M)$. This proves the chain formula under the character identity. In particular it applies to the identity morphism and adjoining any analytic unit coordinates.

Now suppose only the equality of moment maps in the statement. On the source use the joint tuple $(f_B, p^* f_A)$. Its actual image is the graph of a over $t_{f_B}(\mathcal{M}(B))$. Projection of that graph onto its first factor is an integral isomorphism: its inverse is $u \mapsto (u, a(u))$. On the saturated tangent lattices of every corresponding cell these two maps are inverse, so the index of this

projection is one. The augmentation case just proved identifies the graph chain with $\mathcal{T}_{f_B}(M)$ under this isomorphism. The second projection satisfies an actual character identity with the target tuple. Its pushforward is $\mathcal{T}_{f_A}(M)$ by the already proved case, and on the graph it is a after the first projection. The equality of the finite lattice-index sums therefore proves the chain formula under the stated moment-map equality as well.

The full actual source support is compact, so this pushforward is proper. On each full-rank source cell, Lemma 5.46.2 gives the factor $[N_\tau : a(N_\sigma)]$ in the integral. On a rank-dropping cell the top-degree pullback is zero. Grouping these finite cell integrals by their target cells proves the integral identity. No ambient support cutoff is needed here, because all the integration polytopes are compact. Taking p to be the identity and a a coordinate projection proves the last assertion. □

Theorem 5.49.2 (Faithfulness after adjoining analytic units)**.** *Let X be any generalized affinoid space, and let f, g be finite unit tuples. Write*

$$S = t_f(X), \qquad \widehat{S} = t_{(f,g)}(X), \qquad \pi : \widehat{S} \longrightarrow S.$$

Restrict a smooth ambient superform to every tangential face of these actual finite polyhedral sets. These restrictions are independent of subdivision. Such a form on S has all tangential restrictions zero if and only if its pullback has all tangential restrictions zero on $\widehat{S}$.

Tangential equality is preserved by restriction from an affinoid space to any affinoid domain, using the restricted unit coordinates.

Proof. Both actual images have finite polyhedral structures by Theorem 5.39.3, and π is surjective on their actual point sets. A finite subdivision does not change tangential vanishing: the relative interiors of the full-dimensional pieces in each original cell are dense there, and continuity of the coefficients extends vanishing from them to the cell and its faces. The converse follows by restricting an alternating covector to a smaller tangent space.

Refine the target by the images of all source cells and refine the source by the inverse images of the resulting faces. Finite inequality elimination and hyperplane subdivision, as in Theorem 5.17.2, make this a finite polyhedral refinement. Every source cell then maps into a target cell. If the form vanishes tangentially on the target, pullback through these tangent maps vanishes on the source.

For the converse, fix a target cell τ of dimension r. Its relative interior is covered by the images of the finitely many source cells mapping into it. Remove their image faces of dimension less than r. The remaining subset of relint(τ) is dense: in its affine span, a line direction outside finitely many proper linear subspaces meets the corresponding proper affine spans in at most finitely many points. Such a direction is obtained by the polynomial vectors $(1, b, \dots, b^{r-1})$ avoiding finitely many roots; for $r = 0$ no exclusion is needed. At a point v of this dense set some source cell σ has an image of dimension r containing v in its relative interior.

There is a preimage u of v in relint(σ). To verify this elementary convex assertion, choose u_0 in that relative interior. A small ball in its affine span lies in σ; its linear image contains a small ball in the image span, since a surjective map of finite-dimensional real vector spaces has a linear right inverse. Thus $\pi(u_0)$ is in the relative interior of the image. Since v is also there, for some $\varepsilon > 0$ the point $v' = v + \varepsilon(v - \pi(u_0))$ still belongs to that image. Choose $u' \in \sigma$ over v'. Then

$$u = \frac{u' + \varepsilon u_0}{1 + \varepsilon}$$

maps to v and is interior in σ, because the positive coefficient of u_0 brings a scaled open ball with it.

The tangent map from σ onto τ is surjective. Its pullback on each exterior cotangent factor is injective, by a linear right inverse. Vanishing of the joint pullback at u therefore forces the tangential value of the original form at v to be zero. Density and continuity prove vanishing throughout τ. This applies to every cell, including lower-dimensional maximal cells of the actual image, and proves the converse.

Finally the moment image of an affinoid domain is a finite polyhedral subset of the old image, again by Theorem 5.39.3. Refine both complexes by all their defining hyperplanes. Each new cell of the subset lies in a cell of the old complex, so its tangent space is a subspace of that cell's tangent space. Restriction preserves tangential vanishing and hence tangential equality. □

Definition 5.49.3 (Finite affinoid moment-chart data)**.** Let $X = \mathcal{M}(A)$ be pure of analytic dimension d. Finite moment-chart data of bidegree (p, q) consist of a finite affinoid-domain cover $X = \bigcup_{i=1}^{s} V_i$, a finite analytic unit tuple f_i on each V_i, and a smooth (p, q)-superform α_i on a neighbourhood of $t_{f_i}(V_i)$. On every intersection $V_i \cap V_j$, the two forms must have equal tangential pullbacks to the actual joint moment image for (f_i, f_j). A refinement

may restrict the domains, adjoin unit coordinates, and replace a superform by one with the same tangential pullback. Data are identified if they agree on a common finite affinoid refinement.

Theorem 5.49.4 (An integral independent of finite affinoid chart data)**.** *Fix a finite A-module M. For finite moment-chart data of bidegree (d,d) on X, put $V_I = \bigcap_{i\in I} V_i$, $A_I = \mathcal{O}(V_I)$ and $M_I = M \otimes_A A_I$. Choose any $i \in I$ to represent the restricted form on V_I, and set*

$$\mathcal{I}_M(\alpha) = \sum_{\varnothing\neq I\subseteq\{1,\dots,s\}} (-1)^{|I|+1}\mathcal{I}_{M_I,f_i|_{V_I}}(\alpha_i). \tag{5.49.1}$$

An empty intersection contributes zero. The expression is independent of each chosen i, of the finite cover, of the unit tuples and of the representatives within the equivalence of Definition 5.49.3. It is linear in the form and additive in short exact sequences of finite A-modules. It is nonnegative if all chart representatives have nonnegative tangential top coefficients. For a single global moment presentation it is exactly the global integral given by the finite-cell functional.

Proof. Finite intersections are actual affinoid domains by Corollary 2.36.10; their algebras and restriction maps are the actual domain ones. Every nonempty intersection is pure of analytic dimension d by Theorem 5.35.3. Thus all the displayed integrals exist by the finite-cell functional. Compatibility of the chart data restricts to further intersections by Theorem 5.49.2. On V_I, the same-affinoid coordinate augmentation identifies the integrals of any two chosen representatives with the integral of their equal joint pullbacks. This proves independence of the choice of i.

First suppose the data come from a single tuple on X. The domain-cover identity of Theorem 5.48.1 gives exactly (5.49.1). The same identity holds after restricting a single chart presentation to any of its affinoid subdomains.

Now compare compatible data on two finite covers $(V_i)_{i=1}^s$ and $(W_j)_{j=1}^t$. The module on every overlap is the restriction of the same M, by the actual domain tensor identifications of Proposition 1.18.7 and Theorem 2.36.9. For each nonempty I, cover V_I by the $V_I\cap W_j$ and apply the preceding single-chart identity to its chosen representative. Substitution in (5.49.1) gives

$$\sum_{I\neq\varnothing}\sum_{J\neq\varnothing}(-1)^{|I|+|J|}\mathcal{I}_{M|_{V_I\cap W_J}}(\alpha|_{V_I\cap W_J}).$$

The two representatives on each of these intersections have equal integrals by their joint-coordinate comparison. Interchange the two finite sums and apply the domain-cover identity to each W_J. This recovers precisely the expression for the second cover. Thus the value is unchanged under compatible replacement or refinement. For data identified after a common refinement, apply this comparison to each of the two original covers and that common refinement. This proves all claimed independences.

Linearity is termwise. For a short exact sequence of finite A-modules, domain flatness on a single actual domain keeps it exact on every V_I. The global module-chain additivity of the finite-module chain and weights gives additivity of each integral, and hence of the finite alternating sum. The assertion about a single global presentation was proved in the second paragraph.

To verify positivity, order the cover and group the alternating sum by the largest index j in I. The j-th group uses the single representative α_j and is the integral of the chain

$$C_j = \sum_{J \subseteq \{1,\dots,j-1\}} (-1)^{|J|} \mathcal{T}_{f_j|_{V_j \cap V_J}}(M|_{V_j \cap V_J}),$$

with the empty intersection in this formula understood to be V_j. Each C_j is nonnegative. Indeed, choose a common finite subdivision of these actual moment images and their boundary images by the common finite subdivision lemma. The latter have dimension at most $d-1$ by Theorem 5.39.3. At a generic point of a d-cell, apply Theorem 5.47.2 on V_j to the family consisting of V_j itself and the domains $V_j \cap V_i$ for $i < j$. It supplies idempotents e_i in the actual whole-fibre algebra; the member V_j ensures the cover hypothesis. For a transverse Gauss algebra E_Q and its common lattice divisor c_Q, the weight of C_j is

$$\frac{1}{c_Q} \dim_{H_Q} \left(\prod_{i<j} (1 - e_i) \right) \left(M|_{V_j} \otimes_{A_{V_j}} E_Q \right) \geq 0.$$

This is the elementary expansion of the product of the complementary idempotents, with all module structures retained. It is already an integer because it is the displayed alternating sum of integer module weights. Thus every generic coefficient of C_j is nonnegative. Its integral against α_j is nonnegative by the nonnegative cell integral on each cell. Summing these finitely many groups proves positivity. □

5.50 Integration on compact good analytic spaces

The complete field K and its real-valued non-Archimedean absolute value are fixed. Trivial valuation and arbitrary positive affinoid radii are allowed. Compact means quasi-compact and Hausdorff.

Lemma 5.50.1 (Affinoid intersections in a separated good space)**.** *Let X be a good Hausdorff K-analytic space. Any finite intersection of affinoid domains of X is an affinoid domain, with the empty space allowed. Two finite affinoid-domain covers therefore have a common finite affinoid refinement. If X is compact, it has a finite affinoid cover whose ordinary interiors cover X.*

Proof. Lemma 2.53.3, applied to $X \to \mathcal{M}(K)$, makes the analytic diagonal $\Delta : X \to X \times_K X$ a closed immersion. Let $U = \mathcal{M}(A)$ and $V = \mathcal{M}(B)$ be affinoid domains of X. Theorem 2.40.11 makes

$$U \times_K V = \mathcal{M}(A \widehat{\otimes}_K B)$$

an actual affinoid domain of $X \times_K X$. The pullback of Δ to this domain is an affinoid closed subspace. Indeed, the coherent defining ideal restricts to a finite ideal by Theorem 2.39.6, and its quotient is the actual affinoid quotient of Corollary 1.18.4. The arbitrary-domain restriction argument in Lemma 2.53.2 identifies this quotient with the entire diagonal pullback, including its analytic structure.

This pullback is $U \times_X V$. By the domain universal property of Theorem 2.40.8, a map to it is exactly a map to X whose image lies in both U and V. Thus it is the actual analytic domain $U \cap V$. There is no identification of an analytic product with an ordinary product of point sets in this argument. Iteration proves the finite-intersection assertion, using domain transitivity in Proposition 2.40.5. The pairwise intersections of two finite covers form the claimed common refinement. Affinoid domains are compact by Proposition 2.24.1, and hence closed in the Hausdorff space X. Lemma 2.39.2 makes every finite cover by such domains admissible. Finally, goodness supplies an affinoid neighbourhood of each point. Compactness gives a finite subcover of their ordinary interiors. □

Definition 5.50.2 (Pure dimension on a good space)**.** A good analytic space is pure of analytic dimension d if every point has an ordinary affinoid neighbourhood pure of analytic dimension d in the sense of Section 5.35.

Lemma 5.50.3 (Purity is local on affinoid covers)**.** *Let $V_1, \dots, V_s$ be a finite affinoid-domain cover of a nonempty affinoid X. Then X is pure of analytic dimension d if and only if every nonempty V_i is so. Consequently every nonempty affinoid domain of a good Hausdorff space pure of analytic dimension d is pure of analytic dimension d.*

Proof. The forward implication is Theorem 5.35.3. For the converse write $X = \mathcal{M}(A)$ and $V_i = \mathcal{M}(C_i)$, omitting empty members. Fix a minimal prime $\mathfrak{p}$ of A. The actual quotient $A/\mathfrak{p}$ is affinoid by Corollary 1.18.4, and its spectrum is nonempty by Theorem 1.20.1. Theorem 2.36.9 gives an affinoid-domain cover of this spectrum with algebras

$$D_i = C_i \widehat{\otimes}_A (A/\mathfrak{p}) = C_i/\mathfrak{p}C_i.$$

The equality with the ordinary quotient follows from Proposition 1.18.7, applied to the finite canonical A-module $A/\mathfrak{p}$.

Every nonzero D_i is pure of analytic dimension d. To see this, let $\mathfrak{q}$ be a prime of C_i minimal over $\mathfrak{p}C_i$. The domain map $A/\mathfrak{p} \to D_i$ is flat by Proposition 2.38.2. Flat going down, [StacksAlg, Tag 00HS], shows that the minimal prime $\mathfrak{q}/\mathfrak{p}C_i$ contracts to the zero prime of the domain $A/\mathfrak{p}$: otherwise going down to zero would give a strictly smaller prime. Hence $\mathfrak{q} \cap A = \mathfrak{p}$. Choose a minimal prime $\mathfrak{q}_0 \subseteq \mathfrak{q}$ of C_i by [StacksAlg, Tag 00E0(4)]. Its contraction is a prime contained in the minimal prime $\mathfrak{p}$, and so equals $\mathfrak{p}$. Thus $\mathfrak{p}C_i \subseteq \mathfrak{q}_0$. Minimality over $\mathfrak{p}C_i$ gives $\mathfrak{q}_0 = \mathfrak{q}$. The minimal-prime quotient of D_i in question is therefore the minimal-prime quotient $C_i/\mathfrak{q}$, whose analytic dimension is d by the hypothesis on C_i.

A nonempty affinoid whose minimal-prime quotients all have dimension d itself has dimension d. Indeed, each point kernel contains a minimal prime by [StacksAlg, Tag 00E0(4)]. Passage to that quotient does not change its evaluated fraction field or its completed residue field. The maximum formula of Theorem 3.22.7 consequently identifies the dimension with the maximum of those component dimensions. Applying the domain-cover formula 3.22.8 to the displayed cover now gives

$$\dim_K \mathcal{M}(A/\mathfrak{p}) = d.$$

This holds for every minimal prime of A, proving purity. All dimensions here are analytic; no generalized Krull dimension comparison is used.

For the last assertion let V be a nonempty affinoid domain of the good Hausdorff space. Its compact underlying space is covered by finitely many pure affinoid neighbourhoods W_j of points of X. By Lemma 5.50.1, the sets $V \cap W_j$ are affinoid domains of W_j. Their nonempty members are pure of dimension d by Theorem 5.35.3. They cover V, so the implication just proved applies to V. □

Lemma 5.50.4 (Finite module data on an analytic cover)**.** *Let (V_i) be a finite affinoid-domain cover of a good Hausdorff analytic space X. Put $A_i = \mathcal{O}(V_i)$ and $A_{ij} = \mathcal{O}(V_i \cap V_j)$. Finite A_i-modules M_i, with isomorphisms*

$$A_{ij} \otimes_{A_i} M_i \simeq A_{ij} \otimes_{A_j} M_j$$

satisfying the identity and cocycle conditions, determine a coherent $\mathcal{O}_{X_G}$-module $\mathcal{F}$, uniquely up to the isomorphism inducing the given identifications. Conversely every coherent module gives such data. The construction is compatible with morphisms, finite affinoid refinements and short exact sequences. For every affinoid domain $W \subseteq V_i$,

$$\Gamma(W, \mathcal{F}) = \mathcal{O}(W) \otimes_{A_i} M_i$$

with its canonical finite-module norm.

Proof. All finite intersections are affinoid by Lemma 5.50.1. Theorem 2.39.6 associates to M_i a coherent sheaf $\widetilde{M_i}$ on $(V_i)_G$ and identifies its restrictions with the displayed finite tensors. It turns the given module isomorphisms into sheaf isomorphisms on the intersections, with the same cocycle condition.

For any analytic domain $T \subseteq X$, define $\mathcal{F}(T)$ to be the families of sections of $\widetilde{M_i}$ on $T \cap V_i$ whose restrictions agree under these isomorphisms. The domain and covering calculus of Proposition 2.40.5 shows that an admissible cover of T restricts to one of each $T \cap V_i$. Existence and uniqueness of glued sections for the sheaves $\widetilde{M_i}$ therefore prove the sheaf axiom for these families. On a domain contained in V_i, its i-th section determines all the others by restriction and the transition isomorphisms. The cocycle condition makes them compatible. Thus $\mathcal{F}|_{(V_i)_G}$ is $\widetilde{M_i}$; in particular it is coherent. Indeed, finite generation and finite generation of the kernels of maps from finite free sheaves are both checked on this admissible cover, where $\widetilde{M_i}$ is coherent. The same description proves uniqueness and glues compatible module morphisms.

Conversely, sections of a coherent sheaf on each V_i are finite modules by Theorem 2.39.6. That theorem gives both their restriction isomorphisms and the displayed formula on W. Theorem 1.18.3 gives the canonical norms and boundedness of all these module maps, while Proposition 1.18.7 identifies the finite ordinary and completed tensors. The two constructions are inverse on every chart and hence inverse globally by the sheaf axiom. Refinements simply restrict these same sheaves. Finally exactness is local on the cover, and the affinoid equivalence in Theorem 2.39.6 is exact. This proves the assertion for short exact sequences. □

Definition 5.50.5 (Moment-chart data on a compact good space)**.** Let X be compact, good and pure of analytic dimension d. Finite moment-chart data of bidegree (p,q) consist of a finite affinoid-domain cover (V_i), a finite tuple of analytic units f_i on each V_i, and a smooth real (p,q)-superform α_i on a neighbourhood of $t_{f_i}(V_i)$. On each intersection the two forms have equal tangential pullbacks to the actual joint moment image. Data are identified when they agree on a common finite affinoid refinement, allowing adjoining unit coordinates and equality of tangential pullbacks. These are the conventions of Definition 5.49.3, with X no longer required to be affinoid. The same definition is used on a compact analytic domain Q that is a finite union of affinoid domains in an ambient good Hausdorff space pure of dimension d. Its presenting domains are affinoid domains of Q; Q itself may fail to be good.

Theorem 5.50.6 (The integral on a compact good analytic space)**.** *Let X be a compact good K-analytic space pure of analytic dimension d, let $\mathcal{F}$ be a coherent $\mathcal{O}_{X_G}$-module, and let α be finite moment-chart data of bidegree (d,d). For a presenting cover $(V_i)_{i=1}^{s}$ put*

$$V_I = \bigcap_{i\in I} V_i, \qquad M_I = \Gamma(V_I, \mathcal{F}).$$

For nonempty I, choose any $i \in I$. Then

$$\mathcal{I}_{X,\mathcal{F}}(\alpha) = \sum_{\varnothing \neq I \subseteq \{1,\dots,s\}} (-1)^{|I|+1} \mathcal{I}_{M_I, f_i|_{V_I}}(\alpha_i) \tag{5.50.1}$$

is independent of these choices and of the representative of the finite chart data. Empty intersections contribute zero. The integral is linear in α, additive in short exact sequences of coherent modules, and nonnegative if the chart

representatives have nonnegative tangential top coefficients. It may equivalently be constructed from compatible finite module data as in Lemma 5.50.4. For affinoid X it agrees with Theorem 5.49.4.

More generally, let Y be good, Hausdorff and pure of analytic dimension d, and let $Q \subseteq Y$ be the union of finitely many affinoid domains of Y. The same construction and all these conclusions hold for coherent modules and finite moment-chart data on the compact analytic domain Q, including when Q is not good.

Proof. The intersections V_I are actual affinoid domains by Lemma 5.50.1, and their nonempty members are pure of dimension d by Lemma 5.50.3. Lemma 5.50.4 makes M_I a finite module, identified with the restriction of any M_i for $i \in I$. Thus every nonzero term is given by the finite-cell functional on the actual affinoid. Compatibility of the chart forms restricts to every further domain by Theorem 5.49.2. On V_I, adjoining two chosen tuples identifies their integrals with the integrals of their joint pullbacks, by the same-affinoid coordinate augmentation. The pullbacks have the same tangential top coefficients. Their cell integrals agree, proving independence of i.

Consider two compatible presentations on finite covers (V_i) and (W_j). On each V_I the domains $V_I \cap W_j$ form a finite affinoid cover. Apply Theorem 5.48.1 to the chosen single-chart representative on V_I and the module $\Gamma(V_I, \mathcal{F})$. Inserting its formula in (5.50.1) gives the finite double sum

$$\sum_{I \neq \varnothing} \sum_{J \neq \varnothing} (-1)^{|I|+|J|} \mathcal{I}_{\mathcal{F}|_{V_I \cap W_J}}(\alpha|_{V_I \cap W_J}).$$

The modules are the same restrictions of $\mathcal{F}$, and the two local form representatives have equal integrals by the joint-coordinate argument just given. Interchange the finite sums and apply the cover formula on each W_J. This recovers the expression for the second presentation. If two data sets agree only after a common refinement, compare each with that refinement. Lemma 5.50.1 provides the needed finite intersections. Restriction preserves tangential equality by Theorem 5.49.2, and the same-affinoid coordinate augmentation preserves the integral. This proves all the asserted independences.

Linearity follows after passing to a common cover and adjoining the two tuples on each member, where addition is ordinary addition of their pulled-back superforms. For a short exact sequence of coherent modules, the affinoid

exact equivalence 2.39.6 makes its section sequence on every V_I exact. Additivity of the affinoid global chains in the finite-module chain and weights therefore proves additivity of the displayed finite sum.

For positivity, order the cover and use the largest index j of I as the representative in each term. The j-th group is the integral against α_j of the finite d-chain

$$C_j = \sum_{J \subseteq \{1,\dots,j-1\}} (-1)^{|J|} \mathcal{T}_{f_j|_{V_j \cap V_J}} \big(\Gamma(V_j \cap V_J, \mathcal{F})\big),$$

where $V_j \cap V_\varnothing$ means V_j. All moment tuples in this formula are restrictions of the single tuple f_j on the affinoid V_j. By Theorem 5.39.3 and the common finite subdivision lemma, choose a finite common subdivision of these actual images and their boundary images. The boundary images have dimension at most $d-1$, and are empty for $d = 0$.

At the relative interior of any d-cell, its whole fibre in V_j and all its parts in $V_j \cap V_i$ are interior. Near that point the actual image lies in the cell's saturated d-plane. Apply Theorem 5.47.2 on V_j to the family consisting of V_j itself and the $V_j \cap V_i$, $i < j$. The member V_j ensures the cover hypothesis. Write D for its whole-fibre algebra, $e_i \in D$ for the overlap idempotents, E_Q for a transverse Gauss algebra, and c_Q for the common positive lattice index. The coefficient of C_j on this cell is

$$\frac{1}{c_Q} \dim_{H_Q} \left(\prod_{i<j} (1 - e_i) \right) \big(M_j \otimes_{\mathcal{O}(V_j)} E_Q \big) \geq 0.$$

Indeed, expansion of the product gives exactly the alternating sum of the idempotent-restricted module dimensions in C_j. This retains all nilpotent lengths. The coefficient is already an integer, being an alternating sum of the integer module weights. Thus C_j is nonnegative on every d-cell. If its images have dimension less than d, the chain is zero and the assertion is immediate. The nonnegative cell integral on each cell makes its integral against α_j nonnegative. Summing over j proves positivity.

The coherent-module formulation and compatible-module formulation coincide by Lemma 5.50.4. When X itself is affinoid, its defining expression is the one in Theorem 5.49.4, so the affinoid comparison follows.

Finally consider Q in the second assertion. Each of its finitely many affinoid pieces is compact and closed in the Hausdorff space Y. Their finite cover

is a quasi-net by Lemma 2.39.2, so the analytic-domain definition 2.40.4 gives Q its actual analytic-domain structure. It is compact. By the transitivity in Proposition 2.40.5, every affinoid domain of Q is also an affinoid domain of Y. Its finite intersections are therefore affinoid by Lemma 5.50.1 applied to Y, and every nonempty one is pure of dimension d by Lemma 5.50.3 applied to Y.

A coherent sheaf on Q_G restricts to finite modules on these affinoids by Theorem 2.39.6. Conversely, compatible finite modules glue on Q_G by the same section-family construction as in Lemma 5.50.4: for each analytic $T \subseteq Q$, take compatible sections on $T \cap V_i$. The finite cover is admissible, so the sheaf axiom and coherence of its chart restrictions give the coherent glued sheaf, with the stated affinoid restriction tensors. Thus all modules, intersections and finite cover comparisons in the preceding proof are available on Q. Each invocation of the affinoid cover formula occurs on a single affinoid intersection, and the complementary-idempotent positivity calculation occurs on a single affinoid V_j. Neither uses goodness of Q. Those arguments prove precisely the same independence, exact-sequence additivity and positivity on Q, as claimed. □

5.51 Finite pushforward for compact chart integrals

Theorem 5.51.1 (Finite pushforward on compact analytic domains)**.** *Let $p : Y \to X$ be a norm-admissible finite morphism of good Hausdorff analytic spaces pure of the same analytic dimension d, over a complete field with its specified real-valued absolute value. Let $Q \subseteq X$ be a finite union of affinoid domains, and put $R = p^{-1}(Q)$. Let $\mathcal{F}$ be coherent on Y_G. Then R is a finite union of affinoid domains of Y, and both Q and R are compact analytic domains. Neither is required to be good.*

Pulling back the unit tuples defines a pullback of finite moment-chart data on Q to such data on R. For every top-degree datum α,

$$\mathcal{I}_{R,\mathcal{F}|_R}(p^*\alpha) = \mathcal{I}_{Q,(p_*\mathcal{F})|_Q}(\alpha). \tag{5.51.1}$$

Successive applications agree for composable finite morphisms between spaces of the same pure analytic dimension. If $(p_*\mathcal{F})|_Q$ is locally free of constant rank ρ, then

$$\mathcal{I}_{R,\mathcal{F}|_R}(p^*\alpha) = \rho\,\mathcal{I}_{Q,\mathcal{O}_Q}(\alpha).$$

All conclusions allow trivial valuation, arbitrary positive affinoid radii, and nonreduced spaces and modules.

Proof. Choose a finite affinoid-domain cover (V_i) of Q. Each V_i is an affinoid domain of X by the domain transitivity of Proposition 2.40.5. Finiteness of p makes $W_i = p^{-1}(V_i)$ an actual affinoid domain of Y, whose algebra is a finite canonical module over $\mathcal{O}(V_i)$. These domains cover R. The finite-union assertion of Theorem 5.50.6 therefore gives the indicated compact analytic-domain structures. By Lemma 5.50.1, every finite intersection V_I is affinoid, and

$$W_I = \bigcap_{i \in I} W_i = p^{-1}(V_I)$$

is its full finite affinoid inverse image. Every nonempty such domain is pure of dimension d by Lemma 5.50.3.

Suppose that (f_i, α_i) presents the given chart data on the V_i. Its proposed pullback has tuple $p^* f_i$ and the same ambient superform α_i on W_i. Units remain units. On $W_i \cap W_j$ the actual joint moment image is contained in the joint moment image on $V_i \cap V_j$. Both are finite polyhedral sets by Theorem 5.39.3. Refine their complexes by their finitely many defining hyperplanes, using Lemma 5.14.2. Each cell of the source image lies in a cell of the target image, and its tangent space is a subspace of that cell's tangent space. Tangential equality on the target consequently restricts to tangential equality on the source. This proves compatibility of the pulled-back data in every bidegree. The same argument applies to a common refinement of two representatives. Inverse images of its domains are actual finite affinoid domains, and pullback commutes with adjoining units. Thus the pullback depends only on the equivalence class of the data.

Proposition 2.35.15 makes $p_* \mathcal{F}$ coherent and identifies, for each nonempty I,

$$\Gamma(V_I, p_* \mathcal{F}) = \Gamma(W_I, \mathcal{F}).$$

Write $A_I = \mathcal{O}(V_I)$, $B_I = \mathcal{O}(W_I)$ and $M_I = \Gamma(W_I, \mathcal{F})$. The module M_I is finite over B_I by Theorem 2.39.6, and finite over A_I because B_I is finite over A_I. The cited direct-image theorem gives precisely this restriction of scalars, with its compatible canonical norms and domain restrictions.

Assume first that W_I is nonempty and put $f = f_i|_{V_I}$. The two tuples are f and its literal pullback $p^* f$ on the full inverse domain. The character identity therefore holds with the identity map on the moment lattice.

By Theorem 5.39.3, both actual moment images are finite polyhedral sets. The absolute boundary image of V_I has dimension at most $d-1$ and is empty if $d=0$. Use Lemma 5.14.2 to subdivide the two images and that boundary image together. At a relative-interior point w of a target d-cell, choose a small convex open neighbourhood in moment space disjoint from the boundary image and the other cells. The target image is presented there by the given cell. If the source image contains w, it contains that cell and has the same local presentation. The whole target fibre is absolutely interior there. Finiteness gives relative interior everywhere on the actual source affinoid by Theorem 2.33.18, so Proposition 2.33.21 gives absolute interior of the whole source fibre there. With these pure local presentations, Theorem 5.42.2 compares the same finite module M_I over B_I and A_I. The index on the common saturated tangent lattice is one.

If the source image misses w, its compactness lets us avoid it on a neighbourhood of w. For the entire target simultaneous level algebra D_w, the inverse level algebra $B_I \otimes_{A_I} D_w$ is the actual finite pullback by Theorems 2.33.19 and 2.36.9. It is zero by Theorem 1.20.1, since its spectrum is empty. Thus $M_I \otimes_{A_I} D_w = 0$, and further tensoring with the transverse Gauss field gives zero. The target module weight is zero by Theorem 5.40.2, in agreement with the empty source coefficient.

These generic coefficients determine the closed finite-module chains on the common subdivision. Pairing the same ambient form with these equal chains by the finite-cell integral gives

$$\mathcal{I}_{M_I,p^*f_i|_{W_I}}(\alpha_i) = \mathcal{I}_{M_I,f_i|_{V_I}}(\alpha_i),$$

where the right side regards M_I as an A_I-module. An empty inverse image has zero module on both sides. Multiply by $(-1)^{|I|+1}$ and sum over the nonempty index sets. The two finite sums are exactly the compact chart integrals in Theorem 5.50.6, including its non-good-domain variant. This proves (5.51.1).

For a further finite map $q : Z \to Y$, the inverse image of every W_i is again the full finite affinoid inverse image. Apply the same equality first to q and then to p. Pullback of unit functions is associative, and

$$p_*(q_*\mathcal{G}) = (p \circ q)_*\mathcal{G}$$

on sections of every analytic domain, since both sides take sections on its full inverse image. These identities prove the stated compatibility for successive applications.

Finally suppose the indicated direct image is locally free of constant rank ρ on Q_G. Refine its local trivializing cover by affinoid domains and intersect them with the presenting chart domains. The quasi-net and compactness assertions of Lemma 2.39.2 give a finite such refinement. The compact integral is unchanged by this refinement. On every new V_I its finite module N_I is free of rank ρ. At each minimal prime $\mathfrak{p}$ of A_I, $\operatorname{length}((N_I)_{\mathfrak{p}}) = \rho \operatorname{length}((A_I)_{\mathfrak{p}})$. The exact module-weight formula of Theorem 5.40.2 therefore multiplies every top-dimensional global-chain coefficient by ρ. Lower-dimensional cells give no top-dimensional term. Applying the finite-cell integral to the scaled finite-module chain gives

$$\mathcal{I}_{N_I,f_i}(\alpha_i) = \rho\, \mathcal{I}_{A_I,f_i}(\alpha_i).$$

The same finite cover sum proves the last formula. In particular the argument preserves all generic Artinian lengths before multiplying by ρ. □

5.52 Smooth moment germs and compactly supported integration

The complete field and its specified absolute value remain fixed. We use the real superform conventions of Definition 5.46.1.

Lemma 5.52.1 (Tangential equality on a finite affinoid cover)**.** *Let V be a generalized affinoid space, let f be a finite tuple of analytic units, and let $V = \bigcup_{i=1}^{s} V_i$ be a finite affinoid-domain cover. A smooth ambient superform η near $t_f(V)$ has zero tangential restriction on every face of $t_f(V)$ if and only if the same holds on each $t_f(V_i)$.*

Tangential equality on a finite polyhedral set is preserved by d', d'', J, and multiplication by another superform. These assertions hold in every bidegree and in every dimension.

Proof. All the actual images are finite polyhedral by Theorem 5.39.3, and $t_f(V) = \bigcup_i t_f(V_i)$ as point sets. Cut their complexes by the finitely many supporting hyperplanes of all their cells, as in Lemma 5.14.2. This makes every subimage a subcomplex of the resulting complex on the union. Each cell of that union is contained in one subimage: a point of its relative interior belongs to a cell of one subcomplex, and the common face property then puts the entire cell in that subcomplex. Thus vanishing on the subimages

implies vanishing on every cell of the common refinement. Independence of subdivision, proved in Theorem 5.49.2, gives vanishing on the original image. The converse is restriction to a polyhedral subset, as in that theorem.

Fix a cell and choose affine coordinates on its span. Restriction of both cotangent factors commutes with differentiation along that span. If a tangential coefficient vanishes on the relative interior, all its derivatives in tangent directions vanish there. Their continuity extends the assertion to its faces. This proves the claims for d' and d''. The operations J and wedge product commute directly with restriction of alternating covectors. Applying these observations to the difference of two forms proves preservation of tangential equality. □

Definition 5.52.2 (Ordinary smooth moment germs)**.** Let X be a good Hausdorff analytic space and let $x \in X$. A smooth moment representative of bidegree (p, q) at x is a triple (V, f, α), where V is an ordinary affinoid neighbourhood of x, f is a finite tuple of analytic units on V, and α is a smooth real (p, q)-superform on an open neighbourhood of $t_f(V)$. Two representatives are equivalent if, on some ordinary affinoid neighbourhood $W \subseteq V \cap V'$ of x, their pullbacks to the actual joint image for (f, f') have equal tangential restrictions on every face.

For an ordinary open set $U \subseteq X$, write $\mathcal{A}_X^{p,q}(U)$ for the families of such germs at the points of U which are locally represented by one smooth moment representative. Here locally means on the ordinary interior of an affinoid neighbourhood contained in U. The support of a section is the complement of the open set on which all its germs are zero. A top-degree section on a pure-dimensional space is positive if locally it has representatives with nonnegative tangential top coefficients.

On a finite union of affinoid domains, finite moment-chart data mean a finite affinoid cover with unit tuples and smooth ambient superforms whose joint tangential pullbacks agree on every overlap, identified under common finite refinement. This uses the same presentation convention as Definition 5.49.3 in arbitrary dimension; purity is imposed when integrating top-degree forms.

Theorem 5.52.3 (The sheaf of ordinary smooth moment forms)**.** *The relation in Definition 5.52.2 is an equivalence relation. The spaces $\mathcal{A}_X^{p,q}$ form sheaves on the ordinary topology, with well-defined wedge product, J, d' and d''. These operations satisfy the usual exterior-algebra rules,*

$$(d')^2 = (d'')^2 = 0, \qquad d'd'' + d''d' = 0.$$

Every analytic morphism between good Hausdorff spaces over the specified field induces a functorial pullback on these sheaves, commuting with all these operations.

For any affinoid domain $V \subseteq U$, a section on U determines finite moment-chart data on V, canonically up to common refinement and tangential equality. This assignment commutes with further affinoid restriction and all the displayed operations. If the section has zero germ at every point of V, the induced finite chart data are zero. The same assertions hold on a finite union of affinoid domains contained in U.

Proof. We first record the neighbourhood choices used below. In an affinoid spectrum its evaluation topology has a basis of finitely many strict bounds on absolute values. At a point satisfying such bounds, replace each upper bound by a slightly smaller positive real bound still strict at the point, and each positive lower bound by a slightly larger one still strict there. Their weak inequalities define an actual affinoid domain by Theorem 2.31.2 and Corollary 2.36.10. It contains an ordinary neighbourhood of the point and is contained in the prescribed open set. Goodness and domain transitivity 2.40.5 therefore give a basis of ordinary affinoid neighbourhoods in X. Intersections of two such neighbourhoods are affinoid by Lemma 5.50.1 and remain ordinary neighbourhoods of the common point. No choice of a ground-field element with a prescribed real absolute value is needed for these inequalities.

Reflexivity and symmetry of the relation are immediate. For transitivity, restrict three representatives to a common smaller ordinary affinoid neighbourhood and adjoin all three tuples. The two given equalities pull back to that joint image and imply equality of the first and third forms there. Faithfulness under adding coordinates, Theorem 5.49.2, descends this equality to their two-tuple joint image. This proves transitivity. The same argument shows that one may shrink a representative or add unit coordinates without changing its germ.

Sums and wedge products are computed on a common smaller neighbourhood with the joint tuple. The preceding faithfulness and transitivity make

the result independent of the representatives. Apply J, d' and d'' to the ambient forms. Lemma 5.52.1 shows that these operations preserve all the germ relations, so they descend. Their algebraic identities can be checked on the coefficients and constant one-form generators of a representative. Equality of mixed partial derivatives follows from the real calculus proved in Lemma 5.46.2: the two iterated fundamental-theorem expressions for a rectangular second difference are equal; dividing by the two side lengths and letting them tend to zero identifies the continuous mixed derivatives. With the anticommuting one-form generators, the stated differential identities and the graded product rules follow.

The sheaf axiom is pointwise. Families agreeing on overlaps give one family of germs, and its local representatives are the given local representatives. This proves both existence and uniqueness of gluing. All the operations commute with restriction, as their representative constructions do.

Let $h : Y \to X$ be such a morphism and let $y \in Y$. Choose a representative (V, f, α) at $h(y)$ and an ordinary affinoid neighbourhood W of y mapping into V. Continuity of h and the affinoid basis give W. The analytic-domain universal property 2.40.8 makes the restriction an actual morphism $W \to V$. Use (W, h^*f, α) as the pulled-back representative. Its actual moment image is contained in $t_f(V)$. Both sets are finite polyhedral by Theorem 5.39.3. Tangential vanishing restricts to any finite polyhedral subset: a common subdivision puts each of its cells inside a cell of the larger set, where restriction of alternating covectors preserves zero. Thus an equality on a smaller target germ gives an equality on a smaller source germ. This proves well-defined pullback. Composition is checked on the pulled-back unit functions, and the ambient form is unchanged in these coordinates. Pullback consequently commutes with the displayed operations and is functorial.

Now let $V \subseteq U$ be affinoid and let α be a section on U. At every point of V choose a representing neighbourhood W and then an affinoid neighbourhood W' contained in the ordinary interior of W. The preceding basis construction permits this choice. Finitely many of the ordinary interiors of these W' cover the compact set V, by Proposition 2.24.1. The intersections $V \cap W'$ are affinoid domains by Lemma 5.50.1. Restrict the chosen tuples and ambient forms to them.

These representatives agree on every entire overlap. Indeed, each point of an overlap lies in the ordinary interiors of the two original representing neighbourhoods W, so equality of its germs supplies a smaller ordinary affi-

noid neighbourhood on which the joint forms agree. Finitely many such neighbourhoods cover the compact overlap by their interiors. Intersect them with the overlap and apply Lemma 5.52.1 to the fixed joint tuple there. It upgrades the local equalities to tangential equality on the whole joint image of the overlap. Thus the restricted representatives are finite moment-chart data on V.

The same argument applied to two choices shows that they agree on the finite common refinement by all pairwise intersections. It proves independence and compatibility with further restriction. The operations are computed on these same refinements, so commute with the assignment. If every germ on V is zero, apply the overlap argument to each presenting chart and the zero representative. A finite cover suffices by compactness, and Lemma 5.52.1 makes each entire chart representative tangentially zero.

For a finite union of affinoid domains, perform the construction on its finitely many members. The same compact-overlap argument proves compatibility and independence on their union. This also proves the zero-germ assertion there. Its analytic-domain structure is supplied by the finite closed-cover quasi-net in Lemma 2.39.2 and the analytic-domain definition 2.40.4. □

Theorem 5.52.4 (Integration of compactly supported smooth moment forms)**.** *Let X be good, Hausdorff and pure of analytic dimension d, and let $\mathcal{F}$ be a coherent $\mathcal{O}_{X_G}$-module. There is a canonical linear functional*

$$\int_{X,\mathcal{F}} : \mathcal{A}^{d,d}_{X,c}(X) \longrightarrow \mathbb{R}$$

on sections of compact support. It is nonnegative on positive sections and additive in short exact sequences of coherent modules.

Choose finitely many affinoid domains whose ordinary interiors cover the support, and let Q be their union. The functional is the finite-chart integral of the induced data on Q and $\mathcal{F}|_{Q_G}$ from Theorem 5.50.6. It is independent of this compact neighbourhood and of all the presenting charts. It agrees with the earlier affinoid and compact-space integrals whenever those are applied to the induced data.

Proof. Put $S = \operatorname{supp}(\alpha)$. The zero section has integral zero, so first suppose S is nonempty. The affinoid-neighbourhood basis in the proof of Theorem 5.52.3 and compactness of S give the required finite family. Its union Q is a compact analytic domain by the finite-union assertion in Theorem 5.50.6.

Its ordinary interior in X contains S. Theorem 5.52.3 supplies canonical finite chart data on Q. The restriction of a coherent sheaf is coherent, as is seen from its finite-module presentations on affinoid domains and Theorem 2.39.6. The compact-domain assertion of Theorem 5.50.6 therefore defines a real number, even when Q is not good.

We prove independence of Q. Let Q_1, Q_2 be two choices and put

$$O = \mathrm{Int}_{\mathrm{top}}(Q_1, X) \cap \mathrm{Int}_{\mathrm{top}}(Q_2, X), \qquad Z = X \setminus S.$$

Both sets are open, $S \subseteq O$, and $O \cup Z = X$. Cover the compact set $Q_1 \cup Q_2$ by the ordinary interiors of finitely many affinoid domains W_l, each contained either in O or in Z. Goodness and the affinoid basis justify this choice. Mark as central the members contained in O, and mark the remaining members as zero members. Every central member belongs to both Q_1 and Q_2.

Fix finite affinoid presentations $(V_i^{(a)})$ of Q_a, for $a = 1, 2$. A finite affinoid cover of Q_a is given by all the central W_l, together with the domains $V_i^{(a)} \cap W_l$ for the zero members. These are actual affinoid intersections by Lemma 5.50.1 applied in X, and they cover Q_a since the W_l cover $Q_1 \cup Q_2$. The section has zero germ at every point of a zero member. The zero-germ assertion of Theorem 5.52.3 makes its induced finite chart data zero on each zero piece and on every further intersection involving such a piece.

Use these covers to compute the two integrals by the finite inclusion-exclusion formula of Theorem 5.50.6. If a covering member needs several charts, first replace it by its finite presenting chart cover; the independence statement of that theorem allows this refinement. Every term involving a zero piece is zero. The surviving terms involve only the same central members, with the same restricted coherent module and the same section. Choose their finite presenting charts once for both covers. The two finite sums are then identical. This proves independence of the compact neighbourhood. The same argument with no central members proves zero when the support is empty.

Independence of the representatives on a fixed Q is Theorem 5.50.6. For two compactly supported sections, choose one finite affinoid neighbourhood of the union of their supports. Its finite-chart integral is linear, which proves linearity of the functional. If α is positive, compactness permits the finite presenting charts on Q to be chosen from positive local representatives and zero representatives outside its support. Positivity of that same theorem gives the claimed inequality. On every affinoid intersection an exact sequence of

coherent modules has an exact sequence of finite section modules by Theorem 2.39.6. Additivity of the compact-domain integral therefore proves the asserted coherent-module additivity.

The comparisons with the earlier integrals follow by using the same finite affinoid cover and the same inclusion-exclusion expression. In the compact case one may compare any support neighbourhood with X itself by the same central-and-zero cover argument. □

5.53 Smooth cutoffs on good analytic spaces

Lemma 5.53.1 (Compact smooth cutoffs)**.** *Let X be a good Hausdorff analytic space over the specified complete field. The sheaf $\mathcal{A}_X^{0,0}$ identifies with a subsheaf of continuous real-valued functions. For every point x and ordinary open neighbourhood $O \subseteq X$, there is a section $\chi \in \mathcal{A}_X^{0,0}(X)$ such that*

$$0 \le \chi \le 1, \qquad \chi = 1 \text{ on an ordinary neighbourhood of } x,$$
$$\operatorname{supp}(\chi) \text{ is compact in } O.$$

The assertion allows a trivially valued ground field.

Proof. A degree-zero representative evaluates to the continuous function $\alpha \circ t_f$. Two representatives have equal functions near a point exactly when their joint degree-zero form vanishes at every point of the actual joint image on a smaller ordinary neighbourhood. This is precisely the germ relation of Definition 5.52.2. Thus evaluation is injective on germs and identifies the indicated sheaf with a subsheaf of continuous functions. It is closed under composition with a smooth real function: in a representative, compose that function with the smooth ambient coefficient.

We use a smooth real profile ρ with values in $[0,1]$, equal to zero on $(-\infty, 0]$ and to one on $[1,\infty)$. Here is an elementary construction. The power series $e^u = \sum_{n\ge 0} u^n/n!$ and all its termwise derivatives converge uniformly on each bounded interval: after any fixed number of derivatives, their tails are bounded by a constant times a geometric series, once the index exceeds twice the interval bound. Applying the fundamental theorem from Lemma 5.46.2 to the partial sums proves termwise differentiation. The derivative of $e^u e^{-u}$ is zero, so this product equals its value 1 at zero. Hence $e^{-u} = 1/e^u$; positivity follows for $u \ge 0$ from the series and for $u < 0$ from this reciprocal identity. For $t > 0$ put $E(t) = e^{-1/t}$, and put $E(t) = 0$ for $t \le 0$. Each right derivative

is a polynomial in $1/t$ times $e^{-1/t}$. Every such expression tends to zero at zero, since $e^u \geq u^{m+1}/(m+1)!$ for $u > 0$. Induction with difference quotients therefore proves that E is smooth with every derivative zero at zero. The function

$$\rho(t) = \frac{E(t)}{E(t) + E(1-t)}$$

has the required properties; its denominator is positive.

Choose an ordinary affinoid neighbourhood $W = \mathcal{M}(A)$ of x. In its evaluation topology, choose finitely many strict upper and positive lower bounds on absolute values of functions $a_j \in A$ whose intersection contains x and is contained in $O \cap \mathrm{Int}_{\mathrm{top}}(W, X)$. The neighbourhood basis used in Theorem 5.52.3 permits this choice. For each upper condition $|a_j| < b_j$, choose

$$|a_j(x)| < b_{j,0} < b_{j,1} < b_j.$$

Use the factor

$$1 - \rho\left(\frac{\log|a_j| - \log b_{j,0}}{\log b_{j,1} - \log b_{j,0}}\right),$$

with value one where $a_j = 0$. For each lower condition $|a_j| > c_j > 0$, choose

$$c_j < c_{j,0} < c_{j,1} < |a_j(x)|$$

and use the factor

$$\rho\left(\frac{\log|a_j| - \log c_{j,0}}{\log c_{j,1} - \log c_{j,0}}\right),$$

with value zero where $a_j = 0$.

Each factor is a smooth moment section on W. At a zero of a_j it is constant on an ordinary neighbourhood, hence has a constant representative. At a point where a_j is nonzero, choose a smaller ordinary affinoid neighbourhood where $|a_j|$ is bounded below by a positive real constant. The unit criterion 1.20.1 makes its restriction an analytic unit. The displayed expression is then a smooth function of the moment coordinate $-\log|a_j|$. These representatives agree as continuous functions, and hence as germs by the first paragraph. The sheaf theorem 5.52.3 glues them.

Multiply the finitely many factors. The resulting χ_W lies between zero and one and equals one on an ordinary neighbourhood of x. Its support is contained in the subset $C \subseteq W$ defined by the weak upper bounds $|a_j| \leq b_{j,1}$ and weak lower bounds $|a_j| \geq c_{j,0}$. This subset is compact by Proposition 2.24.1,

is closed in the Hausdorff space X, and is contained in $O \cap \mathrm{Int}_{\mathrm{top}}(W, X)$ by the strictly nested choices of bounds. On the open cover

$$X = \mathrm{Int}_{\mathrm{top}}(W, X) \cup (X \setminus C)$$

glue χ_W on the first member and zero on the second. They agree on the overlap. The resulting section has all the stated properties. All thresholds were positive real numbers; the construction never required them to be absolute values of ground-field constants. □

Theorem 5.53.2 (Finite smooth partitions near a compact set)**.** *Let X be good and Hausdorff, let $S \subseteq X$ be compact, and let $O_1, \dots, O_m$ be ordinary open sets covering S. There are compactly supported sections $\chi_i \in \mathcal{A}_X^{0,0}(X)$ such that*

$$0 \le \chi_i \le 1, \qquad \mathrm{supp}(\chi_i) \subseteq O_i,$$
$$\sum_i \chi_i = 1 \quad \text{on an ordinary neighbourhood of } S.$$

If X is pure of analytic dimension d, $\mathcal{F}$ is coherent, and $\alpha \in \mathcal{A}_{X,c}^{d,d}(X)$ has support in S, then

$$\int_{X,\mathcal{F}} \alpha = \sum_i \int_{O_i, \mathcal{F}|_{(O_i)_G}} (\chi_i \alpha)|_{O_i}.$$

Each term is a compactly supported integral on the indicated open analytic subspace.

Proof. The case $S = \varnothing$ uses zero functions. Otherwise, apply Lemma 5.53.1 at each point of S, with one O_i containing it. Compactness gives finitely many resulting functions b_j whose loci where they equal one cover S by ordinary neighbourhoods. Group them by the chosen index and put

$$b_i' = \sum_{j \text{ assigned to } i} b_j, \qquad s = \sum_i b_i'.$$

Thus $s \ge 1$ on S and each b_i' has compact support contained in O_i. Choose a smooth real function η with $0 \le \eta \le 1$, equal to zero for $t \le 1/4$ and to one for $t \ge 1/2$, by the profile construction in that lemma. The function

$$h(t) = \begin{cases} \eta(t)/t, & t > 0, \\ 0, & t \le 0 \end{cases}$$

is smooth, since it is identically zero for $t \le 1/4$. Set $\chi_i = h(s)b_i'$. Smooth composition and the sheaf algebra of Theorem 5.52.3 make these global smooth moment sections. Since $0 \le b_i' \le s$, they take values in $[0,1]$, and their supports are contained in those of b_i'. Their sum is $\eta(s)$, which equals one on the open neighbourhood $\{s > 1/2\}$ of S. This proves the partition assertion.

The equality $\alpha = \sum_i \chi_i \alpha$ holds as sections: it holds on a neighbourhood of its support, and every germ of α off that support is zero. The support of $\chi_i\alpha$ is compact and lies in O_i. By the affinoid-neighbourhood basis, one may choose its finite compact affinoid neighbourhood entirely inside O_i. The same finite-chart formula then computes its integral in X and in O_i, by Theorem 5.52.4. Open subspaces are good by that same neighbourhood basis and Hausdorff by restriction; their nonempty affinoid charts have dimension d by Lemma 5.50.3. Thus all the indicated integrals exist, and linearity gives the displayed formula. □

5.54 Finite projection for compactly supported smooth forms

Theorem 5.54.1 (Finite projection for smooth moment forms)**.** *Let $p : Y \to X$ be a norm-admissible finite morphism of good Hausdorff analytic spaces pure of the same analytic dimension d, over the specified complete field. Let $\mathcal{F}$ be coherent on Y_G. For every $\alpha \in \mathcal{A}^{d,d}_{X,c}(X)$, the form $p^*\alpha$ has compact support and*

$$\int_{Y,\mathcal{F}} p^*\alpha = \int_{X,p_*\mathcal{F}} \alpha.$$

These identities are compatible with composition of finite morphisms. If $p_*\mathcal{F}$ is locally free of constant rank ρ on the analytic G-site over an ordinary open neighbourhood of $\operatorname{supp}(\alpha)$, then

$$\int_{Y,\mathcal{F}} p^*\alpha = \rho \int_{X,\mathcal{O}_X} \alpha.$$

The absolute value is unchanged, and the assertions allow trivial valuation and nonreduced spaces.

Proof. Put $S = \operatorname{supp}(\alpha)$. The ordinary smooth-germ pullback is defined by Theorem 5.52.3. If $y \notin p^{-1}(S)$, a representative of α vanishes on an ordinary

neighbourhood of $p(y)$. Its pullback vanishes near y, by continuity of p and the definition of pullback on representatives. Thus

$$\operatorname{supp}(p^*\alpha) \subseteq p^{-1}(S).$$

Choose finitely many affinoid domains $V_i \subseteq X$ whose ordinary interiors cover S, using the affinoid neighbourhood basis in Theorem 5.52.3. Put $Q = \bigcup_i V_i$. Finiteness of p makes $W_i = p^{-1}(V_i)$ actual affinoid domains, and $R = \bigcup_i W_i = p^{-1}(Q)$ is compact by Theorem 5.51.1. The set $p^{-1}(S)$ is closed in R: S is compact and therefore closed in the Hausdorff space X. It is consequently compact. The support of the pullback is closed and contained in this compact set, which proves the first assertion.

For every i, the open set $p^{-1}(\operatorname{Int}_{\mathrm{top}}(V_i, X))$ is contained in W_i, and therefore in $\operatorname{Int}_{\mathrm{top}}(W_i, Y)$. These interiors cover $p^{-1}(S)$ and hence the support of the pullback. Thus Q and R are valid compact neighbourhoods for the two integrals in Theorem 5.52.4; neither finite union needs to be good.

The coherent direct image $p_*\mathcal{F}$ exists by Proposition 2.35.15. The finite chart data induced on R by the ordinary section $p^*\alpha$ are the pullback of the data induced by α on Q. To check this, take the finite presenting affinoid cover supplied by Theorem 5.52.3. On its full inverse images both constructions use the same pulled-back analytic units and the same ambient superform. Their relations agree on every overlap by that theorem's restriction and pullback compatibility. If further affinoid restriction is needed, both sets of data are compared on that same finite common refinement.

Theorem 5.51.1 now gives

$$\mathcal{I}_{R,\mathcal{F}|_R}(p^*\alpha) = \mathcal{I}_{Q,(p_*\mathcal{F})|_Q}(\alpha).$$

By Theorem 5.52.4, these are precisely the two ordinary compact-support integrals in the statement.

For composable finite maps, functoriality of ordinary pullback is Theorem 5.52.3. Direct images compose on sections over full inverse images, as in Theorem 5.51.1. Applying the proved identity twice therefore gives the identity for the composite.

Finally, under the local rank hypothesis choose all V_i inside the indicated ordinary open neighbourhood of S. The scalar-rank assertion of Theorem 5.51.1 applies on Q. It multiplies the structure-module integral by ρ, with the generic Artinian lengths retained. Independence of compact neigh-

bourhoods in Theorem 5.52.4 identifies that structure-module integral with the one on X. □

5.55 Graded independence and pointed moment images

Let K be a complete non-Archimedean field with its specified real-valued absolute value, possibly trivial. For an analytic point x, write $F_x = \widetilde{\mathcal{H}(x)}^{\mathrm{gr}}$ and $k = \widetilde{K}^{\mathrm{gr}}$. The initial form of a nonzero $a \in \mathcal{H}(x)$ is denoted by $\widetilde{a}$; it is a homogeneous unit of degree $|a|$. Algebraic independence of homogeneous elements means ordinary polynomial independence over the underlying graded ring k. The kernel of polynomial evaluation is graded, so this is equivalent to the absence of nonzero homogeneous polynomial relations. For a graded field generated by finitely many such elements, trdeg_k means the transcendence degree of the fraction fields of the underlying graded domains, or equivalently the size of a maximal algebraically independent subtuple of the homogeneous generators.

Lemma 5.55.1 (Norm rigidity from a graded algebraic initial form)**.** *Let X be a good K-analytic space, let $x \in X$, and let f be an analytic unit on an ordinary neighbourhood of x. If $\widetilde{f(x)} \in F_x$ is algebraic over k, there is an ordinary neighbourhood U of x on which*

$$|f(y)| = |f(x)| \qquad (y \in U).$$

For a finite tuple of units the same assertion holds simultaneously when all its initial forms are algebraic over k. No interior or purity hypothesis is required.

Proof. Put $r = |f(x)| > 0$ and $u = \widetilde{f(x)}$. Take a nonzero homogeneous relation

$$\sum_{j \in J} \bar{c}_j u^j = 0$$

with $J \subset \mathbf{Z}_{\geq 0}$ finite, all $\bar{c}_j$ nonzero and homogeneous, and all the terms of the same degree $R > 0$. Such a relation exists because the kernel of evaluation in the graded polynomial ring is graded. It has at least two distinct exponents, since each $\bar{c}_j u^j$ is nonzero. Lift $\bar{c}_j$ to $c_j \in K$ with $|c_j| r^j = R$, and put $P(T) = \sum_{j \in J} c_j T^j$. Cancellation of the initial forms gives $|P(f(x))| < R$.

Choose c with $|P(f(x))| < c < R$. By continuity, after shrinking to an ordinary neighbourhood U of x,

$$|P(f(y))| < c.$$

Write $a = \min J$ and $b = \max J$; then $a < b$. For a positive real q near r, the sizes of the terms are

$$|c_j| q^j = R(q/r)^j.$$

If $q > r$, the unique largest size is the $j = b$ term; if $q < r$, it is the $j = a$ term. Choose $\varepsilon > 0$ so that the maximum of these finitely many sizes is strictly larger than c whenever $0 < |\log(q/r)| < \varepsilon$. Continuity of $|f|$ allows us to shrink U further to $|\log(|f(y)|/r)| < \varepsilon$. If $|f(y)| \neq r$, the non-Archimedean strong triangle inequality gives

$$|P(f(y))| = \max_{j \in J} |c_j| |f(y)|^j > c,$$

a contradiction. The finite-tuple assertion follows by intersecting the finitely many resulting neighbourhoods. □

Lemma 5.55.2 (Independent initial forms survive Gauss normalization)**.** *Let $V = \mathcal{M}(A)$ be a generalized K-affinoid space, $x \in V$, and let $f_1, \dots, f_s \in A^\times$ have algebraically independent initial forms in F_x over k. Put $r_i = |f_i(x)|$. Give $K(S_1, \dots, S_s)$ the weighted Gauss absolute value with $|S_i| = r_i$ and write L for its completion. There exists an analytic point $x_L \in V_L$ above x with*

$$\widetilde{f_1/S_1}(x_L), \dots, \widetilde{f_s/S_s}(x_L)$$

algebraically independent over $\widetilde{L}$. Moreover $x \in \mathrm{Int}(V/K)$ implies $x_L \in \mathrm{Int}(V_L/L)$.

Proof. Put $H = \mathcal{H}(x)$ and let E be the completion of $H(S_1, \dots, S_s)$ for the same weighted Gauss norm. The given norm on $K(S_1, \dots, S_s)$ is its restriction, so L embeds isometrically in E. Evaluation at x gives a bounded map $A \to H \subset E$. Together with $L \to E$ it induces a bounded map $A \widehat{\otimes}_K L \to E$ and hence a point x_L above x.

Write $u_i = \widetilde{f_i(x)}$ and $s_i = \widetilde{S}_i$. The defining Gauss norm says that the graded Laurent polynomial ring $F_x[s_1^{\pm 1}, \dots, s_s^{\pm 1}]$ embeds in $\widetilde{E}^{\mathrm{gr}}$: a nonzero finite sum has a maximal Gauss term and its initial form does not vanish. Here polynomial independence holds even when two weighted monomials have the

same numerical degree, because the Gauss norm does not cancel distinct monomials. The u_i are independent over k by assumption, while the s_i are independent over the entire F_x. Consequently the u_i/s_i are algebraically independent over the ordinary fraction field of $k[s_1^{\pm 1}, \dots, s_s^{\pm 1}]$: any polynomial relation, after clearing denominators and powers of the s_i, would be a polynomial relation in the u_i with coefficients in $k[s_1^{\pm 1}, \dots, s_s^{\pm 1}]$; independence of the u_i, followed by independence of the s_i, makes each coefficient zero. The degree-one residue field $\widetilde{L}$ is a subfield of this fraction field, as follows directly by reducing fractions for the weighted Gauss norm. Thus the displayed normalized initial forms are independent over $\widetilde{L}$. The inclusion of the graded residue field of $\mathcal{H}(x_L)$ in that of E preserves such independence.

Finally, base-change preservation of relative interior in Proposition 2.33.21, applied over the point $\mathcal{M}(K)$, gives the last assertion. The argument did not change the originally specified absolute value on K. □

Theorem 5.55.3 (Local openness for graded-independent moments)**.** *Let $V = \mathcal{M}(A)$ be a generalized K-affinoid space, let $x \in \mathrm{Int}(V/K)$, and let $f_1, \dots, f_s \in A^\times$ have algebraically independent homogeneous initial forms over k in F_x. Put*

$$t_f(y) = (-\log|f_1(y)|, \dots, -\log|f_s(y)|), \qquad w = t_f(x).$$

For every ordinary neighbourhood U of x in V, the set $t_f(U)$ contains an ordinary Euclidean neighbourhood of w in $\mathbf{R}^s$. In particular, for every ordinary affinoid neighbourhood W of x contained in V, its actual finite polyhedral moment image has dimension s. The assertion holds for the trivial valuation, arbitrary real radii and every analytic dimension of V.

Proof. For $s = 0$ the image is the one-point space $\mathbf{R}^0$, so there is nothing to prove. Assume $s > 0$. Use Lemma 5.55.2 and write $h_i = f_i/S_i$ on V_L. The point x_L is interior, every $|h_i(x_L)| = 1$, and the reductions of the h_i are algebraically independent over $\widetilde{L}$. Thus the actual residue algebra

$$\widetilde{L}[\widetilde{h}_1^{\pm 1}, \dots, \widetilde{h}_s^{\pm 1}] \simeq \widetilde{L}[T_1^{\pm 1}, \dots, T_s^{\pm 1}]$$

is a Laurent polynomial algebra. Its tropicalization over the trivially valued residue field is all of $\mathbf{R}^s$: for any real vector v, the weighted Gauss seminorm on its Laurent ring has moment v.

Let C be a nonempty open rational homogeneous polyhedral cone in $\mathbf{R}^s$. Choose a vector $v \in C$ and integer vectors $m_1, \dots, m_a$ such that the strict

inequalities $\langle m_j, z\rangle > 0$ define a nonempty smaller cone contained in C and contain v. The normalized sector argument applied to (V_L, x_L) and (h_i) says that every ordinary neighbourhood of x_L contains a point where $\langle m_j, t_h\rangle > 0$ for all j. For any $\delta > 0$ apply it to the neighbourhood

$$p^{-1}(U) \cap t_h^{-1}(B_\delta(0))$$

of x_L, where $p : V_L \to V$ is projection. The projected point belongs to U and its moment displacement $t_f(y) - w = t_h(y_L)$ belongs to $C \cap B_\delta(0)$.

Choose an ordinary affinoid neighbourhood $W \subseteq U$ of x by the affinoid-neighbourhood basis established in the proof of Theorem 5.52.3. Apply the previous paragraph with U replaced by the ordinary interior of W. Theorem 5.39.3 gives a finite integral affine polyhedral complex whose support is exactly $t_f(W)$. Because $w \in t_f(W)$, the cells containing w determine a finite union C_W of closed rational polyhedral tangent cones, and for some $\epsilon > 0$ one has

$$t_f(W) \cap B_\epsilon(w) = (w + C_W) \cap B_\epsilon(w).$$

If $C_W \neq \mathbf{R}^s$, its closed conical support has a complementary nonempty open rational homogeneous cone. The preceding sector lifting then produces a moment displacement in this cone arbitrarily close to zero, contradicting the displayed equality. Hence $C_W = \mathbf{R}^s$ and the displayed equality puts $B_\epsilon(w)$ inside $t_f(W) \subseteq t_f(U)$. The dimension assertion follows because the moment image is a subset of $\mathbf{R}^s$ containing a ball. □

Corollary 5.55.4 (The two extreme ranks of pointed tropical germs)**.** *Let V, x be as in Theorem 5.55.3, and let $f = (f_1, \dots, f_n)$ be any finite unit tuple. Put*

$$s = \operatorname{trdeg}_{\widetilde{K}^{\mathrm{gr}}} \widetilde{K}^{\mathrm{gr}}(\widetilde{f_1(x)}, \dots, \widetilde{f_n(x)}).$$

If $s = 0$, there is an ordinary neighbourhood U_0 of x on which t_f is constant. If $s = n$, for every ordinary neighbourhood U of x, the germ $(t_f(U), t_f(x))$ is the full Euclidean germ $(\mathbf{R}^n, t_f(x))$. More generally, if s of the initial forms are algebraically independent, the projection of $t_f(U)$ to those s coordinates contains an ordinary Euclidean neighbourhood of its base point.

Proof. When $s = 0$, each initial form is algebraic over $\widetilde{K}^{\mathrm{gr}}$, so apply Lemma 5.55.1 to the finite tuple. When $s = n$ the tuple itself satisfies Theorem 5.55.3. The projection assertion follows by applying the same theorem to the indicated subtuple. □

Lemma 5.55.5 (Finite tropical witnesses for homogeneous graded relations)**.** *Let k be a graded field, let $r_1, \dots, r_n > 0$, and let $u_1, \dots, u_n$ be nonzero homogeneous elements of degrees r_i in a graded field extension F/k. Put*

$$I = \ker\bigl(k[Z_1^{\pm 1}, \dots, Z_n^{\pm 1}] \longrightarrow F,\ Z_i \longmapsto u_i\bigr), \qquad s = \operatorname{trdeg}_k k(u_1, \dots, u_n).$$

The Laurent polynomial ring is graded by $\deg Z_i = r_i$, and I is homogeneous. Define $C \subset \mathbf{R}^n$ by requiring that for every nonzero homogeneous relation $P = \sum_m c_m Z^m \in I$ the minimum of $\langle m, q\rangle$ over its nonzero terms is attained at least twice. Then C is the support of a finite pure s-dimensional rational polyhedral fan. There are finitely many nonzero homogeneous relations $P_1, \dots, P_N \in I$ whose tropical hypersurfaces already cut out C. If $I = 0$, the list is empty and $s = n$.

Proof. Adjoin algebraically independent homogeneous variables S_i of degrees r_i and let ℓ be the graded fraction field of $k[S_1^{\pm 1}, \dots, S_n^{\pm 1}]$. The degree-one part ℓ_1 is an ordinary field. As the degrees r_i lie in the support of ℓ, replacing Z_i by $S_i H_i$ identifies the degree-one part of

$$(k[Z^{\pm 1}]/I) \otimes_k \ell$$

with a finitely generated ℓ_1-algebra

$$B = \ell_1[H_1^{\pm 1}, \dots, H_n^{\pm 1}]/J.$$

The tensor algebra injects into the graded fraction field of $F[S_1^{\pm 1}, \dots, S_n^{\pm 1}]$. Indeed polynomial independence of the S_i over F preserves the original kernel I after scalar extension, and localization at nonzero homogeneous elements of $k[S_i^{\pm 1}]$ remains injective. Thus B is a domain.

Choose a maximal algebraically independent subtuple of the u_i over k, with s members. The ratios of those members to their corresponding S_i are algebraically independent over ℓ_1: a relation would, after clearing denominators and powers of the S_i, contradict joint independence of the chosen u_i and all the S_i. Every remaining u_j is algebraic over the graded field generated by the chosen subtuple. Its nonzero homogeneous polynomial equation, after the substitutions $u_i = S_i H_i$ and division by a homogeneous unit of ℓ, is an ordinary polynomial equation for H_j over ℓ_1 and the chosen H_i. Consequently

$$\dim B = \operatorname{trdeg}_{\ell_1} \operatorname{Frac} B = s,$$

using the finite-type dimension theorem [StacksAlg, Tag 00P0], already an authorized leaf in the frozen foundation.

The ordinary field ℓ_1 is given the trivial absolute value. Apply the finite tropical basis Lemma 5.38.2 to J. Write $T = \mathrm{Trop}(\operatorname{Spec} B)$. It is a finite rational polyhedral fan; the algebraic tropical pure-dimension theorem 5.19.5, applied to the integral Laurent variety $\operatorname{Spec} B$, gives pure dimension s. A nonzero homogeneous original relation becomes an ordinary Laurent relation after normalization. Therefore $T \subseteq C$. The difficult reverse inclusion requires descending finite witnesses from J to I; we establish that inclusion next.

We now descend a *finite* tropical basis. Choose a finite basis $Q_1, \dots, Q_a \in J$ from the preceding lemma, and let $S \subset \mathbf{Z}^n$ be the finite union of their exponent supports. Put

$$M_S = \bigoplus_{m \in S} kZ^m, \qquad N_S = I \cap M_S.$$

These are graded k-modules, but no assertion about flatness of an infinite coefficient extension is needed. Write $s_i = S_i$ for these auxiliary graded variables.

Fix $q \notin T$. Some normalized Q_j has a unique least q-weight monomial, say with exponent $m_0 \in S$. Rewrite it in the variables $Z_i = S_i H_i$, obtaining

$$Q = \sum_{m \in S} a_m(s) Z^m \in \ell[Z^{\pm 1}],$$

where every nonzero $a_m(s)$ is homogeneous and Q has one common total graded degree. The coefficient at m_0 is nonzero, and all coefficients at other exponents of q-weight at most $\langle m_0, q \rangle$ are zero. Choose a common nonzero *homogeneous* denominator $d(s) \in k[s_1^{\pm 1}, \dots, s_n^{\pm 1}]$ of its finitely many coefficients. Then

$$d(s)Q = \sum_{a \in A} s^a P_a(Z), \qquad P_a \in M_S,$$

for one finite set $A \subset \mathbf{Z}^n$. Every nonzero P_a is homogeneous: in a fixed monomial $s^a Z^m$, the total degree of dQ determines the degree of its k-coefficient, and therefore the total degree of the corresponding terms of P_a.

The normalized relation is zero after substituting $Z_i = u_i$ in the graded polynomial ring $F[s_i^{\pm 1}]$. The s_i are algebraically independent over F, so comparison of their Laurent coefficients gives $P_a(u) = 0$ for every a; hence $P_a \in N_S$. The nonzero Laurent polynomial $d(s)a_{m_0}(s)$ has some nonzero coefficient, so one P_a has a nonzero m_0-coordinate. Since all other coordinates of q-weight at most $\langle m_0, q \rangle$ vanish before multiplication by d, they vanish

in every P_a. This chosen homogeneous P_a has the single initial monomial $c_{m_0} Z^{m_0}$. Thus $q \notin C$, proving $C \subseteq T$ and hence $C = T$.

It remains to replace the resulting weight-dependent choice by a finite list. A *circuit* of N_S is a nonzero homogeneous vector whose exponent support is minimal among supports of nonzero vectors of N_S. For each possible support there is at most one circuit up to multiplication by a nonzero homogeneous scalar: if two had that support, eliminate one coordinate by such a scalar, producing a nonzero vector of smaller support unless they were proportional. There are at most $2^{|S|} - 1$ supports, so there are finitely many circuits up to proportionality.

Given a homogeneous $P \in N_S$ with unique least term m_0, choose a homogeneous vector with nonzero m_0-coordinate, support contained in $\operatorname{supp} P$, and support minimal under those two conditions. If some nonzero vector had support properly contained in that support, either it has a nonzero m_0-coordinate, contradicting minimality, or it can be scaled to cancel a different coordinate without changing the m_0-coordinate, again contradicting minimality. The chosen vector is thus a circuit. Its support lies in $\operatorname{supp} P$ and contains m_0, so its initial at q is still a single monomial. Taking one representative of each circuit gives a finite family of homogeneous original relations, and a vector is outside C precisely when one of these has a single least term. This proves the assertion. □

Lemma 5.55.6 (The actual residual algebra after free Gauss normalization)**.** *Let $V = \mathcal{M}(A)$, $x \in V$, and $f_1, \dots, f_n \in A^\times$ be arbitrary analytic units. Put $r_i = |f_i(x)|$, $F_x = \widetilde{\mathcal{H}(x)}^{\mathrm{gr}}$, $k = \widetilde{K}^{\mathrm{gr}}$, and $u_i = \widetilde{f_i(x)}$. Let L be the completion of $K(S_1, \dots, S_n)$ for the weighted Gauss norm $|S_i| = r_i$, without assuming these radii are free over the value group of K. There is a point $x_L \in V_L$ above x for which the residue algebra*

$$\widetilde{L}[\widetilde{f_1/S_1}(x_L)^{\pm 1}, \dots, \widetilde{f_n/S_n}(x_L)^{\pm 1}]$$

is precisely the ordinary degree-one algebra B constructed in Lemma 5.55.5 from the graded relation ideal of the u_i. If $x \in \operatorname{Int}(V/K)$, then $x_L \in \operatorname{Int}(V_L/L)$.

Proof. Put $H = \mathcal{H}(x)$ and let E be the completion of $H(S_1, \dots, S_n)$ for the same weighted Gauss norm. The formula on finite sums gives an isometric embedding $L \hookrightarrow E$. It also proves the graded identities

$$\widetilde{L}^{\mathrm{gr}} = \operatorname{Frac}^{\mathrm{gr}}(k[s_1^{\pm 1}, \dots, s_n^{\pm 1}]), \quad \widetilde{E}^{\mathrm{gr}} = \operatorname{Frac}^{\mathrm{gr}}(F_x[s_1^{\pm 1}, \dots, s_n^{\pm 1}]),$$

where $s_i = \widetilde{S}_i$ and the fraction fields invert nonzero homogeneous elements. Indeed the maximum Gauss term of a nonzero polynomial has nonzero initial polynomial, distinct Laurent monomials do not cancel, and the initial form of a rational fraction is the quotient of its numerator and denominator initial forms. Passing to the completion adds no homogeneous initial values: approximate every nonzero element by a rational fraction with smaller error.

The bounded evaluation $A \to H$ and the isometric map $L \to E$ produce a bounded map $A\widehat{\otimes}_K L \to E$ and hence x_L above x. The completed residue field $\mathcal{H}(x_L)$ embeds isometrically into E. The graded injection

$$F_x \otimes_k \widetilde{L}^{\mathrm{gr}} \longrightarrow \widetilde{E}^{\mathrm{gr}}$$

comes from the algebraic independence of the s_i over F_x, followed by homogeneous localization. Consequently the kernel of evaluation of the normalized initials u_i/s_i over $\widetilde{L} = (\widetilde{L}^{\mathrm{gr}})_1$ is exactly the degree-one normalization of the scalar extension of the original homogeneous relation ideal I. By the definition of B in Lemma 5.55.5, this is the asserted ordinary residue algebra. The base-change interior inclusion in Proposition 2.33.21 gives the last assertion. □

Lemma 5.55.7 (A graded residual fan bounds a pointed moment germ)**.** *Let $V = \mathcal{M}(A)$ be a generalized K-affinoid space, $x \in V$, and let $f = (f_1, \dots, f_n)$ be a tuple of analytic units. Put $w = t_f(x)$, set $u_i = \widetilde{f_i(x)} \in F_x$, and let C_x be the graded tropical fan of Lemma 5.55.5. There are an ordinary affinoid neighbourhood W_0 of x and $\varepsilon > 0$ such that*

$$t_f(W_0) \cap B_\varepsilon(w) \subseteq (w + C_x) \cap B_\varepsilon(w).$$

This upper bound has pure fan dimension $s = \operatorname{trdeg}_k k(u_1, \dots, u_n)$ and requires no interior or purity hypothesis on V.

Proof. Choose the finite homogeneous relations $P_j = \sum_m \bar{c}_{jm} Z^m$ from Lemma 5.55.5, and lift each nonzero $\bar{c}_{jm}$ to $c_{jm} \in K$ with its exact absolute value. Because P_j is homogeneous, there is an $R_j > 0$ such that

$$|c_{jm}| \prod_i |f_i(x)|^{m_i} = R_j$$

for every monomial of P_j. Put $F_j = \sum_m c_{jm} f^m \in A$. The graded relation gives $|F_j(x)| < R_j$. Choose real b_j with $|F_j(x)| < b_j < R_j$. By continuity, all

the inequalities $|F_j(y)| < b_j$ hold on one ordinary affinoid neighbourhood W_0 of x. Shrink $\varepsilon > 0$ so that for every $v \in B_\varepsilon(w)$, every monomial of the finite list has size

$$|c_{jm}| \exp(-\langle m, v\rangle) > b_j.$$

If $v = t_f(y)$ does not belong to $w + C_x$, then $q = v - w \notin C_x$ and some P_j has one unique least q-weight exponent. All terms of $F_j(y)$ have sizes $R_j \exp(-\langle m, q\rangle)$; the unique least exponent is therefore the unique largest term, and the strong triangle inequality gives $|F_j(y)| > b_j$. This contradicts the choice of W_0. The fan and dimension assertions are precisely those of Lemma 5.55.5. □

Theorem 5.55.8 (Stabilization and purity of pointed tropical germs)**.** *Let $V = \mathcal{M}(A)$ be a generalized K-affinoid space, $x \in \mathrm{Int}(V/K)$, and $f = (f_1, \dots, f_n)$ a tuple of analytic units. Put $w = t_f(x)$ and*

$$s = \mathrm{trdeg}_{\widetilde{K}^{\mathrm{gr}}} \widetilde{K}^{\mathrm{gr}}(\widetilde{f_1(x)}, \dots, \widetilde{f_n(x)}).$$

There is a finite pure s-dimensional rational polyhedral fan $C_x \subseteq \mathbf{R}^n$ and an ordinary affinoid neighbourhood W_0 of x such that for every *ordinary neighbourhood U of x contained in W_0, there is $\varepsilon_U > 0$ with*

$$t_f(U) \cap B_{\varepsilon_U}(w) = (w + C_x) \cap B_{\varepsilon_U}(w).$$

Thus the pointed moment-image germ is independent of the choice of sufficiently small ordinary neighbourhood. Its dimension is exactly s, for every complete real-valued ground field, including the trivial valuation, with the original absolute value fixed. The statement allows nonreduced or nonpure A.

Proof. Let C_x and W_0 be supplied by Lemmas 5.55.5 and 5.55.7. The finite upper relation applies to every smaller neighbourhood $U \subseteq W_0$.

For the opposite inclusion, use Lemma 5.55.6 to make the simultaneous weighted Gauss extension with all n radii and its specified point x_L above x. That lemma identifies the ordinary residual Laurent algebra generated by the normalized initial forms $\widetilde{f_i/S_i}(x_L)$ with the algebra B of Lemma 5.55.5. Its tropicalization is therefore exactly C_x, and x_L is interior over L.

Fix a nonzero vector $q \in C_x$ and a strict rational open homogeneous sector S containing q. The normalized sector argument, applied to the normalized

tuple $h_i = f_i/S_i$ at x_L, supplies points with t_h in S in every ordinary neighbourhood of x_L. To require arbitrarily small displacements, intersect this neighbourhood with $t_h^{-1}(B_\delta(0))$ for any $\delta > 0$. For any prescribed ordinary neighbourhood U of x the inverse image of U under $V_L \to V$ is an ordinary neighbourhood of x_L. Projection then gives points $y \in U$ with $t_f(y) - w \in S$ and $\|t_f(y) - w\| < \delta$.

Choose an ordinary affinoid neighbourhood W of x contained in $U \cap W_0$. The actual image $t_f(W)$ is a finite integral affine polyhedral set by Theorem 5.39.3. In a sufficiently small Euclidean ball about w, it equals $w + D_W$ for the finite closed rational polyhedral tangent fan D_W formed by the cells containing w. By the upper inclusion, $D_W \subseteq C_x$. If some nonzero $q \in C_x$ were absent from D_W, the finite closed conical set D_W would have a strict rational open sector about q disjoint from it. The preceding residue-sector lifting into W would contradict the local equality with $w + D_W$. Since $0 \in D_W$, this proves $D_W = C_x$. Hence $t_f(W)$ agrees near w with $w + C_x$. It is contained in $t_f(U)$, while the upper inclusion for $U \subseteq W_0$ gives the reverse containment near w. Shrinking the Euclidean ball once more proves the displayed equality. The finite pure-dimensional fan calculation in Lemma 5.55.5 gives the dimension assertion. Every field extension was isometric and every projected moment used the original norm on K. □

5.56 Proper morphisms and top-dimensional moment pushforward

Throughout this section, K is a complete non-Archimedean field with its specified real-valued absolute value. The valuation may be trivial. All analytic spaces and completed residue fields use this absolute value. A finite morphism is norm-admissible finite. Compactness and properness have the meanings of Definition 2.53.1. For a unit tuple $f = (f_1, \dots, f_n)$ write $t_f = (-\log|f_1|, \dots, -\log|f_n|)$. The exact polytorus at $w \in \mathbb{R}^n$ is the affinoid domain of the analytic torus on which $|T_j| = e^{-w_j}$ for every j. Empty spaces have zero moment chain and zero integral.

Lemma 5.56.1 (A finite neighbourhood of the entire analytic fibre)**.** *Let $p : Z \to Y$ be a compact morphism of good Hausdorff analytic spaces. Suppose that $y \in Y$, that the underlying set of the analytic fibre Z_y is finite, and*

that every point above y belongs to $\mathrm{Int}(Z/Y)$*. There is an ordinary open neighbourhood N of y such that the full restriction*

$$p^{-1}(N) \longrightarrow N$$

is finite. One may require N to lie in any prescribed ordinary neighbourhood of y. Empty fibres are allowed.

Consequently, if p is proper, the locus of target points with finite analytic fibres is ordinary open, and the full restriction of p to that locus is finite.

Proof. Choose an affinoid neighbourhood V of y inside the prescribed target neighbourhood. It is compact by Proposition 2.24.1. Its inverse image Z_V is compact Hausdorff by compactness of p. The topological identification of Theorem 2.33.11, applied on charts, identifies the points of Z_y with the points of $p^{-1}(y)$.

Suppose first that this fibre consists of $z_1, \dots, z_r$. A finite subset of a Hausdorff space has disjoint ordinary open neighbourhoods of its points: choose separating neighbourhoods for every pair and take the finitely many intersections. Theorem 2.49.1 therefore supplies pairwise disjoint ordinary open neighbourhoods W_i of z_i, ordinary open neighbourhoods N_i of y, and finite maps $W_i \to N_i$. The same theorem permits the W_i to be contained in the chosen disjoint neighbourhoods and in $p^{-1}(\mathrm{Int}_{\mathrm{top}}(V, Y))$.

The set

$$C = Z_V \setminus \bigcup_{i=1}^{r} W_i$$

is compact. Its image is closed in the Hausdorff affinoid space V and does not contain y. Choose N inside $\mathrm{Int}_{\mathrm{top}}(V, Y) \cap \bigcap_i N_i$ and disjoint from $p(C)$. Then

$$p^{-1}(N) = \coprod_{i=1}^{r} \big(W_i \cap p^{-1}(N)\big).$$

Every map in this finite disjoint union is the base change of $W_i \to N_i$, hence is finite by Proposition 2.33.19 and the gluing of Theorem 2.40.8. A finite disjoint union of finite morphisms is finite: over an affinoid target its algebra is the finite product of the finite canonical algebras of the summands. The product norm is the canonical finite-module norm, and its coordinate idempotents identify its spectrum and sheaf with the indicated disjoint union. This proves finiteness of the full restriction.

If the fibre is empty, use $C = Z_V$. The same compact-image argument gives $p^{-1}(N) = \varnothing$, which is the finite space represented by the zero algebra.

For a proper morphism the interior condition holds everywhere. The neighbourhood just constructed consists of finite-fibre points, since finite analytic fibres are finite discrete spaces by Lemma 2.35.1. Thus the finite-fibre locus is open. On this open locus the restrictions are finite on an ordinary open cover of the target; the target-local definition of a finite analytic morphism glues them to the full finite restriction. □

Theorem 5.56.2 (The finite locus at maximal-dimensional analytic points)**.** *Let $p : X \to Y$ be a proper morphism of good Hausdorff analytic spaces, with $\dim_K X \leq d$. If $y \in Y$ satisfies $d_K(y) = d$, then its entire analytic fibre is finite, and p is finite over an ordinary neighbourhood of y. If Y is pure of analytic dimension d, the ordinary finite-fibre locus is open and dense in Y.*

Proof. We first verify the zero-dimensional fact needed for the actual fibre. A nonempty generalized affinoid space of analytic dimension zero has a finite underlying set. Indeed choose a strictifying complete extension by Theorem 1.17.6. Theorem 3.21.8 makes the strict algebra after this extension zero-dimensional. Finite normalization, Theorem 1.12.2, and Proposition 3.21.1 make it finite over the new ground field itself. Its actual strict norm is the canonical finite-module norm by Proposition 1.14.4. Its spectrum is finite by Lemma 2.35.1. The scalar projection onto the original spectrum is surjective by Theorem 2.33.13, so the original spectrum is finite too. This argument concerns analytic dimension, with Krull dimension used only after strictification.

Put $H = \mathcal{H}(y)$. To see that the actual analytic fibre X_y is good, choose at each z above y ordinary affinoid neighborhoods of y and z, the latter mapping into the former. The completed-residue fibre of the resulting affinoid map is affinoid by Theorem 2.33.11. It contains the intersection with the ordinary neighborhood of z and thus is an ordinary affinoid neighborhood in the whole fibre. Its underlying topology is that of $p^{-1}(y)$, and the completed residue field at a point z is the original $\mathcal{H}_X(z)$ with its structural isometric inclusion $H \hookrightarrow \mathcal{H}_X(z)$. These assertions follow on each affinoid chart from Theorem 2.33.11, and agree under the domain restrictions of Theorem 2.40.11. The fibre is compact Hausdorff: it is closed in the compact inverse image of any affinoid neighbourhood of y.

For every point z in this fibre, the valued-field tower formula, Lemma 3.22.2, gives

$$d_H(z) = d_K(z) - d_K(y) \leq \dim_K X - d \leq 0.$$

Here the point-dimension bound is Theorem 3.22.9, and $d_H(z)$ is nonnegative. It is consequently zero. The maximum formula of Theorem 3.22.7 makes every nonempty affinoid chart of X_y zero-dimensional over H. Compactness supplies finitely many such charts, each with a finite underlying set by the first paragraph. Thus the entire fibre is finite. Properness supplies relative interiority of all its points, so Lemma 5.56.1 gives the asserted ordinary finite neighbourhood, including the empty-fibre case.

If Y is pure of dimension d, every nonempty ordinary open subset contains a nonempty affinoid neighbourhood V of dimension d, by goodness and Lemma 5.50.3. The Abhyankar maximum formula supplies a point of V with $d_K(y) = d$. Corollary 2.33.15 leaves its completed residue field unchanged under domain restriction, so it is a point of the finite locus just proved. That locus therefore meets every nonempty ordinary open subset. Its openness is Lemma 5.56.1, proving density. □

Theorem 5.56.3 (Finite moment collars on compact analytic spaces)**.** *Let Z be a compact good Hausdorff analytic space of analytic dimension at most d, and let f be a finite tuple of global analytic units on Z. Choose a finite affinoid-domain cover $(U_i)_{i=1}^{r}$ whose ordinary interiors cover Z, and put*

$$E = \bigcup_{i=1}^{r} t_f(\partial_K U_i).$$

Then E is a compact finite integral-affine polyhedral set of dimension at most $d-1$; it is empty if $d = 0$. For every $w \notin E$ there is a closed rectangular box P about w, with w in its interior, for which

$$Z_P = t_f^{-1}(P) \longrightarrow \mathbb{T}_P$$

is finite. In particular Z_P is an actual affinoid domain of Z. The box can be chosen in any prescribed neighbourhood of w. The inverse image here is the entire inverse image, and restriction to any exact polytorus in P gives the entire original moment fibre with its analytic structure.

Proof. The cover exists by Lemma 5.50.1. Each U_i has dimension at most d by Theorem 3.22.9. The boundary-image assertion of Theorem 5.39.3 proves the claims about E. Each boundary is closed by Proposition 2.33.21 and compact by Proposition 2.24.1, so its image and their finite union are compact.

Let $q : Z \to \mathbb{G}_m^{n,\mathrm{an}}$ be the actual analytic map defined by f, and let $\mathbb{T}_w$ be the exact polytorus at w. The map q is compact: the inverse image of a compact analytic domain in the Hausdorff torus is a closed subset of the compact Hausdorff space Z.

For each i with $w \in t_f(U_i)$, the entire fibre in U_i avoids $\partial_K U_i$. Proposition 5.38.4 supplies a finite map from its full moment neighbourhood to a closed target polyannulus about w. If $w \notin t_f(U_i)$, compactness of this image supplies a box about w with empty inverse image in U_i. Intersect these finitely many boxes and shrink slightly. We obtain a box Q about w such that every restriction

$$U_i \cap t_f^{-1}(Q) \longrightarrow \mathbb{T}_Q$$

is finite, including the empty restrictions.

Fix a point $a \in \mathbb{T}_w$. Its entire fibre in Z is a finite union of fibres of these finite maps, and is therefore finite. At a point z of this fibre, choose i for which $z \in \mathrm{Int}_{\mathrm{top}}(U_i, Z)$. Since w satisfies all inequalities of Q strictly, the affinoid $U_i \cap t_f^{-1}(Q)$ is an ordinary neighbourhood of z, and $\mathbb{T}_Q$ is an ordinary neighbourhood of a. Finite morphisms are everywhere interior by Theorem 2.33.18. Ordinary local testing, Proposition 2.44.6, gives $z \in \mathrm{Int}(Z/\mathbb{G}_m^{n,\mathrm{an}})$. Lemma 5.56.1 now gives an ordinary neighbourhood N_a of a over which the full map q is finite. The union $N = \bigcup_{a \in \mathbb{T}_w} N_a$ is an ordinary open neighbourhood of the whole exact polytorus, and $q^{-1}(N) \to N$ is finite by target locality.

Choose a closed box Q' about w inside the prescribed real neighbourhood. The complement $\mathbb{T}_{Q'} \setminus N$ is compact and its tropical image does not contain w. A smaller closed box P about w can therefore be chosen so that $\mathbb{T}_P \subset N$. The full restriction $q^{-1}(\mathbb{T}_P) \to \mathbb{T}_P$ is finite, proving the assertion. The analytic-domain inverse-image construction 2.40.11 identifies this source with $t_f^{-1}(P)$. Finite base change gives the actual exact-level algebras. No point or factor of the original inverse image has been removed. □

Corollary 5.56.4 (Proper morphisms are finite near generic moment levels)**.** *Let $p : X \to Y$ be a proper morphism of good Hausdorff analytic spaces, with $\dim_K X \le d$. Let $V \subseteq Y$ be an affinoid domain and let f be a unit tuple on V. There is a compact finite integral-affine polyhedral set $E \subseteq \mathbb{R}^n$ of dimension at most $d-1$ such that, for every $w \notin E$, one can choose a closed moment box P about w for which*

$$V_P = t_f^{-1}(P), \qquad X_P = p^{-1}(V_P), \qquad p_P : X_P \longrightarrow V_P$$

are actual affinoid domains and a finite morphism. Empty domains are allowed. The box can be made arbitrarily small.

In particular, if $\mathrm{Fin}(p_V)$ is the ordinary finite-fibre locus of $p_V : p^{-1}(V) \to V$, then

$$t_f\big(V \setminus \mathrm{Fin}(p_V)\big) \subseteq E.$$

The same inclusion holds for the image of every positive-dimensional analytic fibre. When V is pure of dimension d, the complement of E is dense on every d-dimensional cell of its actual moment image.

Proof. Properness makes $Z = p^{-1}(V)$ compact Hausdorff. It is good by the actual product charts. At a point of Z, choose an ordinary affinoid neighborhood U of its image in Y and ordinary affinoid neighborhoods X_0 and V_0 of its projection points in X and V, both mapping into U. The affinoid product $X_0 \times_U V_0$ identifies with the intersection of the two inverse images in $X \times_Y V$ by Theorem 2.40.11. It contains the intersection of the inverse images of their ordinary interiors, an ordinary neighborhood of the chosen point. Its dimension is at most d, since it is an analytic domain of X. Apply Theorem 5.56.3 to Z and the unit tuple p^*f. It gives the set E and a finite map $X_P \to \mathbb{T}_P$. The intermediate domain V_P is affinoid by the actual simultaneous Laurent inequalities of Theorem 2.31.2. Write their algebras as

$$R_P = \mathcal{O}(\mathbb{T}_P) \longrightarrow A_P = \mathcal{O}(V_P) \longrightarrow B_P = \mathcal{O}(X_P).$$

The algebra B_P is finite over R_P, and the same finite generating family makes it finite over A_P.

Here its given norm is the canonical finite-A_P-module norm. Indeed, using Theorem 1.18.3, choose R_P-module generators $b_1, \dots, b_m$ and their controlled lifts for the canonical R_P-module norm. They are also A_P-module generators. Boundedness of $R_P \to A_P$ makes the quotient A_P-module norm bounded above by a constant times the given norm of B_P. Conversely, the bounded

analytic map $A_P \to B_P$ and the finitely many b_i bound the given norm by a constant times that quotient norm. The two norms are therefore equivalent. This proves norm-admissible finiteness over V_P.

Every point of V of weight $w \notin E$ lies in the ordinary interior of V_P, because the defining moment inequalities are strict there. Its full fibre is consequently finite. Lemma 5.56.1 identifies the resulting ordinary finite locus. A positive-dimensional analytic fibre cannot be the finite fibre of a finite morphism: its affinoid pieces would be finite algebras over the completed target residue field and hence have analytic dimension zero, by finite residue extensions and the Abhyankar maximum formula. Finally E has dimension at most $d-1$, so it cannot contain a relatively open subset of a d-cell. This proves the density assertion exactly on those cells. □

Theorem 5.56.5 (Moment chains on compact analytic domains)**.** *Let Z be a compact good Hausdorff analytic space pure of dimension d, let $\mathcal{F}$ be coherent on Z_G, and let f be a global unit tuple. There is a canonical finite nonnegative integral d-chain $\mathcal{T}_{Z,f}(\mathcal{F})$, with support contained in the actual compact image $t_f(Z)$. For any finite affinoid-domain cover $(U_i)_{i=1}^r$, it is given by*

$$\mathcal{T}_{Z,f}(\mathcal{F}) = \sum_{\varnothing \neq I \subseteq \{1,\dots,r\}} (-1)^{|I|+1} \mathcal{T}_{f|_{U_I}}\big(\Gamma(U_I,\mathcal{F})\big), \qquad U_I = \bigcap_{i\in I} U_i.$$

Empty intersections contribute zero. This chain is additive in short exact sequences of coherent modules. For every smooth (d,d)-superform α defined near $t_f(Z)$,

$$\int_{\mathcal{T}_{Z,f}(\mathcal{F})} \alpha = \mathcal{I}_{Z,\mathcal{F}}(t_f^*\alpha).$$

Here the right side is the compact finite-chart integral.

The same construction applies to a finite union of affinoid domains in a good Hausdorff pure d-dimensional ambient space, even if the union is not good. It is additive by finite inclusion–exclusion for covers by such compact analytic domains. The analogous inclusion–exclusion identity holds for compatible finite moment-chart integrals, without requiring one global tuple.

If $Z_P = t_f^{-1}(P)$ is an affinoid moment domain, then

$$\mathcal{T}_{Z,f}(\mathcal{F})|_{\mathrm{int}(P)} = \mathcal{T}_{f|_{Z_P}}\big(\Gamma(Z_P,\mathcal{F})\big)|_{\mathrm{int}(P)}.$$

If global unit tuples g, f on Z satisfy $t_f = a \circ t_g$ for an integral lattice map a, then

$$a_*\mathcal{T}_{Z,g}(\mathcal{F}) = \mathcal{T}_{Z,f}(\mathcal{F}).$$

This pushforward is proper on the actual support. Cells on which a drops rank contribute zero.

Proof. All finite intersections are actual affinoid domains by Lemma 5.50.1, and every nonempty one is pure of dimension d by Lemma 5.50.3. Its sections of $\mathcal{F}$ form a finite module by Theorem 2.39.6. Thus the displayed finite sum is a well-defined integral d-chain. By Theorem 5.39.3, the actual image of Z is the finite union of the polyhedral images of the U_i, so it is compact and finite polyhedral of dimension at most d.

To compare covers (U_i) and (V_j), apply Theorem 5.48.1 on each U_I to its affinoid cover $(U_I \cap V_j)_j$. The first display becomes

$$\sum_{I\neq\varnothing}\sum_{J\neq\varnothing}(-1)^{|I|+|J|}\mathcal{T}_{f|_{U_I\cap V_J}}\big(\Gamma(U_I\cap V_J,\mathcal{F})\big).$$

Interchanging the finite sums and applying the same theorem on each V_J gives the expression for the second cover. This also proves independence under further refinement. Exact sequences remain exact on every affinoid intersection by the coherent equivalence, and the affinoid chains are additive by the additivity of finite-module chains; hence so is this chain.

For nonnegativity, order the cover and group each term by its largest index j. Use the supporting-hyperplane construction of Lemma 5.14.2 to subdivide all images and boundary images together. Consider the relative interior of a d-cell. All occurring full fibres and their overlaps are interior. The complementary-idempotent calculation in Theorem 5.50.6, using Theorem 5.47.2, identifies the coefficient of the j-th group with

$$\frac{1}{e_Q}\dim_{H_Q}\left(\prod_{i<j}(1-e_i)\right)\big(M_j\otimes_{\mathcal{O}(U_j)}E_Q\big).$$

Here $M_j=\Gamma(U_j,\mathcal{F})$, E_Q is the actual transverse Artinian Gauss algebra, e_Q is its lattice index, and the e_i are the idempotents of the overlap domains. Expanding the product gives exactly that group's alternating sum of module dimensions. The displayed coefficient is nonnegative, and the chain coefficient is an integer because it was defined as an alternating sum of integral weights. This proves positivity, including all module nilpotents. The integral identity is precisely the same finite sum as the defining formula of Theorem 5.50.6.

For a finite affinoid union in a good Hausdorff ambient space, the domain, intersection, purity and coherence statements are the ones verified in the last

paragraph of that theorem. The preceding double-cover argument therefore applies verbatim to the chains and to compatible finite chart data. We give the finite-union bookkeeping explicitly. In the commutative ring generated by symbols $[U]$ for the finitely many affinoid domains involved, impose $[U][V] = [U \cap V]$; all these symbols are idempotent. A finite covering family is represented by

$$1 - \prod_i (1 - [U_i]).$$

Expanding gives its inclusion–exclusion expression. Products represent intersection covers: the Boolean identity

$$(1 - \prod_i (1 - x_i))(1 - \prod_j (1 - y_j)) = 1 - \prod_{i,j} (1 - x_i y_j)$$

holds for commuting idempotents. To verify it, expand the identity decomposition into the products which choose either each variable or its complement. On every such product the two sides are the same zero or one. A union of compact domains represented by such covering expressions is consequently represented by $1 - \prod_l (1 - P_l)$. Expansion first by the P_l, or first by their affinoid constituents, gives the same finite sum of intersection symbols. Cover independence just proved permits either presentation of any intersection. Applying its chain or compatible-integral value proves the asserted finite inclusion–exclusion formula.

For the restriction assertion, intersect the chosen cover with Z_P. On the interior of P, the whole moment fibre in every U_I is unchanged. Refine by the finitely many boundary images of both U_I and $U_I \cap Z_P$. At every remaining generic d-cell, the whole-fibre module restriction assertion of Theorem 5.40.2 identifies their weights. Equality on these generic cells is equality of d-chains. The restricted inclusion–exclusion sum is the affinoid cover expression on Z_P, proving the claim.

Finally apply the same-affinoid chain projection to the identity map of each U_I, with its two restricted tuples. It gives the claimed lattice pushforward on each term. Finite linearity of the lattice-index formula gives the equality for their sum. The actual source support is compact, so the pushforward is proper. The rank-dropping convention is the one in that affinoid theorem and is unchanged by finite summation. □

Theorem 5.56.6 (Proper moment pushforward with generic lengths)**.** *Let $p : X \to Y$ be proper, where X and Y are good Hausdorff and pure of the same analytic dimension d. Let $\mathcal{F}$ be coherent on X_G. For an affinoid domain $V \subseteq Y$ and a unit tuple f on V, put $Z = p^{-1}(V)$ and*

$$\mathcal{P}_{p,\mathcal{F},f} = \mathcal{T}_{Z,p^*f}(\mathcal{F}|_Z).$$

This is a finite nonnegative integral d-chain. There is a compact finite polyhedral set E of dimension at most $d-1$ such that at every generic d-cell point $w \notin E$ it has the following description. There is an actual finite restriction

$$p_P : X_P = p^{-1}(V_P) \longrightarrow V_P = t_f^{-1}(P), \qquad w \in \operatorname{int}(P),$$

with affinoid algebras A_P, B_P. For the finite B_P-module $M_P = \Gamma(X_P, \mathcal{F})$ its coefficient is

$$m_{\mathcal{P}}(w) = \sum_{\mathfrak{p} \in \operatorname{Min}(A_P)} \operatorname{length}_{(A_P)_{\mathfrak{p}}}((M_P)_{\mathfrak{p}}) m_{\mathcal{M}(A_P/\mathfrak{p}),f}(w),$$

$$\operatorname{length}_{(A_P)_{\mathfrak{p}}}((M_P)_{\mathfrak{p}}) = \sum_{\substack{\mathfrak{q} \in \operatorname{Min}(B_P) \\ \mathfrak{q} \cap A_P = \mathfrak{p}}} \operatorname{length}_{(B_P)_{\mathfrak{q}}}((M_P)_{\mathfrak{q}}) [\kappa(\mathfrak{q}) : \kappa(\mathfrak{p})].$$

An empty component fibre contributes zero. Residue-field degrees in this expression are full degrees, including their inseparable factors. The coefficient and the chain do not depend on the finite collar or the affinoid cover of Z.

If a global unit tuple g on Z and an integral map a satisfy $t_f \circ p = a \circ t_g$, then

$$a_* \mathcal{T}_{Z,g}(\mathcal{F}|_Z) = \mathcal{P}_{p,\mathcal{F},f}.$$

In particular its generic coefficient is the full lattice-index sum over all full-rank source cells above that target cell; contracted cells contribute zero. For every smooth (d,d)-superform α defined near $t_f(V)$,

$$\mathcal{I}_{Z,\mathcal{F}}(p^* t_f^* \alpha) = \int_{\mathcal{P}_{p,\mathcal{F},f}} \alpha.$$

Proof. The space Z is compact Hausdorff and good as in Corollary 5.56.4. Its affinoid domains are domains of X and are pure of dimension d by Lemma 5.50.3. Thus Z is pure of dimension d, and Theorem 5.56.5 defines the displayed chain with its stated positivity and finiteness.

Choose the exceptional set in Corollary 5.56.4, and enlarge it by $t_f(\partial_K V)$. On a finite common subdivision of the actual image, the source-chain image

and this exceptional set, obtained by Lemma 5.14.2, a generic point w of a d-cell avoids the exceptional set. Near it, the target image lies in the affine span of that cell, with its saturated rank-d tangent lattice. The proper finite-collar theorem gives p_P; choose the box small enough that w satisfies its inequalities strictly. Every point of the entire target fibre is absolute interior in V and interior in the domain V_P. Domain interior and composition, Propositions 2.44.5 and 2.33.21, make it absolute interior in V_P. Every point of its full inverse image is absolute interior in X_P, because p_P is finite. The nonempty domains V_P and X_P are pure of dimension d, and M_P is finite over both B_P and A_P by Proposition 2.35.15.

The restriction statement in Theorem 5.56.5 identifies the source chain near w with that of X_P. Apply the one-affinoid chain calculation in finite pushforward to $p_P : X_P \to V_P$ and the single domain V_P. The finite collar gives norm-admissibility, and the coefficient module is M_P on the full inverse image and the same module regarded over A_P on the target. The source tuple is the literal pullback of $f|_{V_P}$; the map of moment lattices is the identity. The calculation identifies the two finite chains, with index one on each common saturated top tangent lattice and zero target module weight where the source fibre is empty. The generic-length formula of Theorem 5.40.2 is the first equality in the statement. The Artinian local factor calculation of Theorem 5.42.2 is the second. It uses the actual local module lengths, and its simple factors have dimension the full field degree over the target residue field. Thus neither nilpotents nor inseparability have been removed.

Two collars compare on a smaller moment box retaining the whole target fibre and its entire inverse image. Finite base change identifies their restricted algebras and modules with the algebra and module of that same actual inverse image. The whole-fibre module restriction assertion of Theorem 5.40.2 gives the same coefficient. Cover independence also follows from the already canonical compact chain.

The lattice pushforward is the last assertion of Theorem 5.56.5 on Z. It requires only the displayed equality of moment maps; the actual joint-character graph argument is included in its affinoid prerequisite. A common finite refinement of the compact source image gives the finite full-rank lattice-index sum on each generic target cell. Its support is proper, and rank-dropping source cells have zero top-degree contribution. Finally the compact-chain integral identity gives the last display directly. Every construction used the

complete inverse image Z, and every finite collar retained its entire inverse image over the target box. □

Theorem 5.56.7 (Proper projection from generic coefficient agreement)**.** *Let $p : X \to Y$ be proper between good Hausdorff analytic spaces pure of the same dimension d. Let $\mathcal{F}$ and $\mathcal{G}$ be coherent on X_G and Y_G, respectively, and fix $\Delta \in \mathbb{Q}_{\geq 0}$. Let $D \subseteq Y$ be a closed analytic subspace whose defining ideal, on every affinoid domain of Y, is contained in no minimal prime. The empty subspace is permitted.*

Suppose that whenever $W = \mathcal{M}(A)$ is an affinoid domain of $Y \setminus D$ for which $p^{-1}(W) = \mathcal{M}(B) \to W$ is finite, the modules

$$M = \Gamma(p^{-1}(W), \mathcal{F}), \qquad L = \Gamma(W, \mathcal{G})$$

satisfy, for every $\mathfrak{p} \in \operatorname{Min}(A)$,

$$\operatorname{length}_{A_{\mathfrak{p}}}(M_{\mathfrak{p}}) = \Delta \operatorname{length}_{A_{\mathfrak{p}}}(L_{\mathfrak{p}}). \tag{5.56.1}$$

Then for every affinoid domain $V \subseteq Y$ and unit tuple f on V,

$$\mathcal{P}_{p,\mathcal{F},f} = \Delta \mathcal{T}_f\big(\Gamma(V, \mathcal{G})\big).$$

For every ordinary smooth moment form $\alpha \in \mathcal{A}^{d,d}_{Y,c}(Y)$, the pullback has compact support and

$$\int_{X,\mathcal{F}} p^*\alpha = \Delta \int_{Y,\mathcal{G}} \alpha.$$

These scalar formulas multiply under composition when the corresponding coefficient conditions hold for the two maps.

For $\mathcal{F} = \mathcal{O}_X$ and $\mathcal{G} = \mathcal{O}_Y$, condition (5.56.1) uses the ratio of the full generic local lengths. If A is reduced, its denominator is one, so a nonzero such ratio is a positive integer. If an actual finite restriction has integral rings A, B and an injective structural map, its numerator is $[\operatorname{Frac}(B) : \operatorname{Frac}(A)]$, with the full inseparable degree retained.

Proof. Fix V and f. The actual closed subspace $D \cap V$ has moment image of dimension at most $d-1$ by Theorem 5.42.4. This image is compact and finite polyhedral. Add it to the exceptional polyhedral set of Theorem 5.56.6 and take a common finite subdivision by Lemma 5.14.2. At a generic point w of every remaining d-cell, choose the proper finite collar small enough that its

entire target domain V_P misses $D \cap V$. This is possible because the moment image of $D \cap V$ is compact and does not contain w.

Apply (5.56.1) to $W = V_P$. The generic-length formula in Theorem 5.56.6 and the module-weight formula in Theorem 5.40.2 give

$$m_{\mathcal{P}}(w) = \Delta\, m_{\Gamma(V_P,\mathcal{G}),f}(w) = \Delta\, m_{\Gamma(V,\mathcal{G}),f}(w).$$

The second equality is the whole-fibre restriction assertion of that theorem: the full fibre lies in V_P, and the restriction of the coherent module is its actual domain tensor. Equality on the generic part of every d-cell is equality of the finite d-chains. The excluded sets have dimension at most $d-1$ and contain no d-cell. This proves the first assertion, including components of the source whose moment image has dimension smaller than d.

The chain equality and Theorem 5.56.5 give the corresponding integral equality for a single smooth moment representative on any affinoid V. We pass carefully to ordinary forms. Let $S = \operatorname{supp}(\alpha)$. Pullback of representatives in Theorem 5.52.3 gives

$$\operatorname{supp}(p^*\alpha) \subseteq p^{-1}(S).$$

Choose a finite union Q of affinoid domains of Y whose ordinary interiors cover S. Every full inverse image of one of these domains is compact by properness and good by Corollary 2.46.4. Choose a finite affinoid cover of each such inverse image. Thus $R = p^{-1}(Q)$ is a finite union of affinoid domains in X. It is compact Hausdorff, and $p^{-1}(S)$ is closed in it. Consequently the pullback support is compact. The ordinary interior of R contains it, since it contains $p^{-1}(\operatorname{Int}_{\mathrm{top}}(Q, Y))$.

Represent the induced finite chart data of α on Q by a finite affinoid cover (V_i), with one moment tuple and one smooth representative on each member, as in Theorem 5.52.3. Put $Z_i = p^{-1}(V_i)$. Each Z_i is compact good and admits a finite affinoid cover; the same holds for $Z_I = p^{-1}(V_I)$, where $V_I = \bigcap_{i\in I} V_i$. Their pulled-back finite chart representatives agree with the data induced by $p^*\alpha$, because both use the same analytic unit pullbacks on every affinoid refinement. The compact-domain inclusion–exclusion assertion of Theorem 5.56.5 computes the integral on R as the alternating sum of the integrals on the Z_I. On each Z_I, use a representative from any $i \in I$. The single-chart equality just proved identifies this term with Δ times the corresponding integral on V_I. The alternating sum is therefore Δ times the finite-chart integral on Q. Theorem 5.52.4 identifies these two compact-neighbourhood integrals with the stated ordinary compact-support integrals.

For two composable maps satisfying the respective conditions, the pullback of a compactly supported form under the second map has compact support by the assertion just proved. Apply the two integral formulas successively and use the functoriality of ordinary smooth pullback in Theorem 5.52.3. The factors multiply.

Finally, for reduced A, every $A_{\mathfrak{p}}$ at a minimal prime is a field, as checked in Proposition 5.41.2, so its own length is one and the length of a finite module is an integer. For a finite injection of integral rings $A \to B$, localizing B at the nonzero elements of A gives a finite-dimensional domain over $\mathrm{Frac}(A)$, hence a field. It contains B and is contained in $\mathrm{Frac}(B)$; conversely every nonzero element of B is invertible in that field, so it is $\mathrm{Frac}(B)$. Its vector-space dimension is the claimed full degree for this actual finite restriction. □

Corollary 5.56.8 (Proper modifications and generic finite free degree)**.** *Keep $p : X \to Y$ and $D \subseteq Y$ as in Theorem 5.56.7. If p is an isomorphism over $Y \setminus D$ and coherent modules $\mathcal{F}, \mathcal{G}$ are identified there by $\mathcal{F} \simeq p^{*}\mathcal{G}$, then*

$$\int_{X,\mathcal{F}} p^{*}\alpha = \int_{Y,\mathcal{G}} \alpha$$

for every compactly supported ordinary smooth top form. In particular a proper modification which is an isomorphism away from such a closed subspace preserves the structure-module integral. Additional source components mapped into D are allowed, provided X remains pure of dimension d.

More generally, suppose that over $Y \setminus D$ the map is finite and its coherent direct image of $\mathcal{F}$ is locally free of constant rank r on the analytic G-site. Then

$$\int_{X,\mathcal{F}} p^{*}\alpha = r \int_{Y,\mathcal{O}_Y} \alpha.$$

The rank may be the full degree of a finite inseparable map; separability is not required.

Proof. In the isomorphism case the two finite modules on every affinoid restriction disjoint from D are identified. Their generic local lengths are equal, so Theorem 5.56.7 applies with $\Delta = 1$.

For the rank assertion, fix a target affinoid moment chart and exclude the actual moment image of its intersection with D, as in the proof of that theorem. On a sufficiently small proper finite collar about any remaining generic d-cell point, the whole target domain is disjoint from D. The direct

image is therefore analytically locally free of rank r on that domain. The rank formula in Theorem 5.51.1, proved there by an actual finite affinoid trivializing refinement, identifies its finite-module moment chain with r times the structure chain. Equivalently, on that refinement each actual Artinian Gauss factor carries r copies of the original module; inclusion–exclusion gives the same equality on the whole domain. Thus the compact source chain equals r times the target structure chain on every generic d-cell. The ordinary-form argument in Theorem 5.56.7 now gives the displayed equality without replacing analytic local freeness by an unproved algebraic-local assertion.

If a source component maps into D, its image under every pulled-back target tuple lies in the finite polyhedral image of D of dimension at most $d-1$. Its pulled-back top chain and top-form integral are zero. The preceding proof retains it in every full inverse image; its zero contribution is a dimension calculation. All remaining factors are the full finite-module factors, so the field degrees, including inseparable degrees, retain their original normalization. □

5.57 Rational coordinates and initial models along a skeleton

Let K be complete for its specified nontrivial real-valued absolute value. Write $O = K^\circ$, $k = \widetilde{K}$, and $v = -\log|\cdot|$, and fix $\pi \in O$ with $0 < |\pi| < 1$. We use the algebraic model setting of Theorem 5.30.3: $\mathcal{X}$ is a given projective, flat, finitely presented O-scheme, its generic fibre X is smooth and integral, and a finite collection of affine opens covering $\mathcal{X}_s$ has étalemaps to

$$\operatorname{Spec} R_\lambda, \qquad R_\lambda = O[X_0, \dots, X_{r_\lambda}, T_1, \dots, T_{q_\lambda}]/(X_0 \cdots X_{r_\lambda} - a_\lambda), \quad 0 < |a_\lambda| < 1.$$

Let $S \subset X^{\mathrm{an}}$ be the compact skeleton of the completed model. All rational functions below belong to the original field $K(X)$.

For such a chart $\mathcal{V} = \operatorname{Spec} C$ and a nonempty $I \subset \{0, \dots, r\}$, write S_I for its residual stratum over

$$D_I = \{X_i = 0 \ (i \in I),\ X_j \neq 0 \ (j \notin I)\}$$

and Q_I for the finite set of generic points of S_I. These are the strata and labels of Proposition 5.24.2. If $s = x_{\eta,w}$, then $I = \{i : w_i > 0\}$ and $\eta \in Q_I$. An irreducible residual component in this section is a component of this locally closed stratum.

Lemma 5.57.1 (Algebraic coordinates on a common affine open)**.** *There is an affine open $\mathcal{W} = \operatorname{Spec} D$ of $\mathcal{X}$ containing every specialization of S. There is a finite collection of affine étalesemistable charts $\mathcal{V}_\lambda = \operatorname{Spec} C_\lambda$ contained in $\mathcal{W}$ whose completed generic fibres cover S. For each pair (I, η) in a chart one may choose $h_{\lambda,I,\eta} \in C_\lambda$ such that*

$$E_{\lambda,I,\eta} := (S_I)_{\overline{h}_{\lambda,I,\eta}}$$

is a nonempty smooth integral open of the component labelled by η and meets no other component of S_I.

Fix a faithful rational tuple F_0 as in Theorem 5.30.3. There are a finite list $P \subset D \setminus \{0\}$, a dense open

$$U = \operatorname{Spec} D_K \left[1/\prod_{p\in P} p\right] \subset X,$$

and a finite tuple $F \subset K(X)^\times$ with the following properties. The open U is contained in every $\mathcal{V}_{\lambda,K}$ and contains S analytically. The tuple F contains P, F_0, finite nonzero O-algebra generating sets of D and every C_λ, the chart coordinates, and every $h_{\lambda,I,\eta}$. Each member of F is a ratio of members of P, or itself a member of P. All members of F are units on U, and they define a closed immersion $U \hookrightarrow \mathbf{G}_{m,K}^{|F|}$. Its restriction to S is faithful and unimodular on a finite subdivision.

Proof. Proposition 5.30.2 makes the set Z of skeletal specializations finite. Apply Lemma 5.30.1 to obtain $\mathcal{W}$. For each point of Z in an original chart, choose a principal open neighbourhood in that chart contained in $\mathcal{W}$. There are only finitely many choices. A principal open is étaleover its chart, and the restricted map to the standard model is étaleby [StacksAlg, Tag 00U2]. At every skeletal point specializing to the chosen point, the defining function of this principal open has norm one. Lemma 4.13.1 and Proposition 5.23.4 therefore show that these completed opens cover S and have the restricted skeletons claimed.

The algebras D and C_λ are finitely presented over O: apply [StacksAlg, Tag 01TQ] to the restrictions of the finitely presented structural morphism to these affine opens. They are O-flat. Thus they inject into their generic coordinate rings, which in turn inject into $K(X)$.

For fixed (λ, I), the distinct primes in Q_I are incomparable. For each $\eta' \neq \eta$, choose an element of the prime of η' outside the prime of η, and

multiply these finitely many elements. They may be chosen in $C_\lambda \otimes_O k$, by taking the inverse images of the stratum primes in this ring. Lift the product to $h_{\lambda,I,\eta} \in C_\lambda$. If Q_I is a singleton, take $h_{\lambda,I,\eta} = 1$. The stratum is smooth over k, by étalebase change and smooth composition [StacksAlg, Tags 00U2, 036U]; it is reduced by [StacksAlg, Tag 056T]. The principal open thus has exactly the chosen minimal prime and is integral. It is nonempty, smooth, and contains η. In particular each chosen h is a nonzero element of $K(X)$.

Let A be the finite list consisting of F_0, nonzero algebra generators for the charts, their standard coordinates, and the chosen h's. For every $f \in A$ write $f = p_f/q_f$ with nonzero $p_f, q_f \in D$. This is possible because $\mathrm{Frac}(D) = K(X)$; denominators from K can be cleared by a power of π. For each λ, choose $b_\lambda \in D\backslash\{0\}$ whose principal generic open is contained in the nonempty open $\mathcal{V}_{\lambda,K}$ of $\mathcal{W}_K$. Such a principal open exists by the affine open basis; again clear a scalar denominator to put b_λ in D. Let P contain these b_λ, all p_f, q_f, and a finite nonzero generating set for D over O, and put $F = A \cup P$. Zero generators can be omitted.

Every point of S is a norm on $K(X)$ by Proposition 5.30.2. It consequently has generic scheme support and belongs to U^{an}. The elements b_λ give $U \subset \mathcal{V}_{\lambda,K}$. The Laurent coordinate map associated with F surjects onto $D_K[1/\prod P]$: its image contains the generators of D_K and the inverses of every member of P. This proves the closed immersion assertion. Finally all added rational coordinates have finite piecewise $v(K^\times)$-integral-affine values on S by the same proposition. Retaining F_0 retains injectivity and an integral left inverse on every tangent lattice. A common finite subdivision, followed by the integral graph argument in Theorem 5.30.3, gives the last assertion. □

Proposition 5.57.2 (A weighted chart with one residual component)**.** *Fix a chart* $\operatorname{Spec} C$*, a label* $\eta \in Q_I$*, and its separator* h*, and put* $E = (S_I)_{\bar{h}}$*. Choose* $c_i \in L^\times$ *with* $v(c_i) = w_i$ *and* $\prod_i c_i = a$*, taking* $c_j = 1$ *for* $j \notin I$*. Write* $l = \widetilde{L}$*.*

There is an admissible L°*-model* B_0 *of the actual domain in the completed chart over* L *given by*

$$|X_i| = |c_i| \quad (0 \le i \le r), \qquad |h| = 1.$$

Its special fibre is

$$\operatorname{Spec}(B_0/\mathfrak{m}_L B_0) \simeq E_l \times \mathbf{G}_{m,l}^{|I|-1}.$$

This fibre is smooth and geometrically reduced, and B_0 is the spectral unit ball of $B = B_0[1/\pi]$. Every Shilov point of $\mathcal{M}_L(B)$ restricts to s. Consequently, for every $g \in C$ nonzero as a rational function on X,

$$\rho_B(g) = |g(s)| > 0, \qquad |g(\xi)| = |g(s)| \quad (\xi \in \Gamma_B).$$

Proof. Use the separator supplied by Lemma 5.57.1. Choose $i_0 \in I$. Choose the c_i for $i \neq i_0$ first and then put $c_{i_0} = a/\prod_{i \neq i_0} c_i$. The relation $\sum_i w_i = v(a)$ gives its required norm. Consider the algebraic base change

$$A_w = L^\circ[U_0^{\pm 1}, \dots, U_r^{\pm 1}, T_1, \dots, T_q]/(\prod_i U_i - 1),$$
$$C_w = (C \otimes_R A_w)[1/h],$$
$$B_0 = \widehat{C_w},$$

where $X_i \mapsto c_i U_i$ and completion is π-adic. Eliminating U_{i_0} makes A_w a Laurent polynomial algebra with polynomial variables over L°; it is flat by the coefficientwise ideal criterion [StacksAlg, Tag 00HD]. The map $A_w \to C_w$ is étaleby [StacksAlg, Tag 00U2]. Thus C_w is finitely presented and flat over L°, and Lemma 4.13.1 applies.

Its explicit bounded-coordinate presentation imposes the original chart bounds, $|U_i| = 1$, and $|h^{-1}| \leq 1$. As h was already integral, these are exactly the displayed domain conditions. This proves the assertion about the actual analytic domain, with its analytic structure. On reduction, c_i vanishes for $i \in I$ and equals one for $i \notin I$. The coordinates U_j for $j \notin I$ are therefore the invertible stratum coordinates X_j. After eliminating U_{i_0}, the remaining U_i, $i \in I \setminus \{i_0\}$, are independent invertible variables. Reducing the displayed finite presentation gives precisely $E_l \times \mathbf{G}_{m,l}^{|I|-1}$, also for nondiscrete valuations: integral restricted series reduce to polynomials. Smoothness and geometric reducedness follow from [StacksAlg, Tags 00U2, 036U, 056T]. Lemma 4.12.1 identifies B_0 with B° and its special fibre with $\widetilde{B}$.

Let $\xi \in \Gamma_B$. Its reduction is a component generic point by Theorem 3.16.7. The reduced algebra is étale, hence flat, over $l[U_i^{\pm 1} : i \neq i_0, T]$ after the above identification. Flat going down, [StacksAlg, Tag 00HS], makes its minimal prime contract to the zero prime of this Laurent polynomial algebra. The image of ξ in its analytic unit polytorus times polydisc therefore reduces to the generic point. It is the Gauss point: divide any nonzero restricted series by a coefficient of maximum norm; its nonzero polynomial reduction cannot

vanish at that generic point. Polynomial approximation, or Proposition 1.2.2, gives the Gauss value for every series.

Restriction to K gives the standard point z_w. Moreover the reduction of ξ contracts to η in the original stratum. Indeed the field extension $k \to l$ is flat by [StacksAlg, Tag 00HD], and going down applied to $E_l \to E$ contracts a minimal prime to the unique minimal prime of E; adjoining the independent Laurent variables has the same property. Compatibility of algebraic completion, scalar extension and specialization is the explicit presentation comparison of Lemma 4.28.1. Proposition 5.24.2 now says that the restricted point is exactly $x_{\eta,w} = s$. Taking maxima on the finite Shilov boundary gives the last formula. Its value is positive by Proposition 5.30.2. □

Lemma 5.57.3 (Localization at a common Shilov value)**.** *Let L be complete and nontrivially valued, and let B_0 be an admissible L°-algebra with reduced special fibre, and put $B = B_0[1/\pi]$. Suppose $g_1, \dots, g_t \in B$ and $b_1, \dots, b_t \in L^\times$ satisfy*

$$|g_j(\xi)| = |b_j| \quad (\xi \in \Gamma_B, 1 \le j \le t).$$

Put $u_j = g_j/b_j$. Then $u_j \in B_0$, and

$$B_0' = B_0\langle V_1, \dots, V_t\rangle/(u_jV_j - 1 : 1 \le j \le t)$$

is an admissible model of the domain $|g_j| = |b_j|$ for all j. Its reduction is $\widetilde{B}[1/\bar{u}_1 \cdots \bar{u}_t]$, and this open meets every irreducible component, including every geometric component. Its Shilov points are the original Shilov points, regarded in the restricted domain. In particular a smooth special fibre remains smooth after this localization.

Proof. If $B = 0$, then $B_0 = 0$ by π-torsion-freeness, and every assertion is immediate. Assume $B \neq 0$. The Shilov maximum formula gives $\rho_B(u_j) = 1$, and Lemma 4.12.1 gives $u_j \in B_0$. At each component generic point its residue is nonzero by Theorem 3.16.7 and the equality $|u_j(\xi)| = 1$. Apply Proposition 3.17.1 successively. It gives the displayed admissible algebra, the exact domain $|u_j| = 1$, and the principal localization on reduction. Its special fibre is still reduced, so the reduced-model lemma and the generic-point theorem apply again. All original generic points survive. Their original analytic lifts belong to the restricted domain and are the unique lifts of those generic points. This identifies the Shilov boundaries.

After any field extension of the residue field, each minimal prime contracts to an original minimal prime by [StacksAlg, Tags 00HD, 00HS]. None can therefore contain any $\bar{u}_j$. Thus the localization retains every geometric component as well. Finally, restriction to an open preserves smoothness, as in [StacksAlg, Tag 036U]. □

Theorem 5.57.4 (Actual initial models along a projective skeleton)**.** *In the stated model setting, the tuple F of Lemma 5.57.1 can be chosen so that the resulting closed immersion $\varphi : U \hookrightarrow \mathbf{G}_{m,K}^{N}$ has the following additional property. Let $s \in S$, put $\omega = \mathrm{trop}_{\varphi}(s)$, and choose a refined chart containing its specialization, with label (I, η). For every complete isometric L/K realizing the coordinates of ω in its value group, the actual initial scheme of U_L at ω is isomorphic to a principal open of*

$$E_{\lambda,I,\eta,\widetilde{L}} \times \mathbf{G}_{m,\widetilde{L}}^{|I|-1}$$

which meets every geometric irreducible component. In particular this initial scheme is smooth and geometrically reduced. The quotient norm of the normalized tropical-fibre presentation is its spectral norm, and its integral quotient model is the spectral unit ball.

Proof. Use precisely the finite lists constructed in Lemma 5.57.1. Fix s and its chart, and write $h = h_{\lambda,I,\eta}$. The normalization field L exists by Theorem 5.13.6; the argument below works for every such L. Choose the standard-coordinate normalizers with product a_λ as in Proposition 5.57.2. Let B_0 be that proposition's selected weighted model.

We first locate the entire tropical fibre. Every point of the actual fibre

$$Y_\omega = \mathrm{trop}_{\varphi}^{-1}(\omega) \subset U^{\mathrm{an}}$$

has, on every algebra generator of the selected chart, the same absolute value as s, which is at most one. Algebraically U is contained in this chart by construction. Hence the actual bounded-coordinate description of Lemma 4.13.1 puts the entire fibre inside the completed chart. The coordinates X_i impose its weights w_i, and the coordinate h imposes $|h| = |h(s)| = 1$. The same argument over L places the entire base-changed fibre in $\mathcal{M}_L(B_0[1/\pi])$. This also shows explicitly how points outside the selected formal chart are excluded: their chart-generator norms cannot satisfy all these equalities.

For each $p \in P$, choose $b_p \in L^\times$ with $|b_p| = |p(s)|$. The function p is regular on this chart because $\mathcal{V}_\lambda \subset \mathcal{W}$. Proposition 5.57.2 gives this same norm at every Shilov point of $B_0[1/\pi]$. Lemma 5.57.3 therefore gives

$$B_0' = B_0\langle V_p : p \in P\rangle/((p/b_p)V_p - 1 : p \in P).$$

Its reduction is a principal open of the stated smooth product and meets every geometric component.

Its generic fibre is exactly $Y_{\omega,L}$. In one direction this follows from the preceding containment and the equalities $|p| = |p(s)|$. In the other direction those equalities make all members of P invertible and thus put a point in U_L^{an}. Every remaining coordinate of F is p_f/q_f with $p_f, q_f \in P$, so it has the required absolute value as well. The presentations of rational domains identify the analytic structures, not only the sets of points; equivalently, use Proposition 2.33.12 and the universal property of these displayed equations.

It remains to identify the integral model with the actual initial quotient. Choose normalizers b_f for all coordinates of F. Changing them by norm-one constants only changes torus coordinates. Put

$$T_0 = L^\circ\langle Z_f^{\pm 1} : f \in F\rangle, \qquad T = T_0[1/\pi], \qquad Z_f \longmapsto f/b_f.$$

All these images and their inverses belong to B_0'. For $f = p_f/q_f$ this follows by using the normalized p_f, q_f and a norm-one scalar. The map $T_0 \to B_0'$ is surjective, as can be checked on its actual restricted presentation. Every chart algebra generator u is the image of $b_u Z_u$, with $b_u \in L^\circ$ because $|u(s)| \leq 1$. Every $U_i^{\pm 1}$ is the image of $Z_{X_i}^{\pm 1}$ multiplied by a norm-one scalar. The generator h^{-1} is the image of a norm-one scalar times Z_h^{-1}. Finally the generators $(p/b_p)^{-1}$ are the images of Z_p^{-1}. These are all the generators in the displayed construction of B_0'. Their lifts are integral Laurent polynomials of Gauss norm at most one. Substitution lifts every integral restricted series in them to T_0, by Proposition 1.2.3. Thus the map is surjective, rather than merely having dense image.

Let $\mathfrak{a}$ be the algebraic ideal of the closed immersion $U_L \hookrightarrow \mathbf{G}_{m,L}^N$, in these normalized coordinates. Proposition 5.13.2 identifies the generic map with

$$T/\mathfrak{a}T \;\simeq\; B_0'[1/\pi].$$

Since B_0' is L°-flat and is embedded in its generic algebra, the kernel of $T_0 \to B_0'$ is precisely $\mathfrak{a}T \cap T_0$. Consequently

$$T_0/(\mathfrak{a}T \cap T_0) \;\simeq\; B_0'.$$

Proposition 5.13.5 identifies the reduction of this quotient with the actual initial scheme of the algebraic immersion. Its special fibre was computed above. Lemma 4.12.1 now identifies the quotient norm with the spectral norm and the quotient model with the spectral unit ball. The arbitrary-real-weight interpretation and independence of normalization are those of Theorem 5.13.6; the calculation has retained every component throughout. □

Corollary 5.57.5 (Shilov fibres and geometric generic lengths)**.** *For the immersion of Theorem 5.57.4, the original-K tropical fibre at $\operatorname{trop}_{\varphi}(s)$ has Shilov boundary $\{s\}$ for every $s \in S$. The inverse of the faithful map on S is therefore a continuous section over $\operatorname{trop}_{\varphi}(S)$ selecting the unique Shilov point.*

For $s = x_{\eta,w}$, let g_{η} be the number of irreducible components of $E_{\lambda,I,\eta,\bar{k}}$, where $\bar{k}$ is an algebraic closure of k. After any normalization and algebraically closed residue extension, the sum of the generic component lengths of the actual initial scheme at $\operatorname{trop}_{\varphi}(s)$ equals g_{η}. In particular this sum is one if the corresponding residual component is geometrically integral. If every residual component in these charts is geometrically integral, this conclusion holds at every point of S. At weights lying in relative interiors of maximal tropical cells, the sum is the tropical multiplicity of Proposition 5.19.7.

Proof. Normalize the weights over a complete isometric extension L/K. Theorem 5.57.4 and Lemma 5.57.3 identify the Shilov points of the base-changed fibre with those of the selected weighted chart. Every one restricts to s by Proposition 5.57.2. For any analytic function g on the original tropical fibre, its base change consequently satisfies

$$\max_{Y_{\omega,L}} |g| = |g(s)|.$$

The map $Y_{\omega,L} \to Y_{\omega}$ is surjective by Theorem 2.33.13, with scalar compatibility supplied by Proposition 5.13.2. The same maximum formula therefore holds on Y_{ω}. The singleton $\{s\}$ is a boundary, and the existence and minimality of the Shilov boundary in Corollary 3.12.5 give the assertion. The faithful map on the compact S is a homeomorphism onto its image, so its inverse is continuous and has the stated values.

Over an algebraically closed residue field the initial scheme is smooth and hence reduced. Each of its generic local rings is consequently a field and

has length one. The principal localization in Theorem 5.57.4 removes no geometric component. Taking the product with a split torus changes no component count: the Laurent polynomial ring of an integral component is a domain, and the finite minimal-prime decomposition gives all components this way.

For completeness, this count is unchanged by extending the algebraically closed residue field. Every irreducible component over an algebraically closed field is geometrically irreducible by [StacksAlg, Tag 020J]. Thus its base change remains irreducible. The components stay distinct and incomparable: contraction of a prime under a field extension preserves their original defining prime, by faithful flatness of a nonzero extension of fields and [StacksAlg, Tags 00HD, 00HP, 00HQ]. Their finite union still covers the base change. To compare k with the residue field l of a chosen normalization, take an algebraic closure of l and inside it the algebraic closure of k consisting of elements algebraic over k. Applying the preceding argument gives exactly g_η. The asserted length sum follows. For a maximal-cell weight, Proposition 5.19.7 identifies this sum with its registered tropical weight. □

References. This construction reconstructs the rational-coordinate and initial-fibre methods of Gubler–Rabinoff–Werner, *Skeletons and tropicalizations*, arXiv:1404.7044v3, Sections 9–10, in the stated projective algebraic model scope. The non-Archimedean inputs are the internally proved results cited above. The scheme-theoretic initial quotient is identified by its integral presentation, and the arithmetic component count is retained; no independent-priority claim is made.

Chapter 6

Charts, skeleta and faithful tropicalization

Chapter 4 constructed the annular and semistable curve skeleta. We use them here to compare tropical maps, integral lattice indices and canonical analytic lifts. Section 3.8 supplies the residue-dimension calculation for the higher-dimensional local model.

6.1 Skeleta and tropical images

6.1.1 The Gauss section of a torus

For $w \in N_{\mathbb{R}}$, define a weighted Gauss norm on the Laurent algebra by

$$\left| \sum_{m} a_m \chi^m \right|_{\sigma(w)} = \max_{m} |a_m| e^{-\langle m, w \rangle}. \tag{6.1.1}$$

It is a multiplicative norm and therefore a point of T^{an}. The minus sign in the exponential is forced by $v = -\log|\cdot|$. In particular,

$$-\log|\chi^m|_{\sigma(w)} = \langle m, w \rangle, \qquad \mathrm{trop} \circ \sigma = \mathrm{id}_{N_{\mathbb{R}}}.$$

The set $S(T) = \sigma(N_{\mathbb{R}})$ is the torus skeleton. The map σ is continuous and identifies $N_{\mathbb{R}}$ with this subset of T^{an}; a separate deformation-retraction theorem makes $\sigma \circ \mathrm{trop}$ a strong deformation retraction. Having a section alone would not prove that theorem.

Equation (6.1.1) also gives the exact identity

$$-\log|f|_{\sigma(w)} = F_f(w).$$

The Gauss norm retains the largest size among the terms, even when several sizes agree. It does not perform the cancellation that can occur at other points in the same tropical fibre.

References. [GRW16, Sections 3–4]; Proposition 5.5.1.

Example 6.1.1 (The ambient section misses the hypersurface)**.** Let $X = V(1 + z_1 + z_2) \subset \mathbb{G}_m^2$. For every $w \in \mathbb{R}^2$,

$$|1 + z_1 + z_2|_{\sigma(w)} = \max(1, e^{-w_1}, e^{-w_2}) > 0.$$

Thus $\sigma(w) \notin X^{\mathrm{an}}$, including when $w \in \mathrm{Trop}(X) = L$. A point of X^{an} must annihilate its defining equation. The ambient Gauss point does not.

Consequently, restricting σ to L does not produce a section $L \to X^{\mathrm{an}}$. A section for a subvariety, when a theorem supplies one, must choose different analytic points. Likewise, the ambient torus deformation retraction need not preserve X^{an}.

This elementary example is a useful safeguard. The tropicalization is a subset of a real vector space; a skeleton is a subset of an analytic space. A map can identify suitable pieces of them, but the identification is additional structure or an additional theorem.

6.1.2 Annuli, lengths, and integral slopes

The annular skeleton and its retraction were constructed in Section 4.3 and illustrated in Figure 4.1. Its coordinate $t = -\log|T|$ has integral slope one. We now compare the logarithmic metric with lattice indices and model multiplicities.

For the local semistable equation $UV = a$, with $0 < |a| < 1$, the annular skeleton has coordinate $t = v(U)$ and interval

$$0 \le t \le v(a), \qquad v(V) = v(a) - t.$$

If $a = \pi^b$ over a discretely valued field, its length is $b\lambda$, where $\lambda = -\log|\pi|$. It becomes b only after the explicit normalization $\lambda = 1$.

For a curve with a chosen semistable model, annular pieces assemble into a metric graph. Over a non-algebraically-closed residue field, residual degrees can contribute weights to its slope formulas. The model, the graph, its metric, and these weights must all be specified. A smallest skeleton need not contain enough cells to represent every differential form: a curve with good reduction can have a one-point minimal skeleton, although its local differential calculus is not zero.

There are also several kinds of boundary. The endpoints of a closed annulus belong to its analytic boundary, whereas an open annulus is boundaryless. A facet in a chosen polyhedral subdivision is a combinatorial notion. A component removed from an algebraic compactification is yet another notion. Balancing away from an analytic boundary cannot be silently applied at the endpoint of a restricted annulus.

References. [GRW16, Sections 3–4 and 9–10].

For a discretely valued field with uniformizer π, write $\lambda = -\log|\pi|$. The annulus $|\pi|^m \le |T| \le 1$ has length $m\lambda$. Its integral slope for the function $-\log|T|$ is one, while the change in function value is $m\lambda$. The integer m, the real length, and the slope are different quantities. If an algebraic intersection length is m, the associated logarithmic height has the factor λ in this normalization. By contrast, the total mass of the Chern measure of a degree-one model line is one.

Example 6.1.2 (Power maps on annuli)**.** Let $0 < r < R$ and $d \ge 1$. The map $T \mapsto T^d$ takes $A[r, R]$ to $A[r^d, R^d]$. If $t = -\log|T|$, the target skeletal coordinate is dt. Thus the target interval has d times the source length, and the image of the source integral tangent lattice has index d in the target lattice. The map is finite of degree d: the equation $T^d = S$ is monic and the source algebra is free of rank d over the target algebra. This includes the inseparable case. The integral slope and algebraic degree retain the multiplicity that a count of distinct fibres can miss.

6.1.3 A semistable local model and its simplex

Over a discretely valued field, a basic strictly semistable model has an étale local chart

$$\operatorname{Spec}\big(K^\circ[x_0, \dots, x_d]/(x_0 \cdots x_r - \pi)\big), \qquad 0 \le r \le d.$$

Write $\lambda = v(\pi) > 0$. Its skeleton is locally described by

$$t_i = v(x_i) \geq 0, \qquad \sum_{i=0}^{r} t_i = \lambda.$$

This is an r-simplex. Its dimension is r, while the generic fibre has dimension d. The remaining coordinates describe directions not recorded by this simplex.

On the special fibre, the equation becomes $x_0 \cdots x_r = 0$: the components are the coordinate hyperplanes. Their intersections are normal-crossing strata. For $r = 1$ the transversal picture is a node; for larger r, several components meet normally. These semistable equations control the singularities of the special fibre. Over a general valuation ring we do not additionally assert that the underlying formal model is a noetherian regular scheme. A stratum where more components meet corresponds to a simplex of higher dimension. Thus a skeleton records incidence and valuation data, not every residual algebraic direction.

6.1.4 Faithful tropicalization and multiplicity-one sections

In this subsection, let K be complete, algebraically closed, and nontrivially valued. Let $(\mathfrak{X}, H)$ be a strictly semistable pair in the proper algebraic setting of Gubler–Rabinoff–Werner. Its skeleton $S(\mathfrak{X}, H)$ lies in the analytic generic fibre, with unbounded directions when the horizontal divisor H is present. A tropicalization is *faithful* on this skeleton if it is injective there and unimodular on its polyhedral pieces: it preserves the integral tangent lattices, not just the topology.

Theorem 6.1.3 (GRW, Theorem 9.5)**.** *In the strictly semistable-pair setting of [GRW16], there exists a finite collection of nonzero rational functions on the generic fibre whose tropicalization is faithful on $S(\mathfrak{X}, H)$.*

The rational functions are regular units on a suitable dense open containing the relevant skeletal points. The assertion does not say that every preassigned moment map is faithful. Nor does it say that the entire analytic space is homeomorphic to the skeleton. The added rational functions can have divisors outside H; the resulting tropicalization need not factor through the skeletal retraction [GRW16, Remark 9.6].

A different theorem starts with an embedding of a very affine integral variety into a torus. On a subset Z of its tropicalization where the tropical

multiplicity is one, each tropical fibre has a unique Shilov boundary point. These points give a continuous partial section $Z \to X^{\mathrm{an}}$. If Z is contained in the closure of its interior in the whole tropicalization, this is the unique continuous section on Z [GRW16, Theorem 10.6]. This statement concerns multiplicity-one fibres, and is not obtained by restricting the ambient torus Gauss section.

On a curve with good reduction, a natural compact skeleton may consist of one point. If all differential forms factored through that point, every positive-degree form would vanish. Local annular and punctured-disc domains still admit nonconstant tropical coordinates and nonzero forms. Therefore global factorization through a chosen small skeleton is a property of special data, not a general consequence of the existence of a skeleton.

6.1.5 Payne's inverse limit: what is recovered

For a quasiprojective variety over a complete algebraically closed nontrivially valued field, Payne identifies its analytification with the inverse limit of extended tropicalizations over the appropriate system of toric embeddings:

$$X^{\mathrm{an}} \simeq \varprojlim_{\iota} \mathrm{Trop}_{\iota}(X).$$

This is a homeomorphism of topological spaces [Pay09, Theorem 4.2]. The transition maps remember how a larger collection of characters projects to a smaller one.

The reason a whole system is needed can already be seen in one tropical fibre. A fixed tuple of values $|f_i(x)|$ may be shared by many analytic points. Adding more functions can distinguish them. The inverse limit requires compatible values for all such choices and recovers the seminorm, whereas one finite tropicalization records only part of it.

There are three different questions here:

Question	Additional structure needed
Recover the underlying topology	The inverse system of extended tropicalizations.
Recover analytic functions and their norms	Analytic or formal models and compatible sheaves; a bare topological homeomorphism is insufficient.
Recover forms, currents, and their operations	Test spaces, quotient relations, refinements, and continuity of the operations.

A smooth form has locally finite tropical presentations by definition. This fact is not a consequence that every current factors through one finite tropicalization. Likewise, a Hodge theorem on selected tropical spaces does not automatically pass through this inverse limit: the relevant complexes, transition maps, cohomology, and exactness must first be compared.

6.2 Fans and extended tropicalization: keeping the boundary

6.2.1 Cones specify which limits are admitted

A torus excludes the zero and pole loci of its characters. This is convenient locally, but a projective variety cannot in general be embedded in one torus. To describe a compactification, tropical geometry must allow some character valuations to tend to $+\infty$.

A rational polyhedral cone $\sigma \subset N_{\mathbb{R}}$ is generated by finitely many lattice vectors with nonnegative real coefficients. It is strongly convex if it contains no line. Its dual cone and character monoid are

$$\sigma^{\vee} = \{m \in M_{\mathbb{R}} : \langle m, w\rangle \geq 0 \text{ for every } w \in \sigma\}, \qquad S_{\sigma} = \sigma^{\vee} \cap M.$$

The associated affine toric variety is

$$U_{\sigma} = \operatorname{Spec} K[S_{\sigma}].$$

The monoid consists precisely of the characters permitted to extend as regular functions on this affine chart. For $\sigma = \mathbb{R}_{\geq 0} \subset \mathbb{R}$, it is $\mathbb{N}$, and $U_{\sigma} = \mathbb{A}^1$; for the zero cone it is all of M, and the chart is the torus.

A fan Σ is a finite collection of strongly convex rational polyhedral cones, closed under faces, with pairwise intersections common faces. The affine

varieties U_σ glue to the normal toric variety X_Σ. A cone of dimension k corresponds to a torus orbit of dimension $r-k$. The fan is complete if its support is all of $N_\mathbb{R}$; this is equivalent to properness of X_Σ.

Two adjectives must be separated. A cone is *simplicial* when its ray generators are linearly independent over $\mathbb{R}$. It is *smooth* or unimodular when its primitive ray generators are part of a $\mathbb{Z}$-basis of N. The cone spanned by $(1,0),(1,2)$ is simplicial but not smooth. This distinction matters when a theorem assumes a simplicial fan: it has not thereby assumed a smooth toric variety.

References. [Gub13, Section 6.2–6.3 and Appendix A]; [GK17, Appendix A.7].

6.2.2 The topology is part of the construction

Set $\mathbb{R}_\infty = \mathbb{R}\cup\{+\infty\}$, with addition extended by $a+\infty=\infty$. Neighbourhoods of $+\infty$ contain a tail $(c,+\infty]$. The map $t\mapsto e^{-t}$, with $e^{-\infty}=0$, identifies this space with $\mathbb{R}_{\geq 0}$.

Definition 6.2.1 (Extended tropicalization of a toric chart)**.** Define

$$U_\sigma^{\mathrm{trop}} = \mathrm{Hom}_{\mathrm{mon}}(S_\sigma, \mathbb{R}_\infty),$$

where a monoid homomorphism is additive and sends 0 to 0. Give this set the topology of pointwise convergence. A finite set of monoid generators realizes it as a subspace of a finite product of copies of $\mathbb{R}_\infty$.

For a global fan these extended charts assemble into the space

$$N_\Sigma = \coprod_{\sigma\in\Sigma} N(\sigma), \qquad N(\sigma) = N_\mathbb{R}/\operatorname{span}_\mathbb{R}(\sigma). \tag{6.2.1}$$

The extended charts glue along the opens associated to common faces, giving the topology on this disjoint union. It is not the disjoint-union topology. The stratum $N(0)=N_\mathbb{R}$ is dense, and a sequence can converge from it to a lower-dimensional stratum.

For $x\in U_\sigma^{\mathrm{an}}$, the rule

$$m \longmapsto -\log|\chi^m(x)|, \qquad -\log 0 = +\infty,$$

is a monoid homomorphism and gives the extended tropicalization map. These maps glue to $X_\Sigma^{\mathrm{an}}\to N_\Sigma$. The orbit corresponding to σ maps to $N(\sigma)$. For a closed subvariety of X_Σ, its extended tropicalization is the image under this map.

References. [Pay09, Section 3, especially Remark 3.1]; [BGK25, Section 1.13].

Example 6.2.2 (The line, affine line and projective line)**.** For $\mathbb{G}_m$, the target is $\mathbb{R}$. For $\mathbb{A}^1$ with coordinate T, it is $\mathbb{R} \cup \{+\infty\}$, and $T = 0$ maps to $+\infty$. For $\mathbb{P}^1$, the two rays of its complete fan add two endpoints:

$$N_\Sigma = \mathbb{R} \cup \{-\infty, +\infty\}.$$

The point $T = 0$ corresponds to $+\infty$; the point $T = \infty$, with local coordinate T^{-1}, corresponds to $-\infty$. These are toric boundary points. The proper analytic space $\mathbb{P}^{1,\mathrm{an}}$ itself has empty analytic boundary.

For $\mathbb{P}^2$, use the dense-torus coordinates $z_1 = X_1/X_0$, $z_2 = X_2/X_0$, with $x = v(z_1)$, $y = v(z_2)$. Its fan has rays $(1,0), (0,1), (-1,-1)$, and its maximal cones are the sectors between consecutive rays. The extended tropicalization has one dense $\mathbb{R}^2$, three one-dimensional strata $\mathbb{R}$, and three zero-dimensional strata. A useful topological model is the closed triangle

$$(x, y) \longmapsto \frac{(1, e^{-x}, e^{-y})}{1 + e^{-x} + e^{-y}}.$$

The interior is $\mathbb{R}^2$, open sides are the one-dimensional strata, and vertices are the zero-dimensional strata. This model is a homeomorphism, not an identification of integral affine structures with the usual affine structure of a bounded triangle.

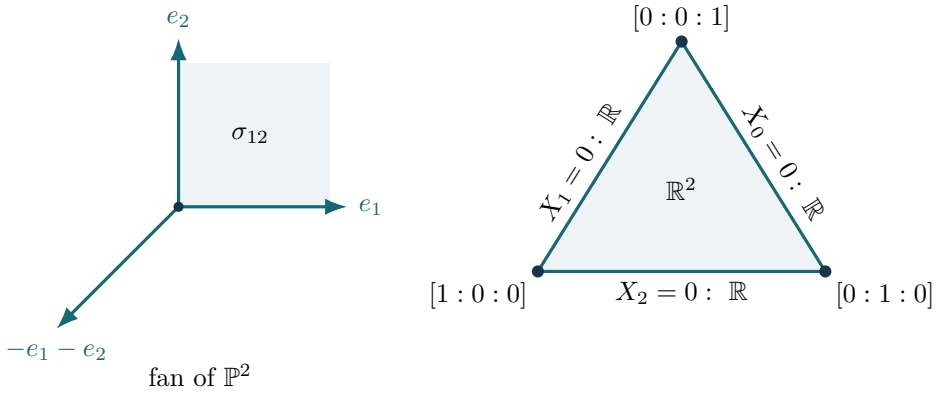

Figure 6.1: A cone of dimension k produces a boundary stratum of dimension $2 - k$. Thus the two-dimensional cone σ_{12} gives the vertex $[1:0:0]$, while the ray e_1 gives the open side $X_1 = 0$. The triangle records topology and strata.

6.2.3 Boundary compatibility and Green functions

A function or form defined on the dense $N_{\mathbb{R}}$ need not extend across these strata. The smooth tropical calculus imposes compatibility with projection to the lower-dimensional stratum: near the boundary, the form must come from that stratum in the directions that disappear. On $\mathbb{R}_{\infty}$, an ordinary smooth function in this sense is constant for all sufficiently large t, locally near $+\infty$; a positive-degree form vanishes there. A function such as t instead has the affine growth expected of a Green potential for a boundary divisor.

This is why extended tropicalization contributes more than a compact picture. It records where a divisor lies and what growth a Green function must have. BGK25 develops the compatible delta-calculus, Green functions and star-products needed to compute local heights on a suitable tropical toric compactification. Its subdivision theorems and boundary conditions are additional results; the affine stable-intersection construction alone does not supply them.

There is a complementary global lesson. Over a complete, algebraically closed, nontrivially valued field, Payne's theorem identifies the analytification of a quasiprojective variety with the inverse limit of its extended tropicalizations over all quasiprojective toric embeddings. One tropicalization forgets information; the compatible system recovers it. This topological reconstruction does not say that every current, metric or potential is represented on a single finite tropicalization.

References. [Pay09, Theorem 4.2]; [BGK25, Sections 1.7–1.11 and 3]. For a systematic further introduction, see [MS15].

Example 6.2.3 (Limits in the extended tropical plane)**.** In the triangle coordinates above, the sequences (n, n), $(n, 0)$, and $(-n, -n)$ have respective limits

$$(1, 0, 0), \qquad (1/2, 0, 1/2), \qquad (0, 1/2, 1/2).$$

The first sequence escapes through the interior of the cone generated by e_1, e_2 and reaches its zero-dimensional stratum. The second escapes along the ray e_1 and reaches the one-dimensional stratum $X_1 = 0$. The third escapes along $-e_1 - e_2$ and reaches the one-dimensional stratum $X_0 = 0$. A divergent sequence need not approach a toric fixed point.

6.3 Skeleta, slope formulas, and tropical degree

6.3.1 Skeleta of semistable pairs

For a strictly semistable pair $(\mathfrak{X}, H)$, the skeleton is assembled from the standard simplices of local semistable equations, with unbounded directions contributed by the horizontal divisor H. Its faces correspond to strata. The resulting integral-affine structure remembers the orders of vanishing of functions along model components and horizontal divisors.

In dimension one this is a metrized graph. In higher dimension, the normal direction along a codimension-one face carries data involving the neighbouring strata and intersection numbers. The higher-dimensional slope formula is therefore not obtained by summing arbitrary Euclidean normal derivatives. The model geometry specifies the correct weights and normalizations.

6.3.2 Slope formulas and principal divisors

If a rational function has divisor supported in the allowed boundary, its logarithmic absolute value restricts to an integral-affine function on each canonical cell of the skeleton. The slope formula expresses the balancing of its divisor data. On a curve it reduces to the familiar sum of outgoing slopes. In higher dimension it uses the incidence and intersection data of the semistable model.

This result is a bridge between algebraic principal divisors and tropical principal divisors. It tells us that the polyhedral data obtained from an analytic function obey the conservation law needed for integration. Conversely, an arbitrary PL function on a chosen skeleton need not be the logarithm of one analytic unit on a neighbourhood; lifting prescribed slopes is a separate problem.

6.3.3 The Sturmfels–Tevelev mechanism

For a generically finite map between suitable varieties in tori, the pushforward of the tropical cycle carries lattice-index weights. In a region where the map is combinatorially well behaved, the target weight is obtained by summing

$$m_\sigma[N_\tau : F(N_\sigma)]$$

over source cells mapping onto the target cell, with the generic degree of the algebraic map accounted for in the cycle pushforward formula. This is the tropical version of counting sheets of a finite map, including ramification and multiplicity.

GRW develops related degree formulas for skeleta and tropicalizations. The lesson for CLD is direct: if a form is presented by a larger moment map and then projected, the calibrated integral must transform by precisely these degrees. The lesson for GK is equally direct: a tropical intersection product has to descend through the same refinement maps.

6.3.4 Existence and scope of faithful tropicalization

The faithful tropicalization theorem says that suitable rational functions can be chosen so that a specified skeleton is mapped injectively and unimodularly on its cells. It does not say that every tropicalization is faithful. Nor does it say that an arbitrary analytic datum factors through the retraction to that skeleton.

The distinction can already be seen on an annulus: the coordinate T^m has slope m and fails unimodularity when $|m| > 1$ as an integer lattice index, while T supplies the primitive parameter. Additional functions can separate cells that a first tropicalization identifies. In higher-dimensional proofs, constructing enough such functions is a geometric theorem involving models and rational functions.

The rational functions supplied for faithfulness may have divisors outside the original boundary divisor. Therefore the theorem should not be strengthened to a global factorization through the original skeleton without checking the actual functions and their domains.

6.3.5 Multiplicity one and the tropical skeleton

For a tropical fibre of multiplicity one, the unique Shilov boundary point gives a canonical candidate for a section of tropicalization. The continuity theorem in GRW applies on the multiplicity-one locus in its stated setting. The stronger uniqueness assertion for a continuous section includes an additional closure-of-interior hypothesis. These are different assertions.

The later paper *Tropical Skeletons* studies the collection of Shilov boundary points of tropical fibres and its topology and functorial behaviour. This is

a more intrinsic construction relative to a tropicalization than simply choosing a semistable skeleton in advance. It helps explain when combinatorial points have canonical analytic lifts.

For the differential calculus, however, even a canonical section of one tropicalization does not eliminate all other charts. Equality of currents still requires every actual test. Chapter 24 explains why a topological inverse-limit theorem or a faithful section does not by itself transfer a Hodge theory.

References. [GRW16, Theorems 6.12, 8.4, 9.5 and 10.6]; [GRW17]; [Gub13].

Tropical contractions and SYZ fibrations. Yamamoto's 2026 theorem gives a further geometric use of tropicalization. For the Batyrev–Borisov degenerations over $k((t))$ specified in [Yam26, Section 3], with k algebraically closed of characteristic zero, a good unimodular subdivision and irreducible generic fibre, tropicalization identifies the essential skeleton piecewise integrally affinely with the dual intersection complex. Composing with a tropical contraction gives an affinoid torus fibration off its discriminant, with the prescribed integral affine structure [Yam26, Theorem 1.1]. This is a structured degeneration theorem; it supplies no general descent theorem for CLD currents or cohomology.

6.4 Recovering an affine analytification from finite coordinate data

Payne's theorem has a useful elementary core: every seminorm identity involves only finitely many functions. We prove a precise affine version using actual tropical images. This also identifies the point at which a topological reconstruction stops short of a differential or cohomological reconstruction.

Let A be a finitely generated reduced K-algebra and $X = \operatorname{Spec} A$. Fix a finite set F_0 of algebra generators. Let $\mathscr{F}$ be the directed set of finite subsets $F \subset A$ containing F_0. The functions in F give a closed embedding $\iota_F : X \hookrightarrow \mathbb{A}^F$. Use absolute-value coordinates and set

$$T_F = \{(|f(x)|)_{f\in F} : x \in X^{\mathrm{an}}\} \subset \mathbb{R}^F_{\geq 0}.$$

For $F \subset G$, coordinate projection maps T_G onto T_F. With $v = -\log|\cdot|$, the same construction takes values in $(\mathbb{R} \cup \{+\infty\})^F$. The value $+\infty$ records a zero and is essential for embeddings into affine space.

Theorem 6.4.1 (Affine coordinate reconstruction)**.** *The natural map*

$$\Phi : X^{\mathrm{an}} \longrightarrow \varprojlim_{F \in \mathscr{F}} T_F$$

is a homeomorphism. Here the analytic space on the left is described by multiplicative seminorms on A extending the absolute value of K, and every T_F is the actual image defined above.

Proof. A point in the inverse limit gives compatible numbers $s_f \geq 0$ for every $f \in A$: choose a finite F containing f and read its coordinate. Directedness and compatibility show that the answer does not depend on the choice. For $a, b \in A$, choose one finite set containing $a, b, a+b, ab, 0, 1$. Its coordinate vector belongs to T_F, so it is realized by an analytic point. Consequently

$$s_0 = 0, \quad s_1 = 1, \quad s_{ab} = s_a s_b, \quad s_{a+b} \leq \max(s_a, s_b).$$

Adding any $c \in K$ to the finite set gives $s_c = |c|$. Hence $f \mapsto s_f$ is a multiplicative seminorm extending K, and determines a point of X^{an}. Its image is the original compatible family. This proves surjectivity. If two analytic points have the same family, they have the same value on every $f \in A$, so they are the same seminorm. This proves injectivity.

Every coordinate of Φ is an evaluation map, so Φ is continuous. Conversely, the topology of X^{an} is generated by all evaluations $x \mapsto |f(x)|$, and each of these is a coordinate projection from some T_F. The inverse map is therefore continuous. No compactness assumption on X^{an} is needed for this final step. □

The proof uses actual images, not an unproved identification with a combinatorial tropical variety. The theorem equating analytic images with algebraically defined tropicalizations is a separate input. Likewise, gluing affine descriptions into the toric-embedding formulation for a quasiprojective variety is the content of the global theorem cited in Section 6.1.5. Keeping these ingredients separate makes the reconstruction argument reusable.

Proposition 6.4.2 (Finite-coordinate neighbourhoods)**.** *Every ordinary neighbourhood of a point in X^{an} contains a neighbourhood defined by finitely many conditions on values $|f_i|$. On the open subset where all f_i are nonzero, these conditions can be written using a finite tropicalization by analytic units.*

Proof. The evaluation topology has a subbasis consisting of inverse images of open subsets of $\mathbb{R}_{\geq 0}$ under single evaluations. Finite intersections form a basis, proving the first assertion. On the common nonvanishing locus, each regular f_i is an analytic unit and the change of coordinate $s \mapsto -\log s$ is a homeomorphism from $\mathbb{R}_{>0}$ to $\mathbb{R}$. This gives the second assertion. If some f_i vanishes at the point, extended coordinates or a different local construction are required; deleting that coordinate would discard information. □

6.5 What a refinement must preserve

The preceding theorem recovers points and topology because their defining relations are finite. Differential forms involve an additional quotient: two presentations may agree after restriction to tangent spaces of the tropical support. Integration also involves weights, and current convergence involves a test topology. These three structures cannot be read from the underlying inverse-limit topology alone.

Example 6.5.1 (A homeomorphism that loses the lattice)**.** The map $F : \mathbb{R} \to \mathbb{R}$, $t \mapsto 2t$, is a homeomorphism and is integral affine, but its tangent-lattice map $\mathbb{Z} \to \mathbb{Z}$ has index two. For a top superform $\alpha = a(y)d'y \wedge d''y$,

$$\int_{\mathbb{R}} F^*\alpha = 2\int_{\mathbb{R}} \alpha.$$

Thus topological injectivity does not give unimodularity, nor does it preserve calibrated integration with weight one. This is why faithful tropicalization includes an integral-affine requirement.

Example 6.5.2 (One tropical coordinate does not determine all tests)**.** On the analytic torus with coordinate z, the map $x \mapsto -\log|z(x)|$ forgets the values of $z - a$ for $a \in K^\times$. On the open locus $z \neq a$, the latter function is a unit and produces the additional smooth coordinate $-\log|z-a|$. Points with the same $|z|$ can have different $|z - a|$. A test depending on this additional coordinate therefore need not be a pullback from the first tropical line. An identity checked only against functions of $-\log|z|$ has not yet been checked against all original smooth tests.

To pass a calculation through chart refinements, one consequently needs: pullback preserving the quotient of forms; compatibility of d' and d'' with that

pullback; the weighted pushforward formula for integration; and continuity on the chosen spaces of compactly supported tests. Chapters 7–9 establish or explicitly import these ingredients in their stated categories. An inverse limit of spaces supplies none of them merely by being a homeomorphism.

The same distinction applies to cohomology. A direct limit of complexes requires actual transition maps of complexes. An identification with a complex on X^{an} then requires exactness or a comparison argument, and a statement about cohomology requires a further passage through kernels and images. This is why a tropical Hodge theorem cannot be transferred to Berkovich cohomology solely by citing Payne's topological theorem. It does not make such a transfer impossible; it specifies the additional mathematical work.

References. [Pay09, Theorem 4.2]; [GRW16, Sections 9–10]. The affine reconstruction above is proved directly for the explicitly defined system of actual images.

6.6 Tropical fibres and their Shilov points

Section 3.4 established the criterion for a singleton Shilov boundary. We now apply it to tropical fibres, using the formal-model comparison rather than identifying two different reductions. Now let U be an integral closed subvariety of a split torus over a complete, algebraically closed, nontrivially valued field. For a tropical point w with coordinates in the value group, the fibre U_w is strictly affinoid. Its algebra A_w is a quotient of a Laurent affinoid algebra. Distinguish its quotient Gauss norm from its spectral seminorm:

$$\|f\|_{\mathrm{quot}} = \inf_{g \mapsto f} \|g\|_w, \qquad \|f\|_{\mathrm{sp}} = \sup_{x \in U_w} |f(x)|.$$

A quotient norm is submultiplicative and need not itself be an analytic point. The polyhedral formal model has the initial degeneration as special fibre; the canonical formal model has the canonical reduction as special fibre. The latter is reduced, and these two special fibres need not agree.

GRW Sections 10.2–10.5 supply a finite comparison of the two formal models and the associated special-fibre projection formula. Under equidimensionality, tropical multiplicity one forces a single component of the canonical reduction, hence a singleton Shilov boundary. The unique point is the spectral seminorm. Identifying it with the quotient norm requires the stronger

reducedness condition on the initial degeneration. For arbitrary real w, the valued-extension and boundary-descent results are additional inputs. This discussion separates the geometric theorem from the elementary norm argument above.

6.7 Adding coordinates without changing the lattice

Lemma 6.7.1. *Let N be a lattice. Suppose $A : N \to \mathbb{Z}^r$ is injective with saturated image. For every integral map $B : N \to \mathbb{Z}^s$, the map (A, B) has saturated image.*

Proof. The cokernel of A is finitely generated and torsion-free, hence free. Therefore A admits an integral left inverse R. Composing R with projection onto the first factor gives an integral left inverse of (A, B):

$$(R \circ \mathrm{pr}_1) \circ (A, B) = \mathrm{id}_N .$$

The image of (A, B) is thus a direct summand, in particular saturated.

□

For tropicalizations, this lemma applies to each tangent lattice after taking a common integral-affine subdivision. It proves that adding coordinates preserves unimodularity wherever it was already established. The existence of a finite subdivision on a semistable skeleton is a separate assertion about the restrictions of rational functions.

Example 6.7.2. On an annular skeleton, the map $t \mapsto mt$ is injective for every nonzero integer m, but its lattice index is $|m|$. The map $t \mapsto (mt, t)$ is unimodular because projection to the second coordinate is an integral left inverse. More generally, $t \mapsto (at, bt)$ is unimodular exactly when $\gcd(a, b) = 1$. Thus injectivity and preservation of the integral lattice are distinct requirements.

6.8 Finite separation on a compact skeleton

Proposition 6.8.1. *Let S be a compact polyhedral space, and let $\mathcal{F}$ be a family of continuous real functions separating its points. Suppose a finite tuple F_0 drawn from $\mathcal{F}$ is locally injective on S and unimodular on a finite subdivision. Assume every further function is integral affine on a finite subdivision. Then a finite tuple extending F_0 gives a faithful embedding of S into a real vector space.*

Proof. Choose finitely many open sets V_i covering S such that F_0 is injective on each V_i. Set

$$O = \bigcup_i (V_i \times V_i), \qquad C = (S \times S) \setminus O.$$

The set O is an open neighborhood of the diagonal. Consequently C is compact and contains no diagonal point. For every pair (x, y) in C, some function f in $\mathcal{F}$ separates x and y. The inequality $f(x) \neq f(y)$ persists on an open neighborhood of the pair. Compactness gives finitely many such functions which separate every pair in C.

Together with F_0 these functions separate all points of S: a pair in O is separated by F_0, and a pair outside O by one of the added functions. Take a common finite subdivision. Lemma 6.7.1 preserves unimodularity on its cells. Finally, a continuous injection from a compact space into a Hausdorff real vector space is a homeomorphism onto its image.

□

Remark 6.8.2. Local injectivity on S is stronger than injectivity on each closed cell separately. Different cells meeting at a vertex may still be folded onto one another. Proposition 6.8.1 does not remove this hypothesis. Nor does its compactness argument apply directly to a noncompact skeleton with horizontal boundary.

In the GRW construction, semistable coordinates first supply integral-affine embeddings of individual canonical polyhedra. The global separation of different polyhedra uses additional rational functions and model geometry. Proposition 6.8.1 explains one possible finite assembly step when its stronger local hypothesis holds; it is not a replacement for the complete global theorem.

6.9 From faithful coordinates to differential calculus

Faithfulness concerns a specified subset of the analytic space. Its conclusions are injectivity and unimodularity on that subset. It does not say that every analytic function, smooth form, or current factors through a retraction onto the subset. A current is still tested on the full admitted test space, and a representative still requires compatibility under refinements.

The distinction matters already for a curve with good reduction: its smallest proper skeleton may be one point, while annular domains carry nonzero differential forms. Enlarging the system of charts recovers these directions. A finite faithful tropicalization of one skeleton therefore cannot by itself transfer a global Hodge or Green theory.

References. [GRW16, Section 9 and Sections 10.1–10.6]; [GRW17, Sections 2 and 8].

6.10 Pure dimension away from the tropicalized boundary

A moment map on a d-dimensional analytic space can have a lower-dimensional tropical image. Affinoidness and avoidance of the analytic boundary restore the expected dimension. The proof is useful beyond the dimension theorem: it turns a tropical projection into a finite morphism of affinoid spaces and then reads dimension at a Shilov boundary point.

Lemma 6.10.1 (A simultaneous integral projection)**.** *Let $P \subset \mathbb{R}^n$ be a finite polyhedral complex of dimension at most d, and let $B \subset P$ be contained in finitely many polyhedra of dimension at most $d-1$. For $\omega \in P \setminus B$, there is an integral linear map $Q : \mathbb{R}^n \to \mathbb{R}^d$ which is injective on every face of P and satisfies $Q\omega \notin Q(B)$. Assume that the stated finite polyhedral cover of B consists of closed polyhedra, none containing ω.*

Proof. For each face σ of P, require Q to be injective on its tangent space L_σ. For each polyhedron τ in the chosen cover of B, require injectivity on the linear span of $\tau - \omega$. The first spaces have dimension at most d, and the second have dimension at most $\dim \tau + 1 \leq d$. For each of these finitely many subspaces, injectivity is a nonempty open condition on the space of real

$d \times n$ matrices; its complement is given by vanishing of all relevant maximal minors and has empty interior. The intersection of the conditions is therefore nonempty and open. It contains a rational matrix. Clearing denominators gives an integral matrix without changing injectivity.

If $b \in B$ had $Qb = Q\omega$, choose a covering polyhedron τ containing b. Then $b - \omega \neq 0$ would lie in the kernel of Q on $\operatorname{span}(\tau - \omega)$, a contradiction. □

In the analytic application, B is compact and polyhedral, so a finite subdivision provides a closed polyhedral cover avoiding ω. The last condition in the lemma is material. Merely knowing that ω is not in a subset of a polyhedron would not imply that projection separates it from the whole covering polyhedron.

Theorem 6.10.2 (Affinoid tropical purity)**.** *Let K be complete and nontrivially valued, let X be a strict affinoid space of pure dimension d, and let $\varphi : X \to (\mathbb{G}_m^n)^{\mathrm{an}}$ be a moment map. Then $\varphi_{\mathrm{trop}}(X)$ has pure dimension d at every point of*

$$\varphi_{\mathrm{trop}}(X) \setminus \varphi_{\mathrm{trop}}(\partial X).$$

Open proof obligation (RC2). Prove the local germ and finite-projection step in the stated dimension, support and base-change scope; GRPL Theorem 6.4 and the proof of 6.6.

Remark 6.10.3. A constant moment map from a positive-dimensional proper space has a point as tropical image, although the source is boundaryless. This does not contradict the theorem, because the source is not affinoid. Conversely, a constant moment map from a positive-dimensional affinoid space sends its boundary to the same point, so the asserted open set is empty. Both hypotheses have visible roles.

This result concerns smooth tropicalization by analytic units. It does not prove purity of the image of a subvariety under the canonical tropicalization of a general abelian variety. That map comes from Raynaud uniformization and may forget an abelian part with good reduction. The distinction becomes important in Chapter 21, where canonical measures can live on cells of several dimensions.

References. [GRPL, Sections 6.1–6.5 and Theorem 6.6]. The proof above expands the finite-projection and Shilov-boundary argument; analytic dimension, properness, reduction and base-change results are explicit geometric inputs.

6.11 Matroids and the local models of tropical manifolds

Balancing is enough for Stokes, but not for all cohomological dualities. The matroidal local models used in tropical Poincaré duality satisfy a stronger incidence structure. This section constructs their fans from finite combinatorial data and proves balancing directly.

Definition 6.11.1. A matroid on a finite set E is specified by a rank function $r : 2^E \to \mathbb{Z}_{\geq 0}$ satisfying $0 \leq r(A) \leq |A|$, monotonicity, and submodularity

$$r(A \cup B) + r(A \cap B) \leq r(A) + r(B).$$

Its closure is $\mathrm{cl}(A) = \{e : r(A \cup \{e\}) = r(A)\}$, with A included. A flat is a set equal to its closure. A circuit is a minimal dependent set, where dependence means $r(A) < |A|$. We assume the matroid is loopless, meaning $r(\{e\}) = 1$ for every e. Its rank is $r(E)$.

For vectors $(v_e)_{e \in E}$ over a field, $r(A) = \dim \mathrm{span}\{v_e : e \in A\}$ gives the basic example. The axioms do not require such a representation. Thus a matroidal tropical model need not arise from a linear subspace over the particular ground field under consideration.

Lemma 6.11.2. *For $e \notin A$, one has $e \in \mathrm{cl}(A)$ if and only if some circuit C satisfies $e \in C \subseteq A \cup \{e\}$.*

Proof. Choose a maximal independent subset B of A. Its cardinality is $r(A)$, and adding e is dependent exactly when $r(A \cup \{e\}) = r(A)$. In that case a minimal dependent subset of $B \cup \{e\}$ is a circuit and must contain e, since B is independent. Conversely, in a circuit C, deleting any element leaves an independent set of rank $|C| - 1 = r(C)$. Thus $e \in \mathrm{cl}(C \setminus \{e\})$, and closure is monotone, giving the assertion for A. The facts about maximal independent sets and monotone closure follow from the rank axioms by adding one element at a time and applying submodularity. □

6.11.1 The circuit and flag descriptions

Let $N = \mathbb{Z}^E/\mathbb{Z}\mathbf{1}$, where $\mathbf{1} = \sum_{e \in E} e_e$. Define the Bergman support by the minimum convention

$$|B(M)| = \big\{ w \in \mathbb{R}^E/\mathbb{R}\mathbf{1} : \#\operatorname{argmin}_{e \in C} w_e \geq 2 \ \mathit{extforeverycircuit} C \big\}.$$

Adding a constant to all coordinates does not change this condition. For a nonempty proper flat F, let e_F be the class of its indicator vector. A flag of proper flats $\mathscr{F} = (F_1 \subsetneq \cdots \subsetneq F_k)$ gives the cone

$$\sigma_{\mathscr{F}} = \mathbb{R}_{\geq 0} e_{F_1} + \cdots + \mathbb{R}_{\geq 0} e_{F_k}.$$

Proposition 6.11.3. *The cones $\sigma_{\mathscr{F}}$ form a fan with support $|B(M)|$. If $r = r(E)$, this fan is pure of dimension $r-1$. Each cone is unimodular in the lattice of its linear span.*

Proof. A weight w satisfies the circuit condition exactly when each nonempty proper upper level set $F_c = \{e : w_e > c\}$ is a flat. If such a level set is not flat, choose $e \notin F_c$ in its closure. Lemma 6.11.2 gives a circuit contained in $F_c \cup \{e\}$, with e its unique minimum. Conversely, a unique minimum e in a circuit is separated from the other circuit weights by a level c, making e lie in the closure of F_c but not in F_c.

The distinct upper level sets form a nested flag. Subtracting the minimum weight expresses w uniquely as a positive linear combination of their indicator vectors. Allowing some coefficients to vanish gives the faces of the cones. Thus intersections of cones are their common flag faces, proving the fan assertion. Strict inclusions of flats increase rank. Every flag can be filled to one containing a flat of each rank $1, \ldots, r-1$, by adjoining an element outside the current flat and taking closure. Hence maximal cones have $r-1$ generators.

To check the lattice, put $F_0 = \varnothing$, $F_{k+1} = E$, and choose an element $b_i \in F_i \setminus F_{i-1}$ for $1 \leq i \leq k+1$. For $1 \leq i \leq k$, the integral coordinate difference $w \mapsto w_{b_i} - w_{b_{i+1}}$ descends to N and takes the value δ_{ij} on e_{F_j}. These differences give an integral left inverse to the generator map $\mathbb{Z}^k \to N$. Its image is saturated, proving both linear independence and unimodularity. □

Theorem 6.11.4 (Weight-one balancing)**.** *Assign weight one to each maximal cone of the flag fan. The resulting weighted fan is balanced.*

Proof. A codimension-one flag omits exactly one rank between two successive retained flats $A \subset B$, with $r(B) = r(A) + 2$; allow $A = \varnothing$ and $B = E$. The maximal cones containing it correspond to intermediate flats G of rank $r(A)+1$. In the rank-two minor $(M|B)/A$, the sets $G \setminus A$ are its rank-one flats. They partition $B \setminus A$: each element has a unique rank-one closure, and

two such closures either agree or are disjoint. If there are s of them, their indicator vectors satisfy

$$\sum_{G} e_G = e_B + (s-1)e_A.$$

Modulo the span of the codimension-one cone, the right side vanishes; when $B = E$, its vector already vanishes in N. By the preceding unimodularity argument, the image of each e_G is the primitive outgoing generator for its adjacent cone. Thus the displayed identity is exactly the balancing equation with all weights one. Rank one has no balancing faces to check. □

The proof uses only the rank-two intervals in the lattice of flats. This explains why matroidal fans have particularly controlled local stars. It also separates two uses of the word smooth: a unimodular cone is a lattice property, whereas being a tropical manifold requires every local model to have the specified matroidal form. A fan all of whose individual cones are unimodular need not have that local form.

References. [AK]; the use of these local models in tropical Poincaré duality is [JSS, Definition 4.15 and Theorem 4.33].

6.12 Accessible skeleta and the limits of functoriality

A semistable skeleton is constructed from a model and comes with its associated retraction. The tropical skeleton of a fixed torus embedding is defined through Shilov boundary points of tropical fibres. Neither description by itself supplies a class stable under all the operations needed in analytic geometry. Ducros–Thuillier introduce accessible skeleta to address this functorial problem. We retain the coefficient data c and the Γ-strict category of their paper. Locally in the G-topology, an accessible skeleton is covered by compact pieces that are images of elementary classical skeleta under analytic morphisms into compact analytic domains. The image is not required to consist only of points with maximal possible Abhyankar rank in the target. This is one reason the accessible category is larger than the classical category.

Theorem 6.12.1 (Ducros–Thuillier, fixed version)**.** *In the category of [DT26], accessible skeleta form the smallest admissible class containing the standard torus skeleta. This class contains classical skeleta, is stable under finite intersections and the specified piecewise linear subspaces, and has the following functorial properties.*

1. *If $f : Y \to X$ and $T \subset Y$ is accessible, with $f|_T$ topologically proper, then $f(T)$ is accessible.*
2. *If $\Sigma \subset X$ is accessible and every fibre over Σ is empty or zero-dimensional, then $f^{-1}(\Sigma)$ is accessible.*
3. *The function $x \mapsto d_K(x)$ is locally constant on an accessible skeleton. Its locus where $d_K(x) = \dim_x X$ is open and closed and is classical.*

Open proof obligation (RC2). Prove the accessible-skeleton geometric image assertion; this block explicitly offers DT26 and APW26 as imported proof.

An accessible skeleton is not, by its definition, a deformation retract of the ambient space. Nor does the image theorem assign the tropical multiplicities needed to push differential forms. To use it in an integration formula one still needs weights, lattice normalizations and compatibility with calibration. To use it in a Green-form construction one additionally needs descent in the chosen sheaf of actual forms. These are separate inputs. There is a further distinction from faithfulness. Faithful tropicalization concerns the behaviour of a chosen map on a chosen skeleton. In the strong faithfulness used in [APW26], injectivity on the relevant dual complex is supplemented by weight one on its top-dimensional tropical faces. The additional weight condition allows multiplicity formulas to control other branches above generic tropical points. A homeomorphism on the chosen skeleton alone supplies no such control.

Part II

Smooth forms and currents

Chapter 7

Superforms and positivity cones

The real differential algebra fixes the signs of integration, curvature and the divisor formula. We develop its positivity cones through their matrix representations, then prove the domination estimates used for currents. The distinction between ordinary and strong positivity is essential in middle degree.

7.1 The differential algebra

Definition 7.1.1 (Real superforms)**.** Let $V = \mathbb{R}^n$ with coordinates $x_1, \dots, x_n$, and let $\Omega \subset V$ be open. Write V'^* and V''^* for two copies of V^*. The algebra of superforms is

$$A^{p,q}(\Omega) = C^\infty(\Omega) \otimes \bigwedge^p V'^* \otimes \bigwedge^q V''^*.$$

All one-form generators anticommute, including generators from different copies. Thus a form is uniquely written as

$$\alpha = \sum_{|I|=p,\ |J|=q} \alpha_{IJ}\, d'x_I \wedge d''x_J, \qquad d'x_I = d'x_{i_1} \wedge \cdots \wedge d'x_{i_p},$$

where indices in a multiindex are increasing. The total degree is $p+q$. In particular,

$$\alpha \wedge \beta = (-1)^{(p+q)(r+s)} \beta \wedge \alpha \quad (\beta \in A^{r,s}).$$

Definition 7.1.2. The involution J is the algebra automorphism exchanging $d'x_i$ and $d''x_i$ and fixing functions. A (p,p)-form is symmetric if $J\alpha = (-1)^p\alpha$.

Moving the primed generators to the left gives

$$J(d'x_I \wedge d''x_J) = (-1)^{pq} d'x_J \wedge d''x_I. \tag{7.1.1}$$

Since p^2 and p have the same parity, symmetry in bidegree (p,p) means precisely $\alpha_{IJ} = \alpha_{JI}$. This is the symmetry that will become ordinary matrix symmetry.

Definition 7.1.3. The differentials are the total-degree derivations determined by

$$d'f = \sum_i \partial_i f \, d'x_i, \qquad d''f = \sum_i \partial_i f \, d''x_i,$$
$$d'd'x_i = d'd''x_i = d''d'x_i = d''d''x_i = 0.$$

For the displayed expansion of α, these definitions give

$$d'\alpha = \sum_{I,J,i} \partial_i \alpha_{IJ} \, d'x_i \wedge d'x_I \wedge d''x_J,$$
$$d''\alpha = (-1)^p \sum_{I,J,i} \partial_i \alpha_{IJ} \, d'x_I \wedge d''x_i \wedge d''x_J.$$

Proposition 7.1.4. *The operators satisfy*

$$(d')^2 = (d'')^2 = 0, \quad d'd'' + d''d' = 0, \quad d'' = Jd'J.$$

For a smooth function f, one has

$$\mathrm{d'd''}f = \sum_{i,j} \partial_i\partial_j f \, d'x_i \wedge d''x_j.$$

Proof. The terms in $(d')^2\alpha$ cancel in pairs: the second derivatives are symmetric in the two new indices, whereas the primed generators are antisymmetric. The same argument applies to d''. In $d'd''\alpha + d''d'\alpha$, the derivatives again agree, and exchanging the two new generators reverses the sign. The identity with J can be checked on functions and the one-form generators, after which the derivation rule proves it on the algebra. Applying d' to $d''f$ gives the last formula. □

Remark 7.1.5 (A sign that must be corrected in the 2012 text). The displayed commutativity exponent in [CLD12, §1.2.6, p. 14] is $pp' + qq'$. Read literally, it would make $d'x_i$ commute with $d''x_j$, contrary to (7.1.1) and to the total-degree Leibniz rule used later in that text. The displayed exponent in [CLD12, §3.1.4, p. 36] is also incompatible with those formulas. Throughout these notes the exponent is $(p+q)(p'+q')$. This is an explicit correction of the displayed formulas, not a second convention being used implicitly.

Proposition 7.1.6 (Conversion of the two operators)**.** *Let J be the involution in Definition 7.1.1. The algebra automorphism in [CLD25, §1.1.2] satisfies*

$$J_{25}(d'x_i) = d''x_i, \qquad J_{25}(d''x_i) = -d'x_i.$$

On forms of bidegree (p,q) one has

$$J_{25} = (-1)^q J, \qquad J_{25}^2 = (-1)^{p+q}\,\mathrm{id}\,. \tag{7.1.2}$$

For a form of type (p,p), the old symmetry condition $J\alpha = (-1)^p\alpha$ is equivalent to $J_{25}\alpha = \alpha$. The strong generators and the signed squares $(-1)^{p(p-1)/2}\beta\wedge J\beta$, with β of type $(p,0)$, are unchanged when J is replaced by J_{25}. Hence the three cones in Definition 7.2.2 agree under this conversion.

Proof. Every double-primed generator contributes one extra minus sign under J_{25}, giving the first equality. Applying it twice gives $(-1)^{p+q}J^2$. The symmetry assertion follows by setting $q = p$. A form β of type $(p,0)$ contains no double-primed factor, so $J_{25}\beta = J\beta$. This proves the statement about the generators and, by the complementary wedge definitions, all three cones. □

Put $s_p = (-1)^{p(p-1)/2}$ and fix the positive top form

$$\mathrm{vol}_n = d'x_1 \wedge d''x_1 \wedge \cdots \wedge d'x_n \wedge d''x_n = s_n\, d'x_{1\cdots n} \wedge d''x_{1\cdots n}.$$

Integration means $\int_\Omega f\,\mathrm{vol}_n = \int_\Omega f\,dx_1\cdots dx_n$. The choice is compatible with the lattice normalization when the coordinates form a lattice basis. Under an arbitrary linear change of coordinates the coefficient of this top form changes by the square of the determinant; the normalization of the integral must therefore be transformed as well.

7.2 Symmetric forms as matrices

Remark 7.2.1 (Matrix normalization). The factor s_p removes the sign caused by collecting all primed generators. For a real $m \times m$ matrix H, where $m = \binom{n}{p}$, define

$$\alpha_H = s_p \sum_{I,J} H_{IJ}\, d'x_I \wedge d''x_J. \tag{7.2.1}$$

Thus H is symmetric exactly when α_H is symmetric. If $a = \sum_I a_I d'x_I$, then

$$s_p\, a \wedge Ja = \alpha_{aa^t}.$$

Definition 7.2.2. A symmetric form α_H is positive if H is positive semidefinite. It is strongly positive if H is a finite sum of matrices aa^t with $a \in \bigwedge^p V^*$ decomposable. It is weakly positive if $z^t H z \geq 0$ for every decomposable p-vector $z \in \bigwedge^p V$.

The zero element is permitted in all three cones. For a smooth form these conditions are imposed at every point. In the definition of strong positivity, the pointwise decomposition need not have smoothly varying summands. This chapter uses the pointwise cone condition; no smooth choice of eigenvectors is needed.

Proposition 7.2.3. *A symmetric form is positive if and only if it is a finite sum $s_p \sum_\nu a_\nu \wedge Ja_\nu$, without a decomposability restriction. There are inclusions*

$$C^p_s \subset C^p_+ \subset C^p_w.$$

All three cones coincide for $p = 0, 1, n-1, n$.

Proof. The spectral theorem gives $H = \sum_\nu \lambda_\nu v_\nu v_\nu^t$ with $\lambda_\nu \geq 0$ precisely when H is positive semidefinite. Take $a_\nu = \sqrt{\lambda_\nu} v_\nu$. The converse follows from $z^t a a^t z = (a^t z)^2$. The two cone inclusions follow from the same formula.

In the four indicated degrees every exterior vector and covector is decomposable. For degree $n-1$, a nonzero exterior vector is contraction of a volume vector by a nonzero covector. A basis in which that covector is the last dual basis vector expresses the contraction as a single wedge of $n-1$ basis vectors. Thus the decomposability restrictions disappear. □

Proposition 7.2.4 (Hessian criterion)**.** *Let $u \in C^\infty(\Omega)$. Then*

$$d'd''u = \sum_{i,j=1}^{n} \frac{\partial^2 u}{\partial x_i \partial x_j} d'x_i \wedge d''x_j.$$

This form is positive if and only if the real Hessian of u is positive semidefinite at every point. If Ω is convex, this is equivalent to convexity of u.

Proof. The displayed formula follows from the definitions. A symmetric $(1,1)$-form is represented by a real symmetric matrix. Evaluating along a real direction v gives the quadratic expression $v^{\mathsf{T}} \operatorname{Hess}(u) v$. The three positivity cones in this degree agree with the cone of positive semidefinite matrices. Finally, the restriction of u to the segment $x + tv$ has second derivative $v^{\mathsf{T}} \operatorname{Hess}(u)(x + tv)v$; the one-dimensional criterion for convexity proves the last assertion. □

Proposition 7.2.5 (Wedge duality)**.** *The wedge pairing between symmetric forms in complementary bidegrees is nondegenerate. Under this pairing the positive cone is self-dual across complementary degrees, and the strongly positive and weakly positive cones are dual.*

Proof. Let $q = n - p$. For increasing multiindices I of size p and A of size q, let $C_{I,A}$ be the sign of $dx_I \wedge dx_A$ relative to $dx_1 \wedge \cdots \wedge dx_n$ when $A = I^c$, and zero otherwise. The matrix C is a signed permutation matrix. Expanding the wedge gives

$$\alpha_H \wedge \alpha_K = \operatorname{tr}(HCKC^t) \operatorname{vol}_n. \tag{7.2.2}$$

Indeed the scalar sign is $s_p s_q (-1)^{pq} / s_n = 1$. Since C is invertible, nondegeneracy follows. Testing against all positive semidefinite K is equivalent to H being positive semidefinite: rank-one tests give all inequalities $z^t H z \geq 0$.

The complement map C takes decomposable q-covectors to decomposable p-vectors. To see this, choose an orthonormal basis adapted to the span of the covectors in their wedge; its complementary basis gives the image under C, up to a scalar and sign. Thus testing against strongly positive K gives exactly weak positivity of H.

For the reverse duality, the strong cone is closed. Normalize its nonzero generators by $\operatorname{tr}(aa^t) = 1$. The resulting set is compact, being the image of the closed set of unit decomposable covectors. Its convex hull is compact in finite dimension. Every nonzero element of the cone is its trace times a point

of that convex hull. A convergent sequence in the cone has bounded traces, so its limit remains in the cone. The finite-dimensional separation theorem now identifies the double dual with the cone itself. □

7.3 A positive control form

The current estimates will require a fixed form dominating every symmetric coefficient matrix. Define

$$\omega = \sum_i d'x_i \wedge d''x_i, \qquad \beta_p = \frac{\omega^p}{p!}.$$

Lemma 7.3.1. *One has $\beta_p = \alpha_{\mathrm{Id}_m}$, where $m = \binom{n}{p}$. In particular β_p is strongly positive and lies in the interior of the ordinary positive cone.*

Proof. The degree-two factors in ω commute, and a repeated factor has zero wedge. Every set of p distinct indices therefore occurs $p!$ times. Moving the double-primed factors to the right contributes s_p, giving (7.2.1) with the identity matrix. The result is a sum of decomposable squares. If a symmetric matrix E has operator norm less than one, $\mathrm{Id}_m + E$ is positive definite; this proves the interior assertion. □

Proposition 7.3.2 (Coefficient domination)**.** *Let $\eta = \alpha_H$ be a smooth symmetric form supported in a compact set $K \Subset \Omega$. Choose $0 \le \chi \in C_c^\infty(\Omega)$ with $\chi = 1$ near K. If $M = \sup_K \|H(x)\|_{\mathrm{op}}$, then*

$$M\chi\beta_p + \eta \ge 0, \qquad M\chi\beta_p - \eta \ge 0. \tag{7.3.1}$$

Both inequalities mean ordinary positivity.

Proof. On K, every eigenvalue of $H(x)$ lies in $[-M, M]$, so $M\mathrm{Id}_m \pm H(x)$ is positive semidefinite. Off K, $H = 0$ and $M\chi\mathrm{Id}_m$ is positive semidefinite. This proves the assertions at every point, without choosing eigenvectors smoothly. □

Consequently every compactly supported symmetric form is a difference of two compactly supported positive forms. This is the decomposition needed for positive currents. Requiring both summands to be strongly positive changes the statement, and the next section shows that the stronger requirement is impossible in general.

Remark 7.3.3. One may replace the operator norm by a coefficient norm. If $|H_{IJ}| \le A$, then $\|H\|_{\mathrm{op}} \le mA$: for $|v| = 1$, $|(Hv)_I| \le A \sum_J |v_J| \le A\sqrt{m}$, and summing over I gives the bound. Constants in chart estimates may therefore depend on the number of coefficient directions, but not on derivatives of the test form.

7.4 The Plücker obstruction

Take $n = 4$ and $p = 2$. Order the exterior coordinates by

$$12,\ 13,\ 14,\ 23,\ 24,\ 34.$$

Define the symmetric matrix

$$B = \begin{pmatrix} 0 & 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & -1 & 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 & 0 \end{pmatrix}.$$

Its quadratic form is

$$z^t B z = 2(z_{12}z_{34} - z_{13}z_{24} + z_{14}z_{23}). \tag{7.4.1}$$

Lemma 7.4.1. *The right side vanishes for every decomposable $z \in \bigwedge^2 \mathbb{R}^4$. Moreover $B^2 = \mathrm{Id}_6$ and $\operatorname{tr} B = 0$.*

Proof. If $z = a \wedge b$, then $z \wedge z = a \wedge b \wedge a \wedge b = 0$. Expanding in the volume basis gives

$$z \wedge z = 2(z_{12}z_{34} - z_{13}z_{24} + z_{14}z_{23})\, e_1 \wedge e_2 \wedge e_3 \wedge e_4.$$

This proves the relation. The matrix B exchanges the first and sixth coordinates, exchanges the second and fifth with a minus sign, and exchanges the third and fourth. Applying it twice is the identity, and all its diagonal entries vanish. □

Theorem 7.4.2 (Failure of strong-cone spanning)**.** *In bidegree* $(2,2)$ *on* $\mathbb{R}^4$*, the strongly positive cone does not span the space of symmetric forms. The weakly positive cone contains the nonzero line* $\mathbb{R}\alpha_B$*. In particular it is not pointed.*

Proof. The nonzero linear functional $\ell(H) = \operatorname{tr}(BH)$ vanishes on every strong generator aa^t, because $\operatorname{tr}(Baa^t) = a^tBa = 0$ for decomposable a. Hence it vanishes on the linear span of the strong cone. But $\ell(B) = \operatorname{tr}(B^2) = 6$, so that span is proper. The same Plücker relation on decomposable vectors gives $z^t(tB)z = 0$ for every $t \in \mathbb{R}$. Thus every $t\alpha_B$ is weakly positive. □

Example 7.4.3 (A positive form which is not strongly positive)**.** Let $a = e_{12}+e_{34}$ in exterior coordinate notation and put $H = aa^t$. Then H is positive semidefinite, while $\operatorname{tr}(BH) = 2$. Since this functional vanishes on the entire strong span, α_H is not even a difference of strongly positive forms.

This example pinpoints the interior error. The form β_2 is strongly positive, but it cannot lie in the interior of the strong cone in the full symmetric space. Every matrix $M\mathrm{Id}_6 + H$ in Example 7.4.3 has $\ell(M\mathrm{Id}_6 + H) = 2$, regardless of M, and therefore is not strongly positive. Enlarging the coefficient of a fixed strong form cannot repair this obstruction.

Remark 7.4.4 (Relation to the sources). This is the obstruction in [BGJK, Example 2.3.6]. It contradicts the real statement of [CLD12, Lemma 5.2.3], even after symmetry is imposed. That lemma's proof uses the interior assertion just disproved. The analytic Lemma 5.3.3 cites it through tropical charts; its printed proof therefore loses this input. An analytic counterexample would additionally require a faithful realization of the relevant forms and positivity through the analytic charts, and is not supplied by the real calculation alone.

Similarly, [GK19, Remark 1.12(i)] asserts that weak positivity of both α and $-\alpha$ implies $\alpha = 0$. The form α_B disproves this assertion in its stated real setting. The analytic uses of this remark, including Lemma 2.16, require a separate analysis of their realization and quotient relations. We do not label those analytic statements disproved solely by this example.

7.5 Pullbacks and products

The corrected coefficient estimates use ordinary positivity. Before passing to currents, we record the operations that preserve this cone. These proofs also explain which cone conditions are available when multiplying a current by a smooth form.

Proposition 7.5.1. *Pullback by an affine map preserves each of strong, ordinary and weak positivity.*

Proof. Let $F : W \to V$ have linear part L. On exterior covectors the pullback is $\bigwedge^p L^*$. It takes a square aa^t to the square of the pulled-back covector; decomposable covectors stay decomposable or become zero. This proves the strong and ordinary assertions. For a decomposable p-vector z on W, the exterior image $(\bigwedge^p L)z$ is decomposable or zero. The quadratic form of $F^*\alpha_H$ evaluated at z is the quadratic form of H evaluated at that image, proving weak positivity. □

Proposition 7.5.2. *Products of positive forms are positive. Products of strongly positive forms are strongly positive. The product of a weakly positive form and a strongly positive form is weakly positive. Products in degrees exceeding the dimension are zero.*

Proof. For exterior covectors a, b of degrees p, r, respectively, the signs give

$$(s_p a \wedge Ja) \wedge (s_r b \wedge Jb) = s_{p+r}(a \wedge b) \wedge J(a \wedge b).$$

Indeed moving b past Ja gives $(-1)^{pr}$ and $s_p s_r (-1)^{pr} = s_{p+r}$. Decompose the positive matrices into squares and use this identity term by term. If both factors are strong, their generating covectors are decomposable, so their wedge is decomposable or zero.

For the last assertion it suffices to consider one decomposable square $s_r b \wedge Jb$. Evaluate the product on a decomposable $(p+r)$-vector and restrict to the subspace it spans. If b restricts to zero there is nothing to prove. Otherwise choose a basis of this subspace so that b is a scalar multiple of the wedge of the last r dual basis vectors. The value of the product is a nonnegative square factor times the value of the first form on the wedge of the first p basis vectors. Weak positivity makes the latter value nonnegative. □

For a smooth function, Proposition 7.1.4 identifies the matrix of $\mathrm{d}'\mathrm{d}''f$ with its Hessian. Thus positivity, strong positivity and weak positivity of $\mathrm{d}'\mathrm{d}''f$ are equivalent. On a convex open set they are equivalent to convexity of f: along every line the second derivative is nonnegative, which is the one-variable criterion for convexity; conversely, second differences of a smooth convex function give a nonnegative Hessian. This special agreement in degree $(1,1)$ must not be extrapolated to all degrees.

7.6 A homotopy formula for the real double complex

The two exterior factors of a superform have different roles when one studies only one differential. This gives an elementary Poincaré lemma on an ordinary real open set, but also explains why a statement about the double complex requires more than two separate exactness statements.

Let $\Omega \subset \mathbb{R}^n$ be open and star-shaped about 0. Write every superform uniquely as

$$\alpha = \sum_{|J|=q} \alpha_J \wedge d''x_J, \qquad \alpha_J \in \Omega^p(\Omega),$$

where the first factor is an ordinary differential form in the $d'x_i$. In this description, d' is the ordinary exterior derivative on each α_J, while the $d''x_J$ form a fixed coefficient space.

Definition 7.6.1. For $p > 0$, define $H' : A^{p,q}(\Omega) \to A^{p-1,q}(\Omega)$ coefficientwise by

$$(H'\alpha)_x(v_1, \dots, v_{p-1}; w_1, \dots, w_q) = \int_0^1 t^{p-1} \alpha_{tx}(x, v_1, \dots, v_{p-1}; w_1, \dots, w_q)\, dt.$$

Set $H' = 0$ for $p = 0$. Define $E'\alpha = 0$ for $p > 0$; for $p = 0$, let E' replace each scalar coefficient of α by its value at 0, retaining the fixed d''-basis.

The semicolon separates the primed and double-primed alternating slots. Only the primed slots are scaled in this formula. In particular, E' is not the full geometric pullback by the constant map: that pullback would also kill positive double-primed degree.

Proposition 7.6.2 (Radial homotopy)**.** *The operators satisfy*

$$d'H' + H'd' = \mathrm{id} - E'.$$

Consequently the d'-cohomology on Ω vanishes in positive primed degree, while in primed degree zero it is the space of constant double-primed forms $\bigwedge^q(\mathbb{R}^n)^*$.

Proof. It suffices to prove the usual homotopy identity for each α_J. Let $F : [0,1] \times \Omega \to \Omega$ be $F(t,x) = tx$. Decompose the ordinary pullback of a primed form as $F^*\alpha_J = dt \wedge \beta_t + \gamma_t$, where γ_t contains no dt. The coefficient of dt in the identity $d(F^*\alpha_J) = F^*(d\alpha_J)$ is

$$\partial_t \gamma_t - d_x \beta_t = \text{the } dt\text{-coefficient of } F^*(d\alpha_J).$$

Integrate from 0 to 1. The boundary term is $\alpha_J - F_0^*\alpha_J$, and $\int_0^1 \beta_t\, dt$ is precisely the coefficientwise operator in Definition 7.6.1. This proves the formula. Smoothness at $t = 0$ follows directly from the displayed pullback, or from the factor t^{p-1} when $p > 0$.

If $p > 0$ and $d'\alpha = 0$, the identity gives $\alpha = d'H'\alpha$. For $p = 0$, closedness says that every coefficient has zero differential. The star-shaped open set is connected, so those coefficients are constant. There are no forms of primed degree -1, giving the asserted degree-zero cohomology. □

There is an analogous statement for d'', obtained by exchanging the exterior factors with the fixed sign convention. The two statements concern separate complexes. The operator H' was not constructed to commute with d'', and no such commutation is needed for Proposition 7.6.2. This point matters when one tries to obtain a $d'd''$-potential by applying two homotopies successively.

7.7 The symmetric Hessian potential theorem

In bidegree $(1,1)$ the extra compatibility has a familiar form: the coefficient matrix must be symmetric. On a star-shaped open set this condition, together with closedness, suffices for a scalar potential.

Theorem 7.7.1. *Let $\Omega \subset \mathbb{R}^n$ be open and star-shaped, and let*

$$\alpha = \sum_{i,j=1}^{n} A_{ij}(x) d'x_i \wedge d''x_j$$

have smooth coefficients with $A_{ij} = A_{ji}$. If $d'\alpha = 0$, then there is a smooth function u with $\alpha = d'd''u$. The potential is unique up to addition of an affine function. If Ω is convex, α is positive if and only if u is convex.

Proof. For each j, the primed one-form $\alpha_j = \sum_i A_{ij} d'x_i$ is closed. Proposition 7.6.2, after translating the star centre to zero, gives a smooth function b_j with $\partial_i b_j = A_{ij}$. Symmetry implies $\partial_i b_j = \partial_j b_i$. Hence the ordinary one-form $\sum_j b_j dx_j$ is closed. Apply the same homotopy formula once more to obtain u with $\partial_j u = b_j$. Its Hessian is A, proving the asserted identity.

If u and v are two potentials, every first derivative of $u - v$ has zero differential and is therefore constant on the connected set Ω. Thus $u - v$ is affine. Finally, positivity of a symmetric $(1,1)$-superform is positive semidefiniteness of its matrix. On a convex domain, the second derivative of the restriction of u to every line segment is $\xi^{\mathsf{T}} A \xi$. Nonnegativity of these second derivatives is equivalent to convexity. □

The same calculation shows that symmetry and d'-closedness imply d''-closedness here: the constructed Hessian is closed under both differentials. It also identifies the ambiguity more precisely than saying only that it is harmonic. In ordinary real coordinates the smooth Hessian kernel consists of affine functions; on an analytic space, current-harmonic functions can form a much larger class.

Example 7.7.2 (Double closedness without a scalar potential)**.** On any open ball in $\mathbb{R}^2$, the constant form

$$\alpha = d'x_1 \wedge d''x_2 - d'x_2 \wedge d''x_1$$

is both d'-closed and d''-closed. It cannot equal $d'd''u$ for a smooth scalar function, because that would give $\partial_1\partial_2 u = 1$ and $\partial_2\partial_1 u = -1$. It cannot have a scalar distributional potential either, since distributional partial derivatives commute. Thus two separate Poincaré lemmas do not imply an unrestricted local $d'd''$-lemma for this real double complex.

7.7.1 The passage to a polyhedral or analytic space

The preceding results are on an open subset of one real vector space. A form on a polyhedral support is a quotient of ambient forms by tangential relations, and the tangent directions can change across faces. Before using a homotopy on that quotient, one must prove that it preserves those relations and has the required support and domain properties. An ambient homotopy formula alone does not do this.

On a Berkovich space there is a further compatibility under refinements of moment charts. A potential constructed on one tropical presentation must be independent of the presentation or be shown to glue with the permitted transition functions. These are precisely the additional issues in local-potential theorems for currents and in comparisons of tropical and analytic cohomology. The explicit Euclidean theorem is a local building block, not a theorem covering every analytic chart quotient.

7.8 A radial homotopy on a polyhedral star

The ordinary de Rham homotopy contracts all covectors of a differential form. For the d'' complex of superforms, the primed degree must remain fixed. The correct operator contracts only the double-primed variables. This produces a local Poincaré lemma and identifies its degree-zero kernel with the multitangent coefficient space.

Let $C \subset \mathbb{R}^r$ be the support of a finite fan, and let B be an open ball centred at its vertex 0. Superforms on $C \cap B$ are restrictions of smooth ambient superforms, with two forms identified when their evaluations on tangent vectors of every cone agree. It is enough to work with germs at 0, so a common ambient representative is available. Write a representative as

$$\alpha = \sum_{|I|=p} d'x_I \wedge \omega_I, \qquad \omega_I = \sum_{|J|=q} a_{IJ}(x)\, d''x_J.$$

With the ordered-wedge convention of this book, d'' acts on each ω_I as $(-1)^p$ times the ordinary exterior derivative. This sign is essential in the homotopy formula.

For an ordinary q-form ω with $q > 0$, set

$$(H\omega)_x(v_1, \dots, v_{q-1}) = \int_0^1 t^{q-1} \omega_{tx}(x, v_1, \dots, v_{q-1})\, dt.$$

For $q = 0$ set $H = 0$, and define

$$K_p\alpha = (-1)^p \sum_{|I|=p} d'x_I \wedge H\omega_I.$$

The operator K_p has bidegree $(0, -1)$. Define $E\alpha$ to be zero for $q > 0$, and for $q = 0$ define it to be the constant-coefficient primed form $\sum_I a_I(0)d'x_I$, restricted to the fan.

Proposition 7.8.1. *The operators descend to superforms on the fan, and satisfy*

$$d''K_p + K_p d'' = \mathrm{id} - E.$$

Consequently every d''-closed germ of bidegree (p, q) with $q > 0$ is d''-exact.

Proof. Suppose an ambient representative vanishes on tangent vectors of every cone. For x in a cone σ, all the points tx with $t > 0$ remain in σ, and $x \in L_\sigma$. Evaluating $K_p\alpha$ on primed and double-primed vectors in L_σ therefore evaluates α_{tx} only on vectors in L_σ, including the inserted vector x. The integrand is zero. Its value at $t = 0$ follows by continuity and does not affect the integral. Thus K_p preserves the relation defining forms on C.

For $q = 0$, if an ambient primed form vanishes on each cone, evaluate along an interior ray of a cone and let its parameter tend to zero. Its constant value at zero annihilates $\bigwedge^p L_\sigma$ for every σ, so E also preserves the relation. For $q > 0$ there is nothing to check for E.

On ambient ordinary forms, differentiation under the integral gives $dH + Hd = \mathrm{id} - e_0^*$, where e_0^* keeps only degree-zero values at the origin. One can check this on a coefficient $a_J(x)$: the surviving integrand is the derivative in t of $t^q a_J(tx)$, with the evaluation on the appropriate vectors. The endpoint at $t = 1$ gives ω; the endpoint at $t = 0$ is zero for $q > 0$ and is $\omega(0)$ for $q = 0$. The two factors $(-1)^p$ from d'' and K_p cancel. Applying this identity to every ω_I proves the displayed formula on ambient forms, hence on the quotient. If $d''\alpha = 0$ and $q > 0$, it gives $\alpha = d''K_p\alpha$. □

7.8.1 The kernel is a multi-tangent dual

Put

$$F_p(0) = \sum_{\sigma \in C} \bigwedge^p L_\sigma \;\subset\; \bigwedge^p \mathbb{R}^r, \qquad F^p(0) = \mathrm{Hom}_{\mathbb{R}}(F_p(0), \mathbb{R}).$$

Corollary 7.8.2. *The space of d''-closed $(p,0)$ germs at the vertex is naturally $F^p(0)$. The local sequence*

$$0 \longrightarrow F^p \longrightarrow A^{p,0} \xrightarrow{d''} A^{p,1} \xrightarrow{d''} A^{p,2} \longrightarrow \cdots$$

is exact on finite polyhedral charts, with the natural face restrictions on F^p.

Proof. For a closed $(p,0)$ form, Proposition 7.8.1 gives $\alpha = E\alpha$ on a sufficiently small star. Thus it is represented by a constant ambient p-covector. Such a covector represents zero exactly when it annihilates every $\bigwedge^p L_\sigma$, equivalently their sum $F_p(0)$. The quotient of $\bigwedge^p(\mathbb{R}^r)^*$ by this annihilator is $F_p(0)^*$, since every linear functional on a subspace of a finite-dimensional vector space extends to the whole space. Exactness in positive double-prime degree is the proposition. Around a point in any face, translate the point to the origin and use the local star. Restriction to a smaller face star induces the indicated restrictions on the coefficient spaces. □

The sum in F_p must be formed after taking exterior powers. Replacing it by $\bigwedge^p(\sum_\sigma L_\sigma)$ changes the coefficient sheaf in general. The two-plane example in Section 24.7 makes the difference explicit. The homotopy proof identifies the correct space directly from the vanishing relation for actual forms.

Remark 7.8.3. If an integral linear map sends one fan to another, the homotopy commutes with its ordinary superform pullback: linear maps commute with radial scaling, and contraction by x corresponds to contraction by its image. Translation gives the same assertion for affine charts with specified centres. This compatibility is enough for the local polyhedral argument. A global homotopy on a Berkovich space would additionally require compatible analytic domains and centres; it is not supplied by this computation.

7.8.2 From a local resolution to global cohomology

On a paracompact polyhedral space with finite-part charts, the sheaves $A^{p,q}$ admit smooth partitions of unity. They are therefore fine. The exact sequence above is a fine resolution of F^p, so its global cohomology computes $H^q(X, F^p)$. Here we use the standard fine-resolution theorem of sheaf cohomology; its mechanism can be seen in a Čech double complex.

For a locally finite cover (U_i) and subordinate partition (ρ_i), a Čech cochain c with values in $A^{p,q}$ has a homotopy

$$(hc)_{i_0\dots i_{k-1}} = \sum_j \rho_j c_{j i_0\dots i_{k-1}}, \qquad \delta h + h\delta = \mathrm{id} \quad (k > 0).$$

The sum is locally finite; extension by zero is valid because the multiplier is supported in U_j. Thus the rows have no positive Čech cohomology. In the other direction, local exactness of the d'' complex leaves only F^p. Passing to sufficiently fine covers, the two computations of the total complex give the desired comparison.

This proves the finite-part local mechanism behind the tropical Dolbeault comparison. Extended tropical spaces also have sedentary boundary strata. Their form definition includes compatibility with projections to those strata, and their local Poincaré lemma requires that additional structure. The full comparison, including compact supports and extended charts, is the theorem of Jell–Shaw–Smacka stated in Chapter 24. The present radial proof does not remove the boundary hypotheses from that theorem.

References. [JSS, Sections 2–3]; the explicit homotopy above is the radial de Rham argument applied only to the double-primed variables, with the quotient and sign checks included.

Chapter 8

Intrinsic smooth forms, integration and Stokes

8.1 Original smooth forms on an analytic space

Let K be a complete non-Archimedean field. For the current constructions below, let X be a good Hausdorff K-analytic space of pure dimension n. When discussing the algebraic presentation, we impose Gubler's hypotheses: K is algebraically closed and nontrivially valued, and X is the analytification of an algebraic variety over K. Statements on that presentation will not be used to enlarge its original hypotheses silently.

Definition 8.1.1 (Tropical presentation of an original smooth form)**.** An analytic moment map on an analytic domain W is an analytic morphism

$$f = (f_1, \ldots, f_r) : W \longrightarrow (\mathbb{G}_m^r)^{\mathrm{an}}.$$

The functions f_i are invertible. We use the tropicalization convention

$$f_{\mathrm{trop}}(x) = (-\log|f_1(x)|, \ldots, -\log|f_r(x)|).$$

An original smooth (p,q)-form is locally represented by a pullback $f_{\mathrm{trop}}^*\alpha$, where α is a smooth superform on the tropical image. Presentations are compared after common refinement, and compatible local presentations are glued as a sheaf. Denote the resulting sheaf by $A_{\mathrm{sm}}^{p,q}$.

Here a superform on a polyhedral subset is the restriction of a superform from a real open neighborhood, modulo forms whose restrictions to tangent

spaces of all its cells vanish. The tangent-space quotient is essential: an ambient form can be nonzero while its restriction to the polyhedral set is zero. Subdivision does not change this quotient. Likewise, the analytic definition requires common refinements and sheafification; it is not the choice of one permanent tropical coordinate system on X.

Remark 8.1.2 (Functions and sheafification). The sheaf $A^{0,0}_{\mathrm{sm}}$ consists of functions locally of the form $\varphi(-\log|f_1|,\dots,-\log|f_r|)$ with φ smooth. On a fixed tropical chart, an arbitrary smooth form need not be represented by a single superform on that same chart; see [Gubler, Remark 5.7]. This is why a definition that merely says "pull back superforms along a tropicalization" is incomplete.

Example 8.1.3 (Continuous and tropically continuous functions)**.** On $\mathbb{A}^{1,\mathrm{an}}_K$, the function $x \mapsto |T(x)|$ is continuous. Near the rigid point $T = 0$, every analytic invertible function has constant absolute value on a sufficiently small neighborhood. Every function given near 0 by a continuous function of finitely many logarithms of invertible functions is therefore locally constant there. The function $|T|$ is not locally constant near 0 and has no such tropical presentation.

Consequently, continuity of a function or metric on X does not mean continuity of its coefficients in one local tropical presentation. This is the distinction made in [CLD12, §3.1.6].

Theorem 8.1.4 (Gubler's algebraic presentation)**.** *Let K be complete, algebraically closed, and nontrivially valued, and let Z be an algebraic variety over K. The smooth-form sheaf constructed on Z^{an} using algebraic moment maps on very affine Zariski open subsets agrees with the original smooth-form sheaf constructed using analytic moment maps. The identification respects d', d'', J, and wedge product.*

Proof. Use the common variety class of NAG-003062 and NAG-003078: integral separated schemes of finite type over the stated field. Use the same coordinates $t_f = -\log|f|$ and the same slot interchange J_0 in both presentations. Restricting algebraic units to an ordinary affinoid neighbourhood gives an analytic moment germ (NAG-002423–002424).

Conversely choose an ordinary affinoid witness for an analytic germ and work inside its ordinary interior. Include in one tuple all units of any finite germ comparison under consideration. By NAG-003062 there are a compact

Laurent affinoid neighbourhood C, a very affine algebraic open U and algebraic units g_i on U such that $C \subset U^{\mathrm{an}}$ lies in the witness and $|g_i| = |f_i|$ throughout C. The construction truncates in the actual Laurent quotient with error smaller than $\min_i \|f_i^{-1}\|^{-1}$ for a nonempty tuple (NAG-003061). It gives an ordinary open chart about the point inside C. On this chart the g_i are constants times characters for the algebraic unit lattice, and their tropicalizations are integral affine functions of its coordinates (NAG-003077).

On the actual joint image of the two tuples the projections agree both on points and on every cell tangent. Thus they induce the same pullback in both alternating factors, including after adjoining further coordinates (NAG-003065). Two choices can be compared on an ordinary common intrinsic refinement inside both witnesses (NAG-003077). Consequently replacement descends through the germ relation and gives an inverse on stalks to the restriction of algebraic presentations; this is the algebraic identification in NAG-003078. Wedge, the two differentials and J_0 commute with these affine pullbacks on the ambient superforms and descend by NAG-002422 and NAG-002424. □

The theorem is an equality of two presentations of the original sheaf. Enlarging the allowed tropicalizations to harmonic ones, or adjoining polyhedral currents, makes a different construction and requires a separate comparison theorem.

8.2 Local structure near classical points

8.2.1 Smooth real functions can be locally constant at rigid points

Let $x \in X(K)$ and let f be an analytic unit near x. Continuity of f gives a smaller neighbourhood on which

$$|f(y) - f(x)| < |f(x)|.$$

The strong triangle inequality then implies $|f(y)| = |f(x)|$. For finitely many units $f_1, \dots, f_r$, choose one neighbourhood where all these equalities hold. Every original smooth function presented as $F(-\log|f_1|, \dots, -\log|f_r|)$ is constant there.

The corresponding positive-degree forms presented by these coordinates vanish there because the local tropical image is a point. This is a distinctive

feature of the original real differential calculus. The word smooth should not evoke a real manifold chart of dimension $2n$ around a rigid point. The useful differential directions occur at nonclassical analytic points and their tropical neighbourhoods.

This does not force a global smooth function on a connected analytic space to be constant. The neighbourhoods on which it is constant can vary with the rigid point, and nonclassical points lie between them. On the projective line, a smooth regularization of the standard metric weight varies near the Gauss point while being constant in appropriate rigid neighbourhoods after local trivialization.

8.2.2 A direct consequence for singular potentials

On a curve, the point mass δ_x at a rigid point is a perfectly meaningful top-degree current: it evaluates smooth scalar tests at x. But it cannot be the curvature of an original smooth function near x, because such a function has zero Hessian on some neighbourhood. Its logarithmic potential is singular. Poincaré–Lelong supplies precisely this kind of potential.

The distinction between a smooth form and a current is therefore already necessary in dimension one. A smooth positive metric can approximate a model metric whose mass concentrates at a nonclassical point; a logarithmic Green function can create a divisor mass at a rigid point. These are different limiting and singularity phenomena.

8.2.3 Restriction of a form and vanishing of its germ

In ordinary differential geometry, a positive-degree form can restrict to zero on a point while remaining nonzero arbitrarily near it. CLD's tropical-dimension support lemmas give stronger vanishing statements for certain degrees at analytic points of small tropical dimension. Their proofs use the local structure of moment maps, not just the formal rule that a form restricts to zero on a lower-dimensional space.

This distinction is used in the higher-codimension extension arguments of CLD25. If a test has degree larger than the relevant tropical dimension along a cycle, the source's support theorem can force its support away from that cycle. This is why a singular expression on the complement may still pair with the differentiated test in a canonical way. One must cite the support

theorem; merely observing that the restriction to the cycle is zero would not justify the extension.

8.2.4 Smooth density does not imply positive density

Original smooth scalar functions are dense in continuous functions in the appropriate local or compact-support topology. This permits the measure-theoretic extension used in defining uT. The approximation can be made with prescribed scalar bounds under the relevant cutoff construction.

However, density of a vector space of smooth functions does not imply density of its psh cone in the continuous current-psh cone. An approximation may develop negative Hessian terms. This is analogous to the difference between approximating an arbitrary continuous function by polynomials and approximating a convex function by convex polynomials on a specified domain: the positivity constraint is an additional problem.

In real convex geometry, convolution on a smaller fixed open set preserves convexity. On an analytic space, a given continuous potential may not be represented by a convex function in one fixed moment chart, and refining charts introduces relations that the approximation must respect. This is the precise reason a local smooth-density theorem is insufficient to prove general psh regularization.

Example 8.2.1 (Local constancy of a unit logarithm)**.** For $f(T) = a + T$ with $a \neq 0$, the strict ultrametric inequality gives $|f| = |a|$ on $|T| < |a|$. Hence $\log|f|$ is constant on that disc. At the Gauss point of radius $r > |a|$, however, $|f| = \max(|a|, r) = r$. These two descriptions are the two regions of $v(f) = \min(v(a), -\log r)$ along the Gauss points. Local constancy near a classical point is compatible with variation along an annular skeleton.

8.3 Integration on weighted polyhedral spaces

8.3.1 The data needed for a top-degree integral

Suppose a pure n-dimensional polyhedral complex has an integral tangent lattice N_σ on every maximal cell σ and a weight m_σ. Choose a lattice basis $e_1, \dots, e_n$ of N_σ. The basis fixes a normalized volume; replacing it by another

lattice basis changes the determinant by ± 1 and does not change the resulting density. A superform of degree (n, n) can be contracted against this volume and integrated over the cell. The total integral is the sum over maximal cells with the weights m_σ.

The three ingredients have distinct roles. The polyhedral support says where integration occurs. The lattice fixes a unit of volume. The weight records the multiplicity of the analytic or algebraic object over that support. The Euclidean volume inherited from an arbitrary ambient embedding generally has the wrong normalization.

Example 8.3.1 (A parametrization of index two)**.** Consider the map $\mathbb{G}_m \to \mathbb{G}_m$, $z \mapsto z^2$. On tropical coordinates it is $t \mapsto 2t$. Its generic algebraic degree is two, including the inseparable case when appropriate scheme-theoretic multiplicities are retained. If one integrates on the target using its standard lattice, the degree formula has a factor two. If instead one treats the source coordinate as a primitive target coordinate, the factor is lost. This simple calculation is the prototype for the lattice indices in tropical pushforward and the calibrated degree formulas of CLD25.

8.3.2 The boundary calculation behind balancing

For a compactly supported $(n-1, n)$-superform, apply ordinary Stokes on every maximal cell. Each codimension-one face receives a sum of contractions with its outgoing primitive normals. The sum vanishes precisely when the weighted normal vectors balance in the quotient by the tangent space of that face. Thus balancing turns a cellwise boundary formula into a global closedness statement.

This also explains why subdividing a cell changes no integral or current. Newly introduced interior faces occur in opposite pairs with compatible lattice volumes. Their boundary contributions cancel. A genuine corner of a function behaves differently: the normal derivatives on the two sides need not agree, and their difference survives as the divisor weight. The same integration-by-parts calculation therefore proves both closedness of a tropical cycle and the corner formula for a PL function.

Example 8.3.2 (Distributional curvature and outgoing slopes)**.** For $f, \eta \in C^2([a,b])$, integration by parts twice gives

$$\int_a^b f''\eta\,dt = \int_a^b f\eta''\,dt + [f'\eta - f\eta']_a^b.$$

If $a < 0 < b$ and η is compactly supported in (a,b), then

$$\int_a^b \max(0,t)\eta''(t)\,dt = \eta(0).$$

The distributional second derivative is therefore δ_0, although the classical second derivative vanishes off the origin. On the balanced tropical line, let the test be induced by an ambient smooth function and compactly supported away from the outer ends. The terms involving the first derivative of the test cancel by balancing. The calculation on the outgoing parameters then gives $(a_1+a_2+a_3)\eta(0)$ for a continuous affine-on-rays function with outgoing slopes a_1, a_2, a_3. The vertex coefficient is the sum of those slopes.

8.3.3 The tangent quotient

A curve can be embedded in a torus of arbitrarily large dimension. Its tropical image remains one-dimensional. A superform on the ambient real vector space is used only through its restrictions to tangent directions of the tropical image. Ambient components that vanish on all relevant tangent spaces represent the zero form on the image. This quotient is essential in the definition of CLD forms; the pullback notation alone does not specify equality of forms.

The example also explains why one cannot prove positivity by examining an arbitrary matrix in arbitrary ambient coordinates without passing to the quotient. Positivity is a condition on the actual tangent directions tested by the space. Refinement by additional moment coordinates must preserve that condition. In the intrinsic construction below, equality and positivity are formulated on common refinements so that the resulting forms do not depend on the original embedding.

8.4 Integration, canonical weights, and Stokes' theorem

8.4.1 Compatibility of integral presentations

Let X have pure dimension n and let α be a compactly supported smooth (n,n)-form. Locally write $\alpha = f_{\mathrm{trop}}^{*}\beta$ for an analytic moment map f. The image $f_{\mathrm{trop}}(X)$ can have singular faces, several analytic branches can map to the same face, and an integral-affine map between two presentations can have a nontrivial lattice index. Therefore the unweighted integral of β on the set-theoretic image cannot be the definition.

CLD assigns a canonical calibration to suitable tropical presentations. In the algebraic torus case, it agrees with the usual tropical multiplicity. In the analytic construction, finite maps and the degrees of the relevant analytic fibres supply the local weights. The compatibility theorem says that passing to a refined moment map and then projecting gives the same weighted integral. This is the essential geometric theorem behind the definition, not a consequence of the notation f_{trop}^{*}.

8.4.2 The construction in three steps

First, on a calibrated polyhedral cell, contract a top-degree superform with its calibrated tangent volume and integrate the resulting density. Second, sum over cells. Lower-dimensional overlaps do not contribute to a top-degree integral, and subdivision creates cancelling interior faces for boundary integrals. Third, use a smooth partition of unity on the analytic space to reduce a general compactly supported form to finitely many tropical presentations.

Independence must be proved at both transitions: common refinements compare local tropical presentations, while the partition-of-unity identity compares decompositions of the global form. For a paracompact good analytic space, the smooth partitions of unity constructed in CLD12 make this procedure available. Compact support is important because the actual integral is a finite local calculation even when the space itself is not compact.

Example 8.4.1 (The annular integral)**.** On an annulus with tropical coordinate $t = -\log|T|$, take a compactly supported form

$$\alpha = f(t)\, d't \wedge d''t.$$

The canonical weight is one, and $\int_X \alpha = \int f(t)\, dt$ in the chosen lattice normalization. Replacing T by T^m changes the real coordinate to $s = mt$. The pullback of $d's \wedge d''s$ has two factors of m, while the calibrated volume and the image parametrization account for the corresponding degree and Jacobian. One cannot change the coordinate and leave the integration normalization unchanged.

8.4.3 Stokes on the analytic space

On every cell, Stokes is ordinary integration by parts. At an interior codimension-one face, the sum of boundary contractions vanishes by the calibrated balancing condition. The remaining contributions lie on the analytic boundary. Thus, when the support of η avoids that boundary,

$$\int_X d'\eta = 0 \quad \text{for } \eta \in A_c^{n-1,n}(X), \qquad \int_X d''\xi = 0 \quad \text{for } \xi \in A_c^{n,n-1}(X).$$

For a compact analytic domain with boundary, there are corresponding boundary integrals. Deleting those terms is justified by the support condition, not by compactness of the domain.

This is the bridge from the balancing equation of Chapter 5 to the closedness of an integration current. It also explains why arbitrary piecewise smooth functions cannot be differentiated cellwise and then treated as smooth global functions. Their internal interfaces contribute additional terms.

8.4.4 The signed boundary measure for ordinary native forms

Theorem 8.4.2. *Let K be complete for a specified real-valued non-Archimedean absolute value, possibly trivial. Let X be a good Hausdorff K-analytic space in the norm-admissible generalized affinoid atlas, analytically pure of dimension $d \geq 1$, and let $\mathcal{F}$ be coherent on X_G. Take an ordinary real smooth moment form β with compact ordinary germ support S. Put $D = d'$ for type $(d-1, d)$, or $D = d''$ for type $(d, d-1)$. There is a unique finite signed Radon measure $\mu^D_{X,\mathcal{F},\beta}$ supported in $S \cap \partial_K X$, where*

$\partial_K X = X \setminus \mathrm{Int}(X/K)$, *such that, for every ordinary smooth real scalar* u *on* X,

$$\int_X u\, d\mu^D_{X,\mathcal{F},\beta} = I^N_{X,\mathcal{F}}\big(D(u\beta)\big). \tag{S1}$$

Here I^N *is the native integral of NAG-002425. In particular the mass is* $I^N_{X,\mathcal{F}}(D\beta)$. *Here support of a signed measure means support of its total variation. For support contained in the analytic interior the measure vanishes.*

We give the proof first for $D = d'$. All charts use $-\log|f|$ and the interleaved positive lattice top generator. The strict integral structure-coefficient estimate (B) below is used only for a single global representative of the primitive. The multiplier in (B) is any ordinary smooth scalar.

The native bulk comparison under free extension. On a pure compact affinoid $Y = \mathcal{M}(B)$, let M be a finite B-module. For a finite free polyradius let $L = K_r$, $B_L = B\widehat{\otimes}_K L$, $M_L = B_L \otimes_B M$, and $p : Y_L \to Y$. For any ordinary top section ω we have

$$I^N_{Y_L,M_L}(p^\natural\omega) = I^N_{Y,M}(\omega). \tag{S2}$$

To see this, extend the units and use the same ambient superform. The full inverse image of an affinoid domain with algebra C has algebra $C_L = C\widehat{\otimes}_K L$: the relative completed tensor with B_L identifies with this algebra by multiplying simple tensors, with inverse $c \otimes l \mapsto c \otimes (1 \otimes l)$ (NAG-001616, 001688, 001846). The free Gauss section is a right inverse on each domain (001569); unit and joint images agree. The inverse image of the ordinary interior of a germ witness is open. Thus the same joint-image equality gives a germ witness upstairs, including at a point of the absolute boundary. Restrictions, products, both differentials and the Lagerberg slot swap commute with this rule, and $p^\natural u = u \circ p$ (002422–24). Finite module restrictions are the tensors with their canonical norms (001565, 001686, 002414). Purity is preserved by free extension (002291).

For a single unit chart on a presenting piece with algebra C and restricted module P, subdivide the common moment image with the boundary images over both fields (002358, 002405). In a top cell, at a relative-interior weight w, both whole levels are interior. Choose an integral projection Q injective on the saturated tangent lattice N. Take the algebra of the whole w-level cut out by all original equalities of moduli, before applying Q. Those Laurent conditions base change, and 002306 gives a finite algebra over the exact-radius

polytorus at Qw. If H, H' are the Gauss fields for that polytorus over K, L, and E, E' the respective Gauss fibre algebras, 002301 gives $E' = E \otimes_H H'$ with $H \hookrightarrow H'$ isometric. In particular

$$(C_L \otimes_C P) \otimes_{C_L} E' \simeq (P \otimes_C E) \otimes_H H'.$$

The dimension over H' equals the original dimension over H; the weight divides that dimension by the same index $[\mathbb{Z}^d : Q(N)]$ over each field (002362). This retains the whole Artinian fibre including its lengths and residue degrees. Lower-dimensional images carry zero top integral. Pairing with the same tangential coefficient and volume proves the single-chart identity. On a finite presentation all actual intersections base change; summing their equalities with the same signs proves (S2) by 002416 and 002425.

For B integral and $\beta = t_f^* \alpha$ on all of Y, choose L nontrivially valued with B_L strict by 001840 (identity domain). It is integral of the same analytic dimension by 002291. Apply (B) upstairs and (S2) to the full derivative downstairs:

$$|I^N_{Y,B}(d'(u\beta))| = |I^N_{Y_L,B_L}(d'((u \circ p)p^\natural \beta))| \le C_{Y_L, p^\natural \beta} \|u\|_{C^0(Y)}. \tag{S3}$$

Choosing this one field gives a bound on the fixed original chart. There is no strictness condition on the local presentations of u. This argument changes the field for the bulk integral, without a comparison of the inverse images of the two absolute boundaries.

Coherent coefficients and finite cuts. On a compact pure Y, put $Y_\mathfrak{p} = \mathcal{M}(B/\mathfrak{p})$ and $\ell_\mathfrak{p}(M) = \operatorname{length}_{B_\mathfrak{p}}(M_\mathfrak{p})$ for $\mathfrak{p} \in \operatorname{Min} B$. The complete quotient is an integral pure affinoid of dimension d by 001562 and analytic purity. For every ordinary top section,

$$I^N_{Y,M}(\omega) = \sum_{\mathfrak{p} \in \operatorname{Min} B} \ell_\mathfrak{p}(M)\, I^N_{Y_\mathfrak{p}, \mathcal{O}}(\omega|_{Y_\mathfrak{p}}). \tag{S4}$$

Here restriction to a closed component is defined by restricting units and ambient coefficients: inverse images of the presenting neighbourhoods are neighbourhoods, and tangential equality restricts to their joint subimages (001846, 002406, 002422–24).

For the coefficient check, use a finite presentation and a nonempty chart intersection $V = \mathcal{M}(C)$. On its inverse image in $Y_\mathfrak{p}$ the algebra is $C/\mathfrak{p}C$, and the tuple is the restricted tuple. Subdivide with all these actual images

and all their boundary images. At w generic in a top cell, every contributing image locally has that same tangent plane, and its whole level is interior. Empty inverse levels give zero. The level with algebra D_w in V is also an affinoid domain of Y by domain transitivity (001609). It is finite over the chosen polytorus algebra R by 002306. Put $E = D_w \otimes_R H$ as above. The whole level on the inverse image in $Y_{\mathfrak{p}}$ is cut out by the same equalities, hence has algebra $D_w/\mathfrak{p}D_w$ and Gauss fibre $E/\mathfrak{p}E$ (001565, 001702, 001846). NAG-002360 applied to $B \to D_w$ gives the exact numerator

$$\dim_H(M \otimes_B E) = \sum_{\mathfrak{p}} \ell_{\mathfrak{p}}(M) \dim_H(E/\mathfrak{p}E).$$

In particular the component lengths refer to the original B even when the multiplier varies through finer charts. Divide by the same index of $Q(N)$ on each contributing image. Integrate the common tangential coefficient and sum on the presenting intersections using 002401, 002405 and 002416. This proves (S4).

For an arbitrary compact affinoid primitive, choose a finite cover by affinoid neighbourhoods whose ordinary interiors cover Y, each carrying one representative of β on the whole domain (002424). On a nonempty intersection $Y_J = \mathcal{M}(B_J)$ choose one restricted representative, and put $M_J = B_J \otimes_B M$. These domains are affinoid and pure (002411, 002413). Apply (S4) to $d'(u\beta)|_{Y_J}$ and then (S3) to the restricted single-chart primitive on each integral component. Every restricted multiplier has norm at most $\|u\|_{C^0(Y)}$. The signed cover formula for this variable top test follows by intersecting the cover with a presenting cover for the top test, applying 002401 on each single chart and interchanging finite sums (002416, 002425). Every nonempty intersection enters, including ones with empty ambient ordinary interior. We get a bound independent of u by summing the finitely many constants with their nonnegative component lengths. This proves boundedness of $T(u) = I^N_{Y,M}(d'(u\beta))$ on the entire compact affinoid.

Compact Radon representation within the ordinary calculus. For $F \in C(Y, \mathbb{R})$ a finite ordinary open cover of oscillation $< \epsilon$ and a smooth partition from 002428 approximate F uniformly by the partition-weighted sum of one value of F per nonempty open. Thus T extends uniquely and boundedly to $C(Y)$ by taking limits. For continuous $f \geq 0$ set $P(f) = \sup_{0 \leq g \leq f} T(g)$ over continuous g. It is finite, nonnegative and positively homogeneous. Split each $0 \leq g \leq f_1 + f_2$ as $\min(g, f_1) + (g - \min(g, f_1))$; in

the reverse direction add two approximate maximizers. This gives additivity. Extending by differences is well defined by additivity; both P and $P - T$ are positive linear functionals.

For each of these two functionals H_0 put

$$m(U) = \sup\{H_0(a) : a \in C(Y),\ 0 \le a \le 1,\ \operatorname{supp} a \subset U\}, \qquad m^*(E) = \inf_{U \supset E,\ U \text{ open}} m(U).$$

Then $m(Y) = H_0(1)$. For a countable union of opens, a test supported in the union has its compact support covered by finitely many of them. Splitting it by a partition near that support proves subadditivity on opens. Open supersets within errors $\epsilon 2^{-i}$ give countable subadditivity of m^*; it is monotone, vanishes at the empty set and agrees with m on opens. For an open U and an open $V \supset E$, choose a test a supported on a compact $K_0 \subset U \cap V$ with $H_0(a) > m(U \cap V) - \epsilon$. Adding any test on $V \setminus K_0$ keeps the sum at most one. Hence $m(V) \ge m^*(E \cap U) + m^*(E \setminus U) - \epsilon$. Infimizing and using subadditivity proves that U splits m^* additively on every set. Such splitting sets are closed under complement and finite union by successive splitting. For disjoint splitting sets B_i, successive splittings bound $m^*(E)$ below by each partial sum of $m^*(E \cap B_i)$ plus $m^*(E \setminus \bigcup_i B_i)$. Subadditivity gives splitting for their union and countable additivity. Disjointification gives closure under countable unions. Restriction to Borel sets therefore gives a finite measure ν, outer regular by construction; outer approximation of complements in compact Y gives compact inner approximation for Borel sets.

For $0 \le f \le N\delta$, approximate each $m(\{f > j\delta\})$ by tests a_j, $j = 1, \dots, N$. Pointwise $\delta \sum_j a_j \le f$, so $H_0(f) \ge \delta \sum_j \nu(\{f > j\delta\})$. The corresponding simple function differs from f by at most δ. Let δ tend to zero with $N\delta \ge \max f$. Apply the resulting lower bound also to $\max f - f$, using $\nu(Y) = H_0(1)$, to obtain $H_0(f) = \int f \, d\nu$. The difference of the measures for P and $P - T$ represents T.

We use the following uniqueness and localization test here and below. If a finite signed Radon measure annihilates smooth scalars compactly supported in an ordinary open U, it vanishes there. For compact $C \subset U$ take an open $C \subset V \subset U$ with variation on $V \setminus C$ as small as desired. A cutoff between zero and one supported compactly in V and equal to one near C exists by 002428. Its zero integral bounds the absolute measure of C by that variation. Compact inner approximation then gives zero on Borel subsets of U. A finite sum of the positive Radon measures in the construction dominates the variation, so the same regular approximations apply to

their signed differences. This proves uniqueness. Tests supported outside $\operatorname{supp}\beta$ give zero. For a scalar compactly supported in $\operatorname{Int}(Y/K)$, the product primitive is compactly supported there, and NAG-002577 annihilates its derivative. We have proved (S1) and the asserted support on Y. In particular (S2) and uniqueness identify the compact scalar-extension comparison on measures with $p_*\mu^{d'}_{Y_L,M_L,p^\natural\beta} = \mu^{d'}_{Y,M,\beta}$: the pushforward is Radon as the map is continuous between compact Hausdorff spaces. This comparison needs no boundary-fibre equality.

Ordinary localization and the closed-cut formula. On X take finitely many compact affinoid neighbourhoods Y_i whose ordinary interiors cover S, and smooth cutoffs χ_i compactly supported in those interiors, summing to one near S (002428). Goodness gives these neighbourhoods, purity holds by 002413, and 002414 gives finite coefficient modules on all their intersections. With $\iota_i : Y_i \hookrightarrow X$, set

$$\mu = \sum_i (\iota_i)_*\big((\chi_i|_{Y_i})\,\mu^{d'}_{Y_i,\mathcal{F}|_{Y_i},\beta|_{Y_i}}\big).$$

Compact-domain pushforwards are finite Radon measures: compact inner approximants have compact images, and outer regularity follows by approximating the complement from inside. Formula (S1) on Y_i, tested on $u\chi_i$, gives the integral of the derivative of the entire product. Its compact collar in the ordinary interior makes both derivative and integral compatible with zero extension by 002580. The sum equals $I^N_{X,\mathcal{F}}(d'(u\beta))$ since $\sum_i \chi_i = 1$ near S. The uniqueness test on ordinary opens now proves independence and gives support in $S \cap \partial_K X$: outside S the product vanishes and on the analytic interior use 002577 on compactly supported scalar multiples. The ambient space itself need not be compact or paracompact.

In particular, on an ordinary open U the restriction of μ is characterized on compactly supported smooth scalars a there by $I^N_{U,\mathcal{F}|_U}(d'(a\beta|_U))$. Indeed a extends by zero and both integrals use the same carrier inside U by 002425. This also works on the ambient ordinary interior of a closed affinoid domain. More generally, for a finite ordinary cover of S, local primitives with germ supports in $S \cap U_i$ have a common measure supported in S precisely when their evaluations on compact smooth overlap scalars agree after the two zero extensions. Necessity is restriction. For sufficiency take the sum of the zero extensions of the measures of $\chi_i\beta_i$ on U_i. Each product is compactly supported there. Testing against a scalar compactly supported in U_k, the products

of that scalar with χ_i are compactly supported in the overlaps; replace their local evaluations by the ones on U_k and sum. This recovers the evaluation on U_k. Uniqueness on each open proves the assertion. True boundary support follows as above locally: an ordinary open has the same structure-map interior on that open (001631). Equality of ordinary primitive germs on the overlaps suffices for the evaluation condition by the common-carrier argument.

There is also an expression without cutoffs. For any finite such closed affinoid cover of the support by ordinary interiors write $D_J = \bigcap_{j\in J} Y_j$, $B_J = \mathcal{O}(D_J)$, $M_J = \Gamma(D_J, \mathcal{F})$, and write i_{Jp} for the inclusion of $\mathcal{M}(B_J/\mathfrak{p})$ into X. Then

$$\mu^{d'}_{X,\mathcal{F},\beta} = \sum_{\emptyset\neq J,\ D_J\neq\varnothing} (-1)^{|J|+1} \sum_{\mathfrak{p}\in \operatorname{Min} B_J} \ell_{\mathfrak{p}}(M_J)(i_{Jp})_* \mu^{d'}_{\mathcal{M}(B_J/\mathfrak{p}),\,\mathcal{O},\,i_{Jp}^*\beta}. \tag{S5}$$

Testing against u, apply (S4) on each intersection and the finite cover formula on their compact union (002416, 002425). This yields (S1), hence equality by uniqueness. Each cut has its own absolute boundary, potentially including an artificial frontier. The support bound on X is for the signed sum. Neither raw restriction to a closed overlap nor addition of the total variations is used.

Finally let J be the native Lagerberg involution. It fixes scalars, interchanges d' and d'', and acts on interleaved top degree by $(-1)^d$, since each of the d pairs is reversed (002388, 002424, 002577). For a compact primitive γ of type $(d, d-1)$ this gives

$$\mu^{d''}_{X,\mathcal{F},\gamma} = (-1)^d \mu^{d'}_{X,\mathcal{F},J\gamma}.$$

Thus (S1) uses the derivative of $u\gamma$ with its own plus convention, and the signed sum and localization statements follow in this bidegree as well.

A uniform scalar bound from the fixed moment image

Let K be complete and nontrivially valued for its specified real non-Archimedean absolute value. Let $Z = \mathcal{M}(A)$ be a nonempty integral strict affinoid of analytic dimension $d \geq 1$, with structure coefficient. Fix analytic units $f = (f_1, \ldots, f_n)$, $t = t_f$ with coordinates $-\log|f_i|$, and a smooth real ambient form α of type $(d-1, d)$ on a neighbourhood of $P = t(Z)$. Write $\theta = t^*\alpha$, and I for the native ordinary top integral. Then there exists $C < \infty$, independent of every chart and cut used for the scalar, such that

$$|I(d'(u\theta))| \leq C\|u\|_{C^0(Z)} \qquad (u \in \mathcal{A}^{0,0}_Z(Z)). \tag{B}$$

The proof estimates a positive bulk integral in the fixed chart. No boundary measure or lifting of boundary sheets is a premise.

A cutoff in the original target. Put $H = t(\partial_K Z)$. By NAG-002358 and 002405, P is compact finite polyhedral of dimension at most d, H is finite polyhedral of dimension at most $d-1$, and the structure chain has fixed finite nonnegative weights m_σ on its d-cells. If H is empty, (B) follows with $C = 0$ from NAG-002577. If $\dim P < d$, the entire second slot of θ vanishes tangentially, giving the same conclusion. Take a finite subdivision of P adapted to H.

For each cell of H, choose a real affine hyperplane $\ell_j = 0$ containing it and containing none of the affine spans of the d-cells of P. Such choices exist: the space of affine functions vanishing on the span of that cell is not contained in the subspace of functions vanishing on any specified d-plane, by the dimension inequality. A finite union of proper linear subspaces cannot cover a real vector space (choose a nonzero linear equation for each and take their product, a nonzero polynomial). Use a smooth $0 \le b \le 1$ equal to one on $[-1,1]$ and zero outside $(-2,2)$, from the elementary smooth profile in the proof of NAG-002427. For $0 < \epsilon < 1$, put

$$\chi_\epsilon = 1 - \prod_j (1 - b(\ell_j/\epsilon)), \qquad \psi_\epsilon = \sum_j b(\ell_j/(2\epsilon)).$$

Then $0 \le \chi_\epsilon \le 1$, it is one on an open neighbourhood of H, and it vanishes off the union of the slabs $|\ell_j| \le 2\epsilon$. On the support of its derivative $\psi_\epsilon \ge 1$ and $\|\nabla \chi_\epsilon\| \le c/\epsilon$, with c fixed. Smoothness here is in real moment coordinates; the hyperplanes do not define new analytic domains.

For every coarse d-cell σ and every j, the lattice volume in σ of $\{|\ell_j| \le 4\epsilon\}$ is at most $c_{\sigma j}\epsilon$ for sufficiently small ϵ. If the restriction is constant nonzero the intersection is empty eventually. Otherwise in integral affine coordinates on the cell span some coordinate has nonzero coefficient a in ℓ_j. Enclose the compact cell in a fixed box and slice parallel to that axis. Each slice has length at most $8\epsilon/|a|$; the remaining box has fixed volume (NAG-002389). This proof applies equally on a compact fine d-cell whenever its projection has rank d and lands in σ, with a constant then allowed to depend on the fine cell.

A positive majorant independent of the multiplier. Order the ambient coordinates once and put

$$\Omega = \sum_{i_1<\cdots<i_d} \bigwedge_{k=1}^{d} (d' x_{i_k} \wedge d'' x_{i_k}).$$

In lattice coordinates on a d-plane its interleaved top coefficient is the sum of the squares of its coordinate d-minors, which is strictly positive. Use $a_\sigma > 0$ for this constant on $\mathrm{aff}(\sigma)$, and ω_σ for the interleaved top generator there. On σ write $d'\chi_\epsilon \wedge \alpha = q_{\epsilon,\sigma}\omega_\sigma$. Compactness, the gradient bound and the finitely many coarse tangent planes give one c_1 such that

$$|q_{\epsilon,\sigma}| \le (c_1/\epsilon)\psi_\epsilon a_\sigma.$$

Indeed $q_{\epsilon,\sigma}$ is linear in the first derivatives of χ_ϵ with bounded coefficients, and vanishes off their support. Define $\Lambda_\epsilon = (c_1/\epsilon)\psi_\epsilon\Omega$. By the coarse chart integral (NAG-002405) and the slab estimate,

$$I(t^*\Lambda_\epsilon) = \frac{c_1}{\epsilon}\sum_\sigma m_\sigma a_\sigma \int_\sigma \psi_\epsilon \, d\mathrm{vol}_\sigma \le c_1 \sum_{\sigma,j} m_\sigma a_\sigma c_{\sigma j} =: C. \tag{1}$$

We claim both top sections

$$\|u\|_\infty \, t^*\Lambda_\epsilon \;\pm\; u\, t^*(d'\chi_\epsilon \wedge \alpha)$$

are positive in the ordinary native sense. At each point use an ordinary affinoid scalar representative $u = v(t_g)$ and adjoin f. Subdivide the joint image so projection π to the f-coordinates maps each cell into a coarse cell. If π on a d-cell has rank $< d$, both pulled-back tops vanish. Otherwise the two coarse top coefficients are pulled back with the same squared determinant in integral coordinates. This is positive whatever the orientation. Use $|v(t_g)| \le \|u\|_\infty$ on the actual joint image and the preceding coefficient inequality. This proves positivity on all local representatives so chosen. NAG-002425, whose positivity includes varying finite domain presentations, now gives

$$|I(u\, t^*(d'\chi_\epsilon \wedge \alpha))| \le C\|u\|_\infty. \tag{2}$$

It is essential to take this inequality for the ordinary integral. Applying an absolute value separately to all signed terms of an arbitrary closed cover would not give (1).

The term containing the derivative of the multiplier. For each fixed u,

$$I((\chi_\epsilon \circ t)d'(u\theta)) \to 0. \tag{3}$$

Choose once for this u a finite cover by ordinary affinoid presentation neighbourhoods, with their interiors covering Z. On every actual nonempty closed intersection use one restricted scalar presentation and its joint tuple with f. The restriction and finite-cover formulae NAG-002416, 002424–25 allow the same finite family for all ϵ. On its joint image the top representative before multiplication by $\chi_\epsilon \circ \pi$ is

$$d'(v\,\pi^*\alpha) = d'v \wedge \pi^*\alpha + v\,\pi^*(d'\alpha),$$

where v is composed with the scalar-coordinate projection. On each d-cell on which π has rank $< d$, this is zero: all d double-primed covectors in both terms come from the coarse target. On each remaining cell the coefficient is bounded on the compact polytope for this fixed presentation. The portion on which $\chi_\epsilon \circ \pi \neq 0$ has lattice volume $O(\epsilon)$ by the fine-cell slab estimate above. All weights are finite and fixed for this u, and the finite signed sum tends to zero. This argument requires no uniform control on the derivatives, weights or number of charts of u.

Finally $(1-\chi_\epsilon \circ t)u\theta$ is identically zero on the inverse image of an ordinary neighbourhood of H. Its support is compact in $\mathrm{Int}(Z/K)$; hence NAG-002577 gives $I(d'((1-\chi_\epsilon \circ t)u\theta)) = 0$. The product rule with the scalar in first position yields

$$I(d'(u\theta)) = I(u\,t^*(d'\chi_\epsilon \wedge \alpha)) + I((\chi_\epsilon \circ t)d'(u\theta)).$$

Take $\epsilon \downarrow 0$ in (2)–(3). This proves (B) with the constant in (1), for multipliers with arbitrary ordinary local charts.

Normal and multiplicity check. For comparison, on a single global joint tuple, take subdivisions adapted to the projection and boundary images. For an incident fine cell–facet flag mapping with full ranks to a coarse flag, let e be the tangent-lattice index on the facet. Modulo the coarse facet lattice the primitive inward normal maps to k times the coarse primitive inward normal, with $k > 0$. In bases completed by these normals the full index is ek (block triangular determinant). In the normal-contraction formula of NAG-002389 the two lists of facet tangent vectors give e^2; the remaining normal gives k, with its tangent component killed by alternation. Scalar facet volume changes by $1/e$ upon passage from fine to coarse, leaving ek times

the original fine weight, with the common inward convention $(-1)^{d(d+1)/2}$. For a facet mapping to smaller facet dimension the tangent lists lose rank, and for a contracted incident d-cell the entire second slot loses rank. Each such flag has zero contraction of the pulled-back primitive. For $d = 1$ the empty facet tangent lists have index one. The generic pushforward of top cells in NAG-002405 counts their full weights times the full index: NAG-002306 and 002362 take the whole Gauss fibre degree with all local lengths and residue degrees and divide by the chosen projection index. Formula (1) uses those resulting coarse weights once. A coarse signed normal can vanish even when the individual incidences have nonzero absolute contractions. The bulk majorant avoids any identification of individual boundary sheets or any assumption that absolute normal masses commute with projection.

8.4.5 A Green identity and its use

Let u, v be smooth real functions, and let T be a closed current of suitable degree. Assume all products under consideration have compact support away from the analytic boundary. Applying the two Leibniz rules and Stokes yields the integration-by-parts symmetry

$$\int u \, \mathrm{d}'\mathrm{d}''v \wedge T = \int v \, \mathrm{d}'\mathrm{d}''u \wedge T$$

when the remaining degrees make these top-degree integrals. A convenient sufficient support assumption is that one factor is compactly supported and the other is defined on a neighbourhood of that support. More general formulations use cutoffs.

The identity is the engine behind several later results: it moves derivatives away from an approximating potential, proves symmetry of mixed expressions, and gives estimates in terms of the sup norm of the potential. However, its use with a nonsmooth potential requires a limiting argument. The formula itself does not authorize a product that has not yet been defined.

Example 8.4.3 (Boundary terms in Green's identity)**.** For $u, v \in C^2([a, b])$,

$$\int_a^b (uv'' - vu'') \, dt = [uv' - vu']_a^b.$$

For $u = 1$ and $v = t^2$, this is $2(b-a)$, which is nonzero when $a < b$. Compactness does not remove boundary terms. If one factor is compactly supported

in (a, b), it and its first derivative vanish near the endpoints, and the displayed boundary term is zero. This is the support mechanism in the current identity.

References. [CLD12, §§3.3–3.12]; the algebraic presentation and integration comparison in [Gubler].

8.4.6 The signed measure of an ordinary top form

Proposition NAG-002970 (Native top-form measures; F8CR-M)**.** *Let Y be good, Hausdorff, and pure of dimension d. For every real ordinary compact (d, d)-form ω, there is a unique finite signed Radon measure $\mu_{Y,\omega}$, supported in $S = \operatorname{Supp}\omega$, with*

$$\int_Y \phi \, d\mu_{Y,\omega} = \int_Y \phi\omega \quad \text{for every ordinary smooth scalar } \phi. \tag{8.4.1}$$

The construction is linear in ω and positive for positive ω. If its compact support is contained in an open subspace, the measure on Y is the zero extension of the measure there. It defines a separate Borel-measure extension; it does not enlarge the class of coefficients admitted by the frozen grid integral. Empty support gives the zero measure.

Proof. We spell out the boundedness and representation steps.

Density and cutoffs on a compact set. For $h \in C(S, \mathbb{R})$ and $\epsilon > 0$, take finitely many ordinary open sets covering S on each of which the oscillation of h on S is less than ϵ. Choose a point x_j of each nonempty piece. By `NAG-002428` there are nonnegative compact ordinary smooth χ_j subordinate to these sets, summing to one near S. Then $\sum_j h(x_j)\chi_j$ approximates h uniformly on S to error ϵ, and is nonnegative on all of Y when $h \geq 0$. Thus ordinary smooth scalar restrictions are dense in $C(S)$. Moreover for a compact $F \subset U \subset S$ with U relatively open, there is a continuous function on S equal to one on F, between zero and one, and with support contained in U. Lift U to an open set of Y, use finitely many point cutoffs from `NAG-002427`, and take $1 - \prod_j (1 - \chi_j)$. Finite partitions on compact supports follow from the same frozen partition theorem restricted to S.

A positive domination. Choose finitely many moment representatives α_j near the compact support and a nonnegative ordinary partition ρ_j with com-

pact supports inside those chart opens, summing to one near S. In the ambient real coordinates $t_1, \dots, t_r$ of a chart, put

$$\Theta_j = \frac{1}{d!} \left(\sum_{k=1}^{r} d' t_k \wedge d'' t_k \right)^d .$$

For $d = 0$ take $\Theta_j = 1$. On a d-plane the coefficient of Θ_j is the Euclidean Gram square and is positive. Replace α_j by $(\alpha_j + (-1)^d J\alpha_j)/2$; this does not change its restriction to any d-plane, since the top generator has J-sign $(-1)^d$. On the compact moment image of $\operatorname{Supp} \rho_j$, its coefficient matrix on $\bigwedge^d \mathbb{R}^r$ is bounded. The elementary finite-dimensional inequality $|v^T C v| \le c_j |v|^2$, for a sufficiently large constant c_j, therefore shows that $c_j \Theta_j \pm \alpha_j$ are nonnegative on all d-planes there. This remains true on the tangent planes of every joint moment refinement, including rank-deficient ones. If $r < d$, both restrictions are zero.

The zero extensions of $\rho_j c_j t_g^* \Theta_j$ define a positive compact form θ satisfying $-\theta \le \omega \le \theta$. For $M = \sup_S |\phi|$, the forms $M\theta \pm \phi\omega$ are positive: on S use the displayed bound and outside S use $\omega = 0$. Positivity of `NAG-002425` gives

$$\left| \int_Y \phi\omega \right| \le C_\omega \sup_S |\phi|, \qquad C_\omega = \int_Y \theta < \infty. \tag{8.4.2}$$

Hence the native functional depends only on $\phi|_S$ and extends uniquely by uniform limits to a bounded linear functional $\Lambda_\omega : C(S) \to \mathbb{R}$. For positive ω the positive approximants above prove that this extension is positive.

Representation of a positive functional, with the construction. For any positive bounded $\Lambda : C(S) \to \mathbb{R}$, define, for open $U \subset S$ and arbitrary $E \subset S$,

$$\begin{aligned} a(U) &= \sup\{\Lambda(g) : g \in C(S),\ 0 \le g \le 1,\ \operatorname{Supp} g \subset U\}, \\ a^*(E) &= \inf\{a(U) : E \subset U,\ U \text{ open in } S\}. \end{aligned}$$

Here $a(S) = \Lambda(1)$, and every quantity is finite. If an open set is covered by countably many open sets, the compact support of any test g is covered by finitely many of them. A finite partition on that support splits g into admissible summands, proving countable subadditivity for a on open sets. Choosing open supersets with errors $\epsilon 2^{-j}$ proves that a^* is an outer measure; it agrees with a on open sets.

Every open U is measurable for this outer measure. Indeed, fix E and choose open $V \supset E$ with $a(V) \le a^*(E) + \epsilon$. Choose a test g supported on

a compact $F \subset V \cap U$ with $\Lambda(g) \geq a(V \cap U) - \epsilon$. For a test h supported in $V \setminus F$, the function $g + h$ is still between zero and one and supported in V. Thus $a(V \setminus F) \leq a(V) - \Lambda(g)$, and

$$a^*(E \cap U) + a^*(E \setminus U) \leq a(V \cap U) + a(V \setminus F) \leq a^*(E) + 2\epsilon.$$

Outer subadditivity supplies the reverse inequality. Let $\epsilon \downarrow 0$. The sets satisfying this splitting equality form a sigma-algebra. Complements are immediate. For disjoint measurable E_j, finite iteration gives, for every H,

$$a^*(H) \geq \sum_{j=1}^{N} a^*(H \cap E_j) + a^* \left(H \setminus \bigcup_{j \geq 1} E_j \right).$$

Pass to the supremum over N and use outer subadditivity on $H \cap \bigcup E_j$ to obtain measurability of the union. General countable unions reduce to disjoint ones by differences. The same finite-iteration inequality and outer subadditivity prove countable additivity of the restricted outer measure. Hence $\mu = a^*|_{\mathrm{Borel}(S)}$ is a finite Borel measure.

For a test g above, $\Lambda(g) \leq \mu(\operatorname{Supp} g)$, since every open set containing that support admits g in its defining supremum. It follows that the measure of an open set is the supremum of the measures of its compact subsets. Outer regularity is built into a^*. Inner regularity for every Borel set follows by taking complements and using finiteness of $\mu(S)$. Thus μ is Radon. Integrals of nonnegative Borel functions are defined by the supremum over dominated nonnegative simple functions; bounded functions may equivalently be approximated uniformly by their finite dyadic step functions.

To verify representation without importing it, let $u \geq 0$ be continuous, $0 \leq u \leq m\delta$. Tests supported in $\{u > k\delta\}$, $k = 1, \ldots, m$, give

$$\delta \sum_{k=1}^{m} \mu\{u > k\delta\} \leq \Lambda(u).$$

For the upper bound put $v_k = \min(1, \max(0, (u - k\delta)/\delta))$, $k = 0, \ldots, m-1$. Then $u = \delta \sum v_k$, and for $k \geq 1$ the support of v_k is contained in $\{u > (k-1)\delta\}$. Consequently

$$\Lambda(u) \leq \delta\mu(S) + \delta \sum_{k=1}^{m-1} \mu\{u > (k-1)\delta\}.$$

The lower simple sum differs from u by at most δ, and the upper one by at most 2δ. Let $\delta \to 0$, choosing $m\delta \geq \|u\|_\infty$. Both bounds tend to $\int u\, d\mu$. Linearity gives $\Lambda(u) = \int u\, d\mu$ for all continuous u. Uniqueness follows from the cutoff formula for open sets and Radon inner regularity.

Signed functionals and locality. For a bounded real Λ, define on $u \geq 0$

$$\Lambda^+(u) = \sup_{0 \leq v \leq u} \Lambda(v).$$

This is finite, nonnegative, positively homogeneous, and additive: for one inequality split any $v \leq u_1 + u_2$ into $\min(v, u_1)$ and $v - \min(v, u_1)$; for the other add two nearly maximizing choices. Extend linearly to all of $C(S)$. It is bounded, since $\Lambda^+(u) \leq \|\Lambda\|\|u\|_\infty$ for $u \geq 0$. The functional $\Lambda^- := \Lambda^+ - \Lambda$ is positive and bounded. The positive construction gives $\mu = \mu^+ - \mu^-$. Any two finite signed Radon representations are equal by comparing the positive measures in their two decompositions and using positive uniqueness. Apply this construction to Λ_ω on S, then extend by zero along the closed inclusion $S \hookrightarrow Y$. This yields (8.4.1). The same uniqueness, density on a compact union of supports, and locality of the frozen integral prove linearity and compatibility with open restrictions wherever the form has compact support.

Cutoffs and the order-zero bound (lines 296–348). For compact $F \subset O \subset S$ with O relatively open, lift O to an ordinary open of Y. Finitely many point cutoffs there give $1 - \prod_j (1 - \chi_j)$ restricted to S, equal to one on F and supported in O. More generally a finite relatively open cover of F lifts to ambient opens; apply 002428 on F and restrict. For $u \in C(S)$, a finite such cover of S by sets of oscillation less than ϵ gives an approximant $\sum_j u(x_j)\chi_j$ of uniform error at most ϵ. If $u \geq 0$ the approximant is nonnegative. No continuous extension of u to Y is required.

In each moment presentation on a neighbourhood of S, use the interleaved form $\Theta = (\sum_k d't_k \wedge d''t_k)^d/d!$. In interleaved coordinates a tangent d-frame with Plücker vector v evaluates Θ to $\sum_I v_I^2$ and the given coefficient matrix to $v^{\mathrm{t}}Av$ (absorbing the fixed coordinate sign in A). The latter has absolute value bounded by $c\sum_I v_I^2$ on the compact chart region used by its cutoff. Projection of a frame under refinement uses the same calculation, including $v = 0$. In dimension zero take $\Theta = 1$. With the finite nonnegative partition, sum the cutoff multiples of $c\Theta$, extended by zero, to get a compact positive form θ bounding $\pm\omega$.

Here is a way to use precisely $M = \sup_S |\phi|$ even if ϕ is much larger just outside S. For $\epsilon > 0$ choose a smooth real scalar truncation β equal to the identity on $[-M - \epsilon/2, M + \epsilon/2]$ and bounded in modulus by $M + \epsilon$. For example multiply the identity by the cutoff profile of 002427 applied to $2(M + \epsilon - |t|)/\epsilon$; this factor is constant near zero. Then $\beta(\phi)\omega = \phi\omega$ as sections. Nonnegativity in common charts and 002425 give

$$\left| \int_Y \phi\omega \right| \leq (M + \epsilon) \int_Y \theta.$$

Let ϵ decrease to zero. For empty S take the zero measure. Otherwise the estimate and the approximants above extend the functional uniquely to a bounded linear Λ on $C(S)$: use limits of the real integrals of uniform approximants. Positivity is preserved for positive ω.

Positive representation (lines 350–425). For $\Lambda \geq 0$ let $a(O)$ be the supremum of $\Lambda(g)$ over $0 \leq g \leq 1$ continuous with support in an open $O \subset S$, and put $m(H) = \inf_{O \supset H} a(O)$ over open supersets. An open cover of $\operatorname{supp} g$ admits a finite subordinate partition there as above. Splitting g by the partition gives countable subadditivity of a on open covers. Taking open supersets of H_j within $\epsilon 2^{-j}$ of $m(H_j)$ gives countable subadditivity of m. It is monotone, $m(\varnothing) = 0$, $m(O) = a(O)$ for open O, and $m(S) = \Lambda(1) < \infty$. For arbitrary H and open O, choose open $V \supset H$ within ϵ of $m(H)$ and an admissible g in $V \cap O$ within ϵ of $a(V \cap O)$. Put $F = \operatorname{supp} g$. Any admissible test in $V \setminus F$ can be added to g without exceeding one. Thus $m(H \cap O) + m(H \setminus O) \leq m(H) + 2\epsilon$. Subadditivity gives the reverse inequality after passage to the limit.

The finite-intersection step implicit at lines 379–392 is as follows. Call A splitting if $m(H) = m(H \cap A) + m(H \setminus A)$ for every H. Complements split. For splitting A, B, split H by A, then $H \cap A$ by B. The last two pieces $(H \cap A) \setminus B$ and $H \setminus A$ have union $H \setminus (A \cap B)$. Subadditivity yields the splitting inequality for $A \cap B$, and the opposite inequality always holds. Hence splitting sets form an algebra. For disjoint splitting A_j, $A = \bigcup_j A_j$, finite iteration and monotonicity give

$$m(H) \;\geq\; \sum_{j \leq N} m(H \cap A_j) + m(H \setminus A).$$

Taking the supremum over N and using countable subadditivity on $H \cap A$ proves A splits. Finite differences in the algebra now disjointify any countable

union. Taking $H = A$ gives countable additivity on disjoint splitting sets by the same inequalities. Since all opens split, $\mu = m|_{\mathrm{Borel}}$ is a finite measure.

For an admissible g, $\Lambda(g) \le m(\operatorname{supp} g)$ by taking the infimum over open supersets of its support. This gives inner regularity on opens; outer regularity is by construction. For any Borel A, an open outer approximation to $S \setminus A$ has compact complement inside A, giving inner regularity there too. To check representation, fix $u \ge 0$ continuous, $0 \le u \le m_0\delta$. Put $O_k = \{u > k\delta\}$. For $1 \le k \le m_0$ choose near-maximizing tests g_k in O_k. The pointwise inequality $\delta \sum_k g_k \le u$ gives the lower sum $\delta \sum_{k=1}^{m_0} \mu(O_k) \le \Lambda(u)$ by finite approximation. For the upper sum, $u = \delta \sum_{k=0}^{m_0-1} \min(1, \max(0, u/\delta - k))$. For $k \ge 1$ each summand has support in O_{k-1}. Thus the upper sum is $\delta\mu(S) + \delta \sum_{k=1}^{m_0-1} \mu(O_{k-1})$. The two simple functions approximate u uniformly to within 2δ. Finiteness gives $\Lambda(u) = \int u \, d\mu$; differences give the identity on $C(S)$. Any positive Radon representation λ satisfies $\lambda(O) = a(O)$: use compact inner approximation and a cutoff equal to one on each chosen compact. Outer regularity then gives uniqueness on Borel sets.

Signed measures and locality (lines 427–446). For arbitrary bounded real Λ use the source construction $\Lambda^+(u) = \sup_{0 \le v \le u} \Lambda(v)$ on continuous $u \ge 0$. Splitting $v \le u_1 + u_2$ into $\min(v, u_1)$ and the remainder, and adding nearly maximizing tests in the other direction, prove additivity. Positive homogeneity gives a linear extension by differences, since $u - v = u' - v'$ implies $u + v' = u' + v$. Both Λ^+ and $\Lambda^- = \Lambda^+ - \Lambda$ are positive and bounded; for the first use $|\Lambda^+(w)| \le \Lambda^+(|w|) \le \|\Lambda\| \|w\|_\infty$. Let $\mu_\pm$ be their positive Radon representatives. Then $\sigma = \mu_+ - \mu_-$ represents Λ.

For conventions requiring regular *total variation*, the following argument is internal to this proof. Put $\nu = \mu_+ + \mu_-$. It is regular: for any Borel A, take the union of two compact inner approximants and the intersection of two open outer approximants. Define $v(A)$ by the supremum of $\sum_i |\sigma(A_i)|$ over finite Borel partitions of A. Then $v \le \nu$. On disjoint Borel A_j, intersecting any finite partition of their union with each A_j gives $v(\bigcup_j A_j) \le \sum_j v(A_j)$ by countable additivity of σ and the triangle inequality. Conversely combine near-optimal finite partitions on the first N pieces, adding the remainder as one block; take the supremum and then let N increase. Thus v is a finite measure. Compact and open approximants $F \subset A \subset O$ with $\nu(O \setminus F) < \epsilon$ give $v(O \setminus F) < \epsilon$, so $v = |\sigma|$ is Radon. Conversely, any candidate signed measure with regular finite variation decomposes as $(|\sigma| + \sigma)/2 - (|\sigma| -$

$\sigma)/2$ into positive measures dominated by its variation and hence regular by the same estimate. Signed uniqueness therefore reduces, by adding the opposite positive parts, to positive uniqueness. This proves what is needed here without borrowing the downstream NAG-002973.

The compact carrier S is closed in Hausdorff Y. Push each positive measure forward along $S \hookrightarrow Y$; compact inner approximants stay compact, and an outer open of S lifts to an open of Y to which $Y \setminus S$ may be added. This gives the claimed signed Radon measure on Y. For linearity compare on the compact union of the carriers by density. For support inside an open, the local integral equals the ambient integral on every multiplier by 002425 and 002428. Uniqueness on the same compact carrier proves the zero-extension assertion. □

8.5 The tropical infrastructure: charts, calibration, and smoothness

8.5.1 Paralinéaire means piecewise affine geometry

The French term *paralinéaire*, abbreviated pl, refers to piecewise affine geometry. Local polyhedral pieces carry affine structures, and subdivisions allow maps and functions to be described affinely on smaller cells. This is not yet the integral structure supplied by the character lattice of an algebraic torus. The abstract real framework separates what is needed for differential calculus from the additional rational or integral structure needed for arithmetic applications.

The reason for this separation can be seen in an ordinary PL function. Its graph has an honest piecewise affine structure, even at a corner where the graph is not the graph of one affine function. A cellwise derivative exists. A global distributional derivative has an additional interface term. CLD25 arranges the definitions so that these two operations remain distinguishable.

8.5.2 G-local descriptions and ordinary smooth descriptions

A G-tropical chart may be defined on an analytic or polyhedral domain, and a G-cover may assemble several such domains along interfaces. Pulling back ambient smooth superforms through these charts gives G-forms. Ordinary smooth forms require the refined affine structure to provide suitable descrip-

tions on ordinary neighbourhoods. A function can therefore be G-smooth without being ordinary smooth.

Take $u(t) = |t|$. On the two half-lines it is affine; as a G-local object it has zero cellwise Hessian away from the interface. As a function on the ordinary neighbourhood of 0, its current Hessian is $2\delta_0$. The distinction persists in higher degree and on analytic spaces. It is not removed by choosing a finer subdivision: refinement moves the interface into the combinatorics but does not eliminate its contribution to the current derivative.

This example also explains why a current originally defined on ordinary smooth tests cannot automatically be evaluated on every G-form. The larger testing operation requires either an extension theorem, measure coefficients with a compatible G-local construction, or a structured current for which the action is defined geometrically.

8.5.3 Calibrations are the replacement for an orientation and a density

On a smooth real manifold, integration uses an orientation and a top-degree density. On a tropical space there are several tangent pieces at a point, each possibly carrying a multiplicity. A calibration packages the appropriate tangent-volume data so that forms can be contracted and integrated. Positivity of a calibration corresponds to nonnegative weights in familiar integral polyhedral examples.

The calibration must be compatible under changes of chart. In a tropicalization of an analytic space, these compatibilities are degree formulas. In an abstract tropical space they are part of the structure and its axioms. The definitions involving skeletal subsets and their volume forms are designed to let integration depend on the intrinsic space instead of on a chosen embedding into $\mathbb{R}^r$.

8.5.4 Richness and harmonic compatibility

The vocabulary of CLD25 Chapters 5–6 can initially obscure a simple requirement: there must be enough calibrated polyhedral pieces to detect forms and enough balancing to prove Stokes. Richness provides sufficient skeletal geometry to represent the local differential data. The stronger interior hypotheses ensure that the relevant top-dimensional data are visible. Differential sepa-

ration ensures that the chosen functions and forms distinguish the directions needed by the calculus. Harmony expresses the cancellation of calibrated boundary contributions in tropical charts.

These descriptions explain the role of the axioms; they do not replace their exact definitions. In Definition 6.6.2, a tropical space of level n is a calibrated and refined G-tropical space satisfying richness, together with a specified closed boundary and further interior conditions. The traces of boundaries on skeletal subsets must also be negligible in the required dimension. Thus the level and boundary belong to the structure.

An ordinary balanced weighted polyhedral complex is a useful model, but the framework is designed to include analytic spaces whose polyhedral descriptions vary with the chart. A single global complex is not required. CLD25 Chapters 12–14 prove the necessary analytic facts rather than assuming that a Berkovich space is literally a polyhedron.

8.5.5 Stokes in the abstract tropical framework

Once the calibration and harmony conditions hold, Stokes follows by applying the cellwise formula and cancelling interior faces. Partitions of unity pass from one chart to arbitrary compactly supported forms. The later analytic proof consists in identifying the canonical analytic calibration with this abstract one and verifying the hypotheses. This division makes the theory modular: a new class of spaces or charts can be tested against the same integration requirements.

The useful question when reading a new result is therefore: which part is formal tropical calculus, and which part verifies an analytic hypothesis? A proof of a formula for calibrated polyhedra does not by itself prove independence from analytic presentations. Conversely, once the analytic compatibility theorem is established, repeating every polyhedral calculation on Berkovich spaces is unnecessary.

References. [CLD25, Chapters 2–6, especially Definition 6.6.2].

8.6 Analytic realization of the tropical framework

8.6.1 Graded algebra and residual intersection theory

CLD25 Chapter 10 supplies the algebra needed to carry residual geometry through changes of value group and field. A normed object has reductions at many radii, so the graded setting is the natural one. The chapter also treats Zariski–Riemann spaces and intersection numbers of residual bundles. Such a space organizes compatible data over modifications rather than choosing one preferred model.

The point of this machinery becomes visible later: a PL metric can have a residual line bundle at an analytic germ, and a curvature product can be compared with a residual intersection number. These numbers must be independent of auxiliary models and compatible with scalar extension. The descent results in the graded chapter are what makes that numerical comparison meaningful in the non-strict setting.

This is a different use of models from defining the entire analytic calculus as an inverse system of algebraic cycles. The ordinary test forms and currents are already analytic objects. Residual models are used to calculate and characterize particular currents arising from geometric metrics.

8.6.2 Analytic dimension and the source of polyhedra

CLD25 Chapter 11 collects the analytic dimension, finite-morphism, and reduction facts used later. CLD25 Chapter 12 studies the skeletal loci of moment maps and their characteristic polyhedra. The tropical dimension of a point is tied to how many independent real directions its analytic functions can expose. The Abhyankar invariants from Section 3.7 control this dimension.

The richness theorems in CLD25 Chapter 12 say, in the source's precise sense, that there are enough analytic skeletal subsets to detect the differential data; the boundaryless case supplies the stronger interior properties. These are existence and compatibility theorems. They do not assert that every analytic neighbourhood is homeomorphic to one finite polyhedron or that one fixed skeleton detects every current.

8.6.3 Degrees, multiplicities, and canonical calibration

CLD25 Chapter 13 defines the relevant degrees of quasi-finite morphisms, incorporating generic multiplicities and residue-field extensions. CLD25 Chapter 14 uses these degrees to calibrate suitable tropical cells. A local analytic map can be many-to-one even when the real tropical map is injective on a cell; the calibration records the missing degree.

A proof of a canonical integral must show compatibility under three operations: subdivision of cells, refinement of the moment map, and passage through finite analytic maps. The calibrated degree formula handles the last operation; the variation results ensure that these weights behave correctly in analytic families. This is the analytic counterpart of the lattice-index pushforward formula used in ordinary tropical intersection theory.

8.6.4 A family calculation and why it matters for Green currents

Suppose a family of fibres is cut out by analytic functions and a fixed compactly supported test is tropicalized by additional units. Under the source's equidimensional hypotheses, the calibrated tropical images of nearby fibres stabilize in the relevant sense. The integral of that fixed test over the fibres can therefore be compared with its integral over the central fibre.

This mechanism is used in the proof of the Bochner–Martinelli formula. A truncated logarithmic maximum has curvature concentrated over a small Gauss point in the parameter space. As the truncation level tends to zero, the calibrated fibre calculation identifies its action on the fixed test with integration over the complete intersection. Thus the higher-codimension formula depends on the analytic degree and variation machinery, not only on a formal differentiation of a maximum.

8.6.5 Analytic forms and finite pushforward

CLD25 Chapter 15 realizes the abstract differential calculus on analytic spaces, including scalar extension, finite maps, support, and integration. CLD25 Chapter 16 develops currents in this realization. Proper pushforward is defined by duality with smooth pullback, with the appropriate degree shift. Projection formulas are then proved on their stated domains.

One should keep finite-map trace and arbitrary proper pushforward separate. A finite map can preserve dimension and carries a degree normalization. A general proper map may change dimension and collapse directions. Neither operation supplies a general descent theorem for actual delta-form representatives merely because a pushforward current exists.

8.7 Tropical geometry in the analytic calculus

The same tropical constructions enter several analytic theories, but at different stages. In the CLD construction, the integral tangent lattice and canonical multiplicities normalize integration. Balancing then supplies Stokes' theorem, so that differentiation of currents is independent of a cell decomposition. The passage to the analytic space still requires compatibility under refinements of moment maps; a formula on one polyhedron is only a presentation of that construction. These steps are developed in Sections 8.1 and 8.4.

In the GK calculus, a tropical cycle also occurs as a factor in a form. The corner formula becomes a differential identity with a cycle-valued contribution. Stable intersection supplies the multiplication of these contributions under the hypotheses of the delta-calculus. Thus GK uses more than the set-theoretic tropicalization: tangent lattices, multiplicities, refinements, and intersection products all enter. Sections 16.1 and 15.7 explain how the resulting objects descend through algebraic tropical charts.

Skeleta provide a different kind of comparison. Their integral-affine structures and slope formulas relate model divisors to tropical functions. Faithful tropicalization controls a chosen skeleton, while the multiplicity-one section selects analytic points over a suitable tropical locus. Neither assertion identifies every analytic form with data on one preassigned skeleton. The precise geometric statements are used in Section 6.3; the distinction between topological reconstruction and differential comparison is taken up in Section 24.1.

Extended tropicalizations retain the boundary strata required by Green functions. Their role in the BGK theory is therefore complementary to the affine corner calculus: they allow compatible data on toric compactifications and local-height calculations on a common tropicalization. The valuation convention remains the same throughout. A lattice index is an integer multiplicity, whereas a logarithmic distance records the scale of the absolute value.

References. For tropicalization and multiplicities, see [Gub13, MS15]. For the analytic integration construction, see [CLD12, Chapters 2–4] and [CLD25]. The intersection and skeletal developments are [GK17, GRW16, GRW17]; the extended tropical intersection theory is [BGK25].

8.8 Scope and geometric inputs

Throughout the detailed construction below, K is complete, algebraically closed and nontrivially valued, and X is a separated integral algebraic variety of dimension n over K. We work on a paracompact open subset $W \subset X^{\mathrm{an}}$. The statements below concern the original smooth forms, not harmonic or weakly smooth forms. These assumptions are retained in every analytic consequence.

A very affine variety is a closed subvariety of a split algebraic torus. For a very affine open $U \subset X$, the group of units modulo constants gives a canonical torus T_U and a closed immersion $\varphi_U : U \to T_U$, determined up to translation. Its tropicalization is

$$\tau_U : U^{\mathrm{an}} \longrightarrow N_{U,\mathbb{R}}, \qquad x \longmapsto (-\log|f_1(x)|, \dots, -\log|f_r(x)|).$$

Here the chosen units give coordinates; their tropical image is denoted $\mathrm{Trop}(U)$. A tropical chart is $V = \tau_U^{-1}(\Omega)$, where Ω is relatively open in $\mathrm{Trop}(U)$.

Theorem 8.8.1 (Geometric inputs from Gubler)**.** *The following results are used with the hypotheses above.*

1. *Tropical charts form a basis. Intersections have common refinements coming from intersections of very affine opens; transition maps of tropicalizations are integral affine.*
2. *A superform on the image of a tropical chart defines zero on the analytic chart if and only if it is zero on that tropical image.*
3. *The algebraic-chart sheaf agrees with the original CLD sheaf using analytic moment maps.*
4. *Smooth partitions of unity subordinate to open covers exist, with locally finite compact supports.*

Open proof obligation (RC2). Supply native proofs of the geometric moment-image, boundary and degree inputs. The historical source expressly imports the listed Gubler16 results.

8.9 The quotient on a polyhedral image

Let P be a locally finite polyhedral subset of a real affine space and let $\Omega \subset P$ be relatively open. Choose an ambient open neighbourhood. Restrict ambient superforms to each face using its tangent space, and declare two representatives equal when all these restrictions agree. Subdivision does not change the resulting space.

Proposition 8.9.1. *The kernel of restriction is stable under d', d'', J and wedge multiplication. Thus these operations descend to the polyhedral quotient. Pullbacks along affine maps mapping faces into faces also descend.*

Proof. On the relative interior of a face, restriction is ordinary affine pullback. It commutes with the two differentials by their coordinate formulas, and with J and wedge by their algebraic definitions. A form restricting to zero has zero tangential coefficients; their tangential derivatives vanish on that relative interior. Continuity gives the same conclusion on its closure. Applying this argument face by face proves the kernel assertions. For an affine map, a representative vanishing on a target face pulls back to zero on every source face mapping to it. □

One must quotient by tangent restrictions, not merely by the values of the scalar coefficients on P. For example, on the line $x_2 = 0$ in $\mathbb{R}^2$, the form $d'x_2$ vanishes after restriction although its ambient coefficient is the constant one. The two cotangent copies are both restricted.

8.10 Gluing the analytic sheaf

Definition 8.10.1. A smooth (p, q)-form on W is a family of superforms on the images of a tropical-chart cover, whose pullbacks agree on common refinements of overlaps. Two families are identified if they agree after refining their covers. Write this sheaf as $A_X^{p,q}$.

Proposition 8.10.2. *This defines a sheaf. The operations d', d'', J and wedge descend to it and satisfy the identities of Chapter 7.*

Proof. A common refinement of three covers is obtained by successive intersections, so agreement after refinement is transitive. Restriction is restriction of each family. If forms on an open cover agree on overlaps, take the union of their chart families; the agreement condition makes this a global compatible family. Uniqueness is tested on the same covering charts. Proposition 8.9.1 proves that applying an operation to equal representatives preserves equality. Its algebraic identities therefore pass to the quotient and then to the glued sheaf. □

The support is the complement of the locus where the germ vanishes. The chart injectivity in Theorem 8.8.1 identifies vanishing of a form presented on one chart with vanishing of its superform on that chart's image. It does not say that every form on a fixed chart has a single presentation on that chart; a further cover may be needed [Gubler, Remark 5.7].

Example 8.10.3 (Behaviour at a classical point)**.** If $x \in X(K)$ and f is an analytic unit near x, then on a sufficiently small neighbourhood $|f(y) - f(x)| < |f(x)|$. The strong triangle inequality gives $|f(y)| = |f(x)|$. For finitely many units, intersect these neighbourhoods. A smooth function expressed through their logarithms is constant there, and positive-degree forms in these tropical coordinates vanish there. Thus these coordinates are not real-manifold coordinates near a classical point.

8.11 Compactly supported tests

Write $A_c^{p,q}(W)$ for forms with compact support. A fixed presentation consists of finitely many tropical charts and compact polyhedral subsets of their images, together with compatible coefficient representatives. Tropicalization is proper in the very affine setting, so their inverse images are compact. On each such presentation use the coefficient C^∞ seminorms on its fixed compact sets, with tangential restrictions on the faces. The actual test space has the final locally convex topology of all these finite presentations, as in [Gubler, §6.1–6.2]. Equivalently, a current is a linear functional continuous on each of the presentation spaces. In this book a functional on (q,q)-tests has bidimension (q,q) and bidegree $(n-q, n-q)$. Gubler's notation in §6.2

uses the test degree as the current index; this indexing difference changes no pairing. This topology is essential: a sequence that is smooth in a different chart at every stage is not automatically convergent in a fixed presentation. Arguments below that use uniform convergence of scalar functions will be justified by measures, rather than by pretending that the scalar functions all have a common chart.

8.12 Cutoffs and scalar density

Lemma 8.12.1. *For compact $C \subset W$ and an open neighbourhood O of C, there is $0 \le \chi \le 1$ smooth, compactly supported in O, and equal one near C.*

Proof. Choose $C \subset O' \Subset O$ using local compactness and compactness of C. Apply the partition theorem to the cover $\{O, W \setminus \overline{O'}\}$. Only finitely many members of the locally finite partition meet C. Sum all members meeting a smaller neighbourhood of C, chosen to avoid the other supports and to lie in O'. Every selected support is compact and lies in O. Their sum is one on that smaller neighbourhood and lies between zero and one everywhere. □

Proposition 8.12.2. *Every $f \in C_c(W)$ admits smooth approximants converging uniformly on W, with all supports in one compact subset. If $f \ge 0$, the approximants may be chosen nonnegative.*

Proof. Take a compactly supported cutoff χ equal one near $\operatorname{supp} f$, and put $L = \operatorname{supp} \chi$. Restrictions of global smooth functions form a real algebra containing constants on L. They separate points: a cutoff supported in a neighbourhood of one point and avoiding another separates those points. The real Stone–Weierstrass theorem gives smooth a_j converging uniformly to f on L. Then $\chi a_j \to f$ uniformly on W because $\chi f = f$, with supports in L. For nonnegative f, approximate $\sqrt{f}$ on L by smooth b_j and use χb_j^2 instead. □

This theorem is scalar density only. It does not preserve a positive Hessian and gives no general regularization theorem for current-psh functions. The approximation class in Chapter 11 remains a separate hypothesis.

8.13 Ordinary-positive domination on actual tests

An actual symmetric form is positive if locally it has a chart presentation whose restrictions to the faces are ordinary positive. This property is preserved by refinement because affine pullback preserves positivity. Multiplication by a nonnegative smooth scalar also preserves it, even if that scalar requires a further chart.

Proposition 8.13.1. *For every fixed finite test presentation and compact supports, there are a compactly supported actual positive form θ and a constant c such that every symmetric test η in that presentation satisfies*

$$c\|\eta\|_{D,0}\theta + \eta \geq 0, \qquad c\|\eta\|_{D,0}\theta - \eta \geq 0.$$

Here $\|\eta\|_{D,0}$ is a coefficient seminorm in that fixed presentation.

Proof. First localize by a fixed finite nonnegative smooth partition over the prescribed supports. For one chart, choose an ambient Euclidean norm and the constant form $\beta_q = \omega^q/q!$. On every tangent space its restriction has identity coefficient matrix in an orthonormal exterior basis. Restricting a coefficient tensor to that tangent space has uniformly bounded norm: the chosen Euclidean metric makes orthogonal restriction contractive. Thus the matrix estimate of Proposition 7.3.2 gives positive domination on every face by a common multiple of β_q. Multiply this control form by a cutoff equal one on the localized support and compactly supported inside the chart, then extend by zero. It is an actual positive form. Summing the finitely many control forms and constants gives the assertion. Tangent spaces of dimension less than q contribute zero to both the test and control form. □

8.14 Intrinsic continuous multiplication

The next construction avoids taking a quotient of arbitrary continuous chart coefficients. Each measure is attached directly to an actual smooth test form.

Theorem 8.14.1. *Let T be a symmetric linear functional on $A_c^{q,q}(W)$ nonnegative on ordinary positive tests. Then T is a current, of order zero in every fixed presentation. For every actual smooth compactly supported test η, there is a signed Radon measure $\mu_{T,\eta}$ determined by*

$$\int \phi \, d\mu_{T,\eta} = T(\phi\eta), \qquad \phi \in C_c^\infty(W).$$

Its support lies in $\operatorname{supp}\eta$*. For* $f \in C^0(W)$ *the formula*

$$(fT)(\eta) = \int f \, d\mu_{T,\eta}$$

defines an intrinsic current. It is positive when $f \geq 0$*, and agrees with smooth multiplication when* f *is smooth.*

Proof. Actual domination gives current continuity exactly as in Proposition 9.9.1; that proposition is purely functional analytic and does not use this theorem. If η is positive, then $\phi \mapsto T(\phi\eta)$ is nonnegative for nonnegative smooth ϕ, and

$$|T(\phi\eta)| \leq \|\phi\|_{\operatorname{supp}\eta,\infty}\, T(\eta).$$

Scalar density and the Riesz theorem give a positive Radon measure. It is supported in $\operatorname{supp}\eta$ because all tests outside that set pair to zero. For symmetric η, Proposition 8.13.1 writes η as a difference of two actual positive tests. Take the difference of their measures. Its values on smooth scalar tests determine it uniquely by scalar density; hence it is independent of the decomposition. Symmetrization handles all tests. This also proves linearity in the actual test η, including every relation among its chart presentations.

It remains to check continuity of fT. In a fixed presentation put $M = c\|\eta\|_{D,0}$ and use its fixed control form θ. The positivity of $M\theta \pm \eta$ implies

$$-M\mu_{T,\theta} \leq \mu_{T,\eta} \leq M\mu_{T,\theta}.$$

Consequently $|\mu_{T,\eta}| \leq M\mu_{T,\theta}$ and

$$|(fT)(\eta)| \leq c\|\eta\|_{D,0} \int |f| \, d\mu_{T,\theta}.$$

The final integral is finite because θ has compact support. This proves continuity on every presentation. Positivity and agreement with smooth multiplication follow from the defining measure formula. □

Proposition 8.14.2. *The construction commutes with restriction and satisfies* $f(gT) = (fg)T$ *for continuous* $f, g \geq 0$*. The same equality holds for signed continuous multipliers by linearity.*

Proof. For smooth compactly supported ϕ, uniqueness of the representing measures gives $\mu_{T,\phi\eta} = \phi\mu_{T,\eta}$. It follows that

$$(gT)(\phi\eta) = \int g\phi \, d\mu_{T,\eta}, \qquad \mu_{gT,\eta} = g\mu_{T,\eta}.$$

Integrating f proves associativity. The same uniqueness argument on open subsets proves restriction compatibility. Decompose a signed continuous multiplier into its positive and negative parts to obtain the signed version. □

Thus the relation problem for multiplication by a continuous scalar is resolved in the stated original algebraic CLD setting. This does not resolve the different kernel problem $\mathrm{d}'\mathrm{d}''[h] = 0 \Rightarrow \mathrm{d}'\mathrm{d}''(hT) = 0$: the latter concerns the action of curvature-equivalent potentials, not relations between presentations of one actual smooth test.

8.15 The degree in change of tropical coordinates

The foundations identify the origin of the three factors in an integral: the analytic fibre degree, the tangent lattice, and the Euclidean density. We now prove the elementary change-of-variables calculation and isolate the geometric comparison needed to apply it to analytic charts. This section uses the algebraic CLD setting of Section 8.8.

Lemma 8.15.1. *Let $F : \sigma \to \tau$ be an affine isomorphism between n-dimensional polyhedra whose linear part is integral and injective on their tangent lattices. Put $e = [N_\tau : F(N_\sigma)]$. For a compactly supported top-degree superform β on τ, in lattice-normalized integration,*

$$\int_\sigma F^*\beta = e \int_\tau \beta.$$

Proof. Choose integral bases of the two lattices, with real coordinates x, y. Write $y = Mx + b$. The positive top-degree generator has two cotangent factors. Its pullback acquires $(\det M)^2$, whereas ordinary real change of variables contributes $|\det M|^{-1}$. The resulting factor is $|\det M| = e$. This calculation is independent of the chosen bases, whose transition determinants have absolute value one. □

After subdividing a polyhedral map into cells on which it is injective, apply the lemma cell by cell. If source weights are m_σ, the target weight is

$$m_\tau = \sum_{F(\sigma)=\tau} m_\sigma [N_\tau : F(N_\sigma)].$$

Cells whose images have dimension below n contribute zero because top-degree pullback vanishes there. For a finite collection of cells and a form

whose relevant pullback has compact support, summing gives the projection formula for the weighted integrals.

Example 8.15.2. On an annulus write $t = -\log|T|$ and replace the moment coordinate T by T^m, with integer $m \geq 1$. Then $s = mt$ and

$$\int m^2 b(mt)\, dt = m \int b(s)\, ds.$$

The tropical image for this presentation has calibration m. The algebraic map $T \mapsto T^m$ is finite free of rank m, with basis $1, T, \ldots, T^{m-1}$, also when the residue characteristic divides m. The factor records algebraic degree, not the number of visibly distinct points of a fibre. A top form $a(t)d't \wedge d''t$ is represented in the s coordinate by $m^{-2}a(s/m)d's \wedge d''s$; integrating it with weight m gives the original integral.

8.15.1 Independence of the analytic integral

For two analytic presentations, adjoining all their unit coordinates gives a common moment map. The geometric input says that its calibrated weights push forward to the weights of either presentation. In the algebraic chart construction this is the tropical degree comparison used in [Gubler, Proposition 4.11 and Lemma 5.15]; the analytic construction is in [CLD12, §§3.3–3.8]. The lemma proves equality of the two local integrals once this geometric weight identity is known. It does not prove the weight identity itself.

The remaining partition argument is formal but useful to record. Let (ρ_i) and (σ_j) be two subordinate smooth partitions near the compact support of a form α, and denote the corresponding local integral functionals by I_i and J_j. Only finitely many terms meet the support. Refining both presentations where $\rho_i\sigma_j\alpha$ is supported, the local comparison gives

$$\begin{aligned}\sum_i I_i(\rho_i\alpha) &= \sum_{i,j} I_i(\rho_i\sigma_j\alpha) \\ &= \sum_{i,j} J_j(\rho_i\sigma_j\alpha) = \sum_j J_j(\sigma_j\alpha).\end{aligned}$$

Thus the global integral is independent of charts and partitions. The analytic-domain and sheaf constructions of Chapter 2 make the refinements meaningful; the tropical degree theorem supplies the nonformal part. For Stokes one further uses balancing and support away from the analytic boundary, as defined in Section 2.7. None of these steps is supplied by the homeomorphism type of a skeleton alone.

8.15.2 Ordinary presentation topologies on compact tests

Fix a complete non-Archimedean field K with its original real-valued absolute value. Let X be good and Hausdorff. We use the ordinary smooth moment sheaf $\mathcal{A}_X^{p,q}$ of `v037:forms:ordinarysmoothgerm` and `v037:forms:germsheaf`, and write $\mathcal{E}^{p,q}(X) = \mathcal{A}_{X,c}^{p,q}(X)$. All supports in this note are ordinary compact supports. A version with boundary-avoiding tests is obtained by applying the construction to a specified ordinary open subspace of the analytic interior. There is no boundary vanishing assertion in the topology construction. All one-form generators anticommute, and the positive top generator is $d'x_1 \wedge d''x_1 \wedge \cdots \wedge d'x_n \wedge d''x_n$, as in `v037:integration:conventions`.

For an open $\Omega \subset \mathbb{R}^N$, let $E^{p,q}(\Omega)$ be the space of smooth ambient superforms with the coefficient seminorms

$$p_{L,m}(\eta) = \max_{I,J,\,|a|\le m} \sup_{u\in L} |\partial^a \eta_{I,J}(u)|, \qquad L \Subset \Omega.$$

Empty coefficient slots give the zero space.

Definition 8.15.3 (The two generating families)**.** A cutoff presentation $i = (V, f, \Omega, \chi)$ consists of an affinoid domain $V \subset X$, a unit tuple f on V, an open set $\Omega \supset t_f(V)$, and $\chi \in \mathcal{A}_c^{0,0}(X)$ with $\operatorname{supp}\chi \subset \operatorname{Int}_{\mathrm{top}}(V, X)$. Here $t_f = -\log|f|$. Its map is

$$Q_i : E^{p,q}(\Omega) \longrightarrow \mathcal{E}^{p,q}(X), \qquad Q_i\eta = \operatorname{ext}_0(\chi t_f^*\eta).$$

Let τ_{cut} be the locally convex topology generated by all seminorms P on $\mathcal{E}^{p,q}(X)$ for which PQ_i is continuous for every i. This is the definition F8-T1 in the supplied candidate.

An ordinary presentation s consists of finitely many such charts (V_j, f_j, Ω_j), without cutoffs, and a compact set $K_s \subset \bigcup_j U_j$, where $U_j = \operatorname{Int}_{\mathrm{top}}(V_j, X)$. Let

$$H_s \subset \prod_j E^{p,q}(\Omega_j)$$

be the linear subspace of tuples (η_j) for which the induced ordinary sections agree on $U_j \cap U_k$ and vanish on $U_j \setminus K_s$. Give H_s its coefficient subspace topology. The sections glue with zero on $X \setminus K_s$ to a section $R_s\eta \in \mathcal{E}^{p,q}(X)$. Give $B_s = H_s/\ker R_s$ its quotient topology and let τ_{ord} be the final locally convex topology for the maps $B_s \to \mathcal{E}^{p,q}(X)$, equivalently for all R_s.

Both definitions refer to ordinary sections. In particular, the relations in H_s are not compatibility solely on a finite closed affinoid cover. Every compactly supported section belongs to some $\operatorname{im} R_s$: choose finitely many ordinary representing neighbourhoods over its support and take K_s to be that support. The cutoff maps also span the test space, by the finite partition of `v037:forms:compactpartition` on these same neighbourhoods.

Theorem 8.15.4 (Comparison of the two final topologies)**.** *In every bidegree,*

$$\tau_{\mathrm{cut}} = \tau_{\mathrm{ord}}.$$

More precisely, each R_s is a finite sum of cutoff presentation maps composed with continuous linear maps, and each Q_i factors continuously through one ordinary presentation space H_s. The charts, cutoffs and factorizing maps in each assertion are fixed before the variable ambient forms are chosen.

Proof. Fix s. Apply `v037:forms:compactpartition` to K_s and (U_j), obtaining fixed χ_j supported compactly in U_j, with sum one near K_s. If $\eta = (\eta_j) \in H_s$, then

$$R_s\eta = \sum_j Q_{(V_j,f_j,\Omega_j,\chi_j)}\eta_j.$$

On K_s this follows from the partition and compatibility; off K_s all relevant sections are zero. The coordinate projections from H_s are continuous. Thus every R_s is continuous for τ_{cut}.

Conversely, fix $i = (V, f, \Omega, \chi)$ and put $K_s = \operatorname{supp}\chi$. The empty-support case is zero. Otherwise choose finitely many affinoid neighbourhoods $W_j \subset \mathrm{Int}_{\mathrm{top}}(V, X)$ whose interiors cover K_s, such that χ is represented on W_j by a fixed smooth scalar coefficient c_j in a fixed unit tuple g_j. To do this, shrink inside an ordinary representing neighbourhood of χ before taking W_j; the neighbourhood basis and restriction assertion are part of the proof of `v037:forms:germsheaf`. On W_j use the joint tuple $h_j = (f|_{W_j}, g_j)$ and the ambient open set $\Omega \times \Omega_{g_j}$, where $\Omega_{g_j} \supset t_{g_j}(W_j)$. Set

$$L_j\eta = \pi_g^* c_j \, \pi_f^*\eta.$$

For every compact L in this product and every m, the product and chain rules give

$$p_{L,m}(L_j\eta) \le C_{j,L,m}\, p_{\pi_f(L),m}(\eta).$$

The derivatives of the fixed coefficient c_j are absorbed in $C_{j,L,m}$. The tuple $(L_j\eta)_j$ belongs to the fixed space H_s: its components represent the same

ordinary section $\chi t_f^* \eta$ and vanish off K_s. It depends continuously on η, and its glued section is $Q_i \eta$. Therefore Q_i is continuous for τ_{ord}.

A seminorm is continuous for either final topology exactly when its composites with that topology's generating maps are continuous. The two factorizations prove equality of these families of seminorms. □

Proposition 8.15.5 (The available direction of the tangential comparison)**.** *Let $P \subset \Omega \subset \mathbb{R}^N$ be a compact finite polyhedral set, and let N_P be the ambient smooth forms with zero tangential restriction on every face. Give $E^{p,q}(\Omega)/N_P$ its quotient topology. For each face σ, fix an affine tangent basis. The suprema, on compact subsets of σ, of tangential coefficient derivatives of any fixed finite order are well-defined continuous seminorms on this quotient. Consequently the topology they generate is no finer than the ambient quotient topology.*

Proof. In a tangent basis, restriction of each covector factor is a fixed linear map. Each tangential derivative is a fixed linear combination of ambient partial derivatives. Its coefficient supremum is bounded by a constant times the ambient seminorm of the same order on the same compact set. If a form belongs to N_P, its restricted coefficients vanish on the relative interior of every face. Their derivatives along that face vanish there and, by continuity, on its boundary. Thus the seminorms annihilate N_P and descend. The defining property of the quotient gives continuity of each descended seminorm. □

The intrinsic tangential comparison here gives continuity from the ambient quotient for each fixed compact polyhedral image. A converse would require a bound for ambient representatives. A comparison with general chart and support families would also require matching the underlying sheaves and the systems of presentations.

8.15.3 Multiplication in chart and support topologies

Fix bidegrees and an order $r \in \mathbf{N} \cup \{\infty\}$. The coefficients are smooth real scalars. The order r specifies which coefficient derivatives define the topology. For $r = \infty$, use every finite derivative order.

Let X be a Hausdorff G-tropical space with the following chart and sheaf data. Smooth forms on a compact chart image are tangential restrictions

of local ambient smooth forms on a finite polyhedral set. For every compact domain W in a chart $f : V \to E$, the image $f(W)$ is compact and finite polyhedral, and a form on it is uniquely determined by its pullback to W. Compact domains cover chart domains in the G-topology. The smooth G-form sheaf has restrictions and exterior products compatible with the corresponding affine pullbacks and is determined on G-covers. Domains restrict to chart intersections, with joint coordinates available for common refinements.

Definition 8.15.6 (Intrinsic seminorm on a compact image)**.** Let C be a compact cell, use affine coordinates on its affine span, and write a tangential form as $\alpha = \sum_{|I|=p,|J|=q} \alpha_{IJ}\, d'x_I \wedge d''x_J$. Put

$$\|\alpha\|_{C,m} = \max_{I,J,\,|a|\le m} \sup_{C} |\partial^a \alpha_{IJ}|, \qquad m \ge 0.$$

The derivatives at the boundary are the continuous restrictions of those on the relative interior. Coefficient slots with degree exceeding the dimension are zero. For a compact finite polyhedral set P, choose a finite cell decomposition $\mathcal{C}$ and affine coordinates on each cell; a standard seminorm is

$$\|\alpha\|_{P,m} = \max_{C\in\mathcal{C}} \|\alpha|_C\|_{C,m}.$$

Use the seminorms for $m \le r$, all finite m if $r = \infty$. This is the intrinsic cell topology on the space of smooth forms on P.

Different affine coordinates give equivalent seminorms: the tangential covectors change by fixed minors, and their derivatives by fixed linear combinations. Passing to a common finite subdivision gives the same cell topology. On a subdivided cell of full relative dimension the smooth coefficient derivatives are restrictions of the old ones; conversely these subcells cover a dense subset of the original cell, so the original suprema follow by continuity. Lower-dimensional cells are handled by their tangent restrictions. This uses only finitely many coordinate changes. It asserts no bounded ambient extension across faces.

For an affine map $a : P \to Q$ of compact polyhedral sets, subdivision of the source and target gives, for each m, a finite constant $c_{a,m}$ with

$$\|a^*\alpha\|_{P,m} \le c_{a,m}\|\alpha\|_{Q,m}. \tag{8.15.1}$$

To see the estimate, restrict to a source cell mapped into a target cell. The coefficients of pullback are sums with coefficients given by the p- and q-minors

of the fixed tangent matrix. A derivative of order $\ell \le m$ adds products of ℓ matrix entries, by the chain rule. Take the maximum of these finitely many constants. Translation contributes no derivatives. This proves the forward continuity needed below; no strictness assertion for a surjective affine map is used.

Definition 8.15.7 (A single-chart space)**.** Let $f : V \to E$ be a chart on a domain of X. Define $\mathcal{A}^{p,q}_{f,G}(X)$ to be the subspace of smooth G-forms ω on X for which, for *every* compact domain $W \subset V$, there is $\alpha_{f,W} \in \mathcal{A}^{p,q}(f(W))$ satisfying

$$\omega|_W = (f|_W)^* \alpha_{f,W}.$$

The compact-nullity prerequisite makes $\alpha_{f,W}$ unique. Transport the intrinsic topology from $\mathcal{A}^{p,q}(f(W))$ to its pullback space on W, and give $\mathcal{A}^{p,q}_{f,G}(X)$ the initial topology for all these restriction maps. Explicitly it is generated by

$$\rho_{f,W,m}(\omega) = \|\alpha_{f,W}\|_{f(W),m}, \qquad W \subset V \text{ compact}, \quad m \le r.$$

Definition 8.15.8 (A fixed chart family)**.** For a family $\mathcal{D} = \{f_i : V_i \to E_i\}$ put

$$\mathcal{A}^{p,q}_{\mathcal{D},G}(X) = \bigcap_i \mathcal{A}^{p,q}_{f_i,G}(X),$$

and give it the initial locally convex topology $T_{\mathcal{D},r}$ for all the inclusions into the single-chart spaces. Thus its seminorms are the restrictions of all $\rho_{f_i,W,m}$; neighbourhoods require only finitely many of these seminorms at a time. Families and compact domains need not be finite or countable. If the domains form a G-cover, compact nullity and the sheaf property imply that this topology is Hausdorff: vanishing of every seminorm gives zero on every chart domain and hence on X.

We use the word *refinement* with its geometric meaning. A chart $g : V' \to F$ refines $f : V \to E$ if $V' \subset V$ and $f|_{V'} = a \circ g$ for a fixed affine map $a : F \to E$. A family refines another if every chart in it has such a factorization through a chart of the latter. From a coarse family $\mathcal{D}$ to a refining family $\mathcal{R}$ one obtains an inclusion

$$\mathcal{A}^{p,q}_{\mathcal{D},G}(X) \longrightarrow \mathcal{A}^{p,q}_{\mathcal{R},G}(X).$$

It is continuous. For a compact W in the domain of $g \in \mathcal{R}$, the representative on $g(W)$ is $a^* \alpha_{f,W}$. Estimate (8.15.1) bounds each target seminorm by one source seminorm, proving continuity of the inclusion.

Definition 8.15.9 (Support and chart families)**.** The support of a G-form is the complement of the largest ordinary open set on which it is zero. A support family Φ is a family of ordinary closed subsets of X containing $\varnothing$, closed under finite unions and under taking ordinary closed subsets. Let Γ be a nonempty collection of G-covering chart families, admitting a common refining family in Γ for any two members.

For $\mathcal{D} \in \Gamma$ and $F \in \Phi$, let

$$\mathcal{A}^{p,q}_{\mathcal{D},G,F}(X) = \{\omega \in \mathcal{A}^{p,q}_{\mathcal{D},G}(X) : \operatorname{supp}\omega \subset F\},$$

with its subspace topology from $T_{\mathcal{D},r}$. Define

$$\mathcal{A}^{p,q}_{\Gamma,\Phi}(X) = \bigcup_{\mathcal{D}\in\Gamma,\, F\in\Phi} \mathcal{A}^{p,q}_{\mathcal{D},G,F}(X).$$

Common refinements and unions of supports make this a vector space. Its C^r topology is the locally convex final topology of all these stage inclusions. Equivalently its continuous seminorms are exactly those seminorms whose restrictions to every stage are continuous.

Consequently a linear map from this space to a locally convex space is continuous exactly when its restriction to each stage is continuous. This follows from the defining seminorms by composing with every continuous seminorm of the target.

Definition 8.15.10 (Ordinary smooth specialization)**.** In the ordinary affine specialization, the specified affine coordinates locally present the ordinary smooth forms on domain interiors. Use the nonempty family Γ_X of all affine chart families whose domain interiors cover X. A common refinement is obtained on the intersections using joint coordinates. For a support family Φ the ordinary test space here is $\mathcal{A}^{p,q}_{\Gamma_X,\Phi}(X)$ with the topology of Definition 8.15.9.

Proposition 8.15.11 (Multiplication by a fixed smooth form)**.** *Fix $r \in \mathbf{N} \cup \{\infty\}$. Let Γ and Φ, Ψ be as in Definition 8.15.9. Suppose the fixed smooth G-form α of bidegree (p', q') belongs to $\mathcal{A}^{p',q'}_{\Gamma}(X)$, using all ordinary closed supports. Assume that every ordinary closed subset of* $\operatorname{supp}\alpha$ *belonging to Φ also belongs to Ψ. Then*

$$M_\alpha : \mathcal{A}^{p,q}_{\Gamma,\Phi}(X) \longrightarrow \mathcal{A}^{p+p',q+q'}_{\Gamma,\Psi}(X), \qquad \omega \longmapsto \alpha \wedge \omega,$$

is well-defined, linear, and continuous for the C^r topologies. In particular this holds for ordinary smooth forms with $\Gamma = \Gamma_X$.

Proof. Choose once a family $\mathcal{E} \in \Gamma$ that tropicalizes α. Fix a source stage $(\mathcal{D}, F)$. A common refining family $\mathcal{R} \in \Gamma$ tropicalizes both α and every form in the source stage. Refinement gives a continuous linear inclusion from $\mathcal{A}_{\mathcal{D},G}$ to $\mathcal{A}_{\mathcal{R},G}$ by the preceding affine estimate.

On a compact domain W of a chart $h \in \mathcal{R}$ write $\alpha|_W = h^*a$ and $\omega|_W = h^*b$. In tangential cell coordinates, each coefficient of $a \wedge b$ is a finite signed sum of products of coefficients. For each finite $m \le r$, the product rule gives

$$\|a \wedge b\|_{h(W),m} \le N_{p,q,p',q',h(W)}\, 2^m \|a\|_{h(W),m}\, \|b\|_{h(W),m}. \tag{8.15.2}$$

Here N is a finite upper bound for the number of coefficient products in a fixed output slot on these finitely many cells. No ambient normal derivatives occur. The coefficient $\|a\|_{h(W),m}$ is fixed and finite. Thus for every target chart seminorm, multiplication is bounded by a constant times a continuous source seminorm after refinement. For $r = \infty$ apply this argument separately at each finite m.

For every source form its product has support in $G_F = F \cap \operatorname{supp}\alpha$. This is an ordinary closed subset of both F and $\operatorname{supp}\alpha$; hence $G_F \in \Phi$ and the support hypothesis gives $G_F \in \Psi$. The stage map therefore has its image in $\mathcal{A}^{p+p',q+q'}_{\mathcal{R},G,G_F}(X)$, equipped with the subspace topology. The continuous map into $\mathcal{A}_{\mathcal{R},G}$ just constructed is continuous into that subspace. Composing with its canonical continuous inclusion into the target final space proves continuity on the source stage. The linear universal property of the source final topology proves continuity of M_α. All choices of $\mathcal{R}$ and G_F depend only on the source stage and the fixed α, not on ω. □

In particular a fixed ordinary smooth cutoff acts continuously on the compact test space. If the compact support family is taken inside a specified ordinary open of the analytic interior, the same argument gives an endomorphism for that family because the support can only decrease.

8.15.4 Estimates on bounded sets in final test spaces

For an arbitrary locally convex space E, write E'_b for its continuous dual with the topology of uniform convergence on bounded subsets of E. Bounded means bounded for every continuous seminorm. No separation or completeness assumption will be needed. In this section E is spanned by the images of linear maps $Q_i : E_i \to E$, and has the locally convex final topology for these maps.

Theorem 8.15.12 (Uniform eventual equality on bounded sets)**.** *Let $D_M : E \to \mathbb{R}$ be linear, for real $M \geq 0$. Assume that every $D_M Q_i$ is continuous, and that for every i there is $H_i < \infty$ such that*

$$D_M Q_i = 0 \qquad \text{for all } M \geq H_i. \tag{8.15.3}$$

Then each D_M is continuous. For every bounded set $B \subset E$ there exists $H_B < \infty$ such that

$$D_M(b) = 0 \qquad (M \geq H_B,\ b \in B). \tag{8.15.4}$$

In particular $D_M \to 0$ in E_b'. No bounded-set lifting, countable cofinality, regular inductive limit, or uniform bound on the H_i is assumed.

Proof. Continuity of D_M is exactly the final seminorm criterion. Every $x \in E$ is a finite sum of elements of presentation images, so (8.15.3) makes $D_M(x)$ eventually zero. Suppose (8.15.4) fails. Choose $M_j \geq j$ and $b_j \in B$ with $D_{M_j}(b_j) \neq 0$, and put

$$c_j = \frac{j}{|D_{M_j}(b_j)|}, \qquad P(x) = \sum_{j \geq 1} c_j |D_{M_j}(x)|.$$

The sum is finite for every x, so P is a finite-valued seminorm. For each fixed i all terms with $j \geq H_i$ vanish on $Q_i(E_i)$. Thus PQ_i is a finite sum of continuous seminorms and is continuous. The final topology makes P continuous on E. But $P(b_j) \geq j$, contradicting boundedness of B. This contradiction proves (8.15.4), for the full real parameter family. □

For the following estimate, let $D_M : E \to \mathbb{R}$ be linear for each real $M \geq 0$.

Proposition 8.15.13 (A quantitative estimate across presentations)**.** *Let p_i be a continuous seminorm on E_i, let $w_i > 0$, and let $\varepsilon(M) > 0$. Suppose*

$$|D_M Q_i(\eta)| \leq \varepsilon(M) w_i p_i(\eta) \quad \text{for all } i, M, \eta. \tag{8.15.5}$$

Then the finite-decomposition gauge

$$P_w(x) = \inf_{x = \sum_{i \in F} Q_i \eta_i} \sum_{i \in F} w_i p_i(\eta_i), \qquad F \text{ finite}, \tag{8.15.6}$$

is a continuous seminorm on E, and

$$\sup_{x \in B} |D_M(x)| \leq \varepsilon(M) \sup_{x \in B} P_w(x) \tag{8.15.7}$$

for every bounded set B. Hence $\varepsilon(M) \to 0$ gives strong-dual convergence, even when no presentation is fixed for the members of B. The premise must hold with the actual generators of the topology whose bounded sets are used.

Proof. The spanning assumption makes the infimum finite. Concatenating finite decompositions proves subadditivity (with arbitrary small errors before taking infima); scaling proves absolute homogeneity. Repeated indices can be merged by the seminorm triangle inequality. Thus P_w is a seminorm, possibly with a kernel. The one-term decomposition gives $P_w Q_i \le w_i p_i$, so every composite is continuous. The final criterion gives continuity of P_w. Apply (8.15.5) to any finite decomposition, sum, and take its infimum to get $|D_M(x)| \le \varepsilon(M) P_w(x)$. Boundedness now proves (8.15.7). □

Chapter 9

Currents, order zero and continuous multipliers

9.1 Test spaces, currents, and their operations

Definition 9.1.1 (Test forms)**.** Write $A^{p,q}_{\mathrm{sm},c}(X)$ for the original smooth forms whose support is compact and disjoint from the analytic boundary ∂X. The topology is determined by finite tropical presentations: on a fixed finite family of tropical charts, with support in fixed compact subsets, the coefficients of smooth representatives and every derivative of their coefficients converge uniformly. Equivalent representatives are given the quotient topology, and the test space is given the final locally convex topology over these presentation spaces.

In the algebraic setting, this is the stagewise continuity formulation in [Gubler, §6.1–§6.2]; compare [CLD12, §4.1.1]. The description includes support control, fixed presentations, and all derivatives. Uniform convergence of functions alone is a different topology. No claim that this space is a strict countable LF limit is needed here.

The support convention is also substantive. In [CLD12, §4.2.1], "support propre" means compact support avoiding ∂X. If X has no analytic boundary, this reduces to ordinary compact support. On a space with boundary, a measure supported on ∂X vanishes on all these test functions and is not detected by the corresponding currents.

Definition 9.1.2 (Bidimension and bidegree)**.** A current of bidimension (p,q) is a continuous linear functional on $A^{p,q}_{\mathrm{sm},c}(X)$. Put

$$D^{\mathrm{sm}}_{p,q}(X) = \big(A^{p,q}_{\mathrm{sm},c}(X)\big)', \qquad D^{p,q}_{\mathrm{sm}}(X) = D^{\mathrm{sm}}_{n-p,n-q}(X).$$

The latter notation records bidegree. Thus a current of bidegree (p,q) acts on test forms of bidegree $(n-p,n-q)$.

For example,

$$[\omega](\alpha) = \int_X \omega \wedge \alpha, \qquad \omega \in A^{p,q}_{\mathrm{sm}}(X),$$

has bidegree (p,q). Integration over a d-dimensional algebraic cycle has bidimension (d,d) and bidegree $(n-d,n-d)$. A Radon measure acts on functions, so its bidimension is $(0,0)$ and its bidegree is (n,n). These examples prevent an ambiguous use of the phrase "a current of degree zero." See [CLD12, §4.2.2] and [Gubler, Examples 6.3, 6.5, and 6.7].

Definition 9.1.3 (Differentiation and symmetry of currents)**.** For T of bidegree (p,q), define

$$\langle d'T, \alpha\rangle = (-1)^{p+q+1}\langle T, d'\alpha\rangle,$$
$$\langle d''T, \beta\rangle = (-1)^{p+q+1}\langle T, d''\beta\rangle,$$

where α and β have the complementary test degrees. Set

$$\langle JT, \gamma\rangle = (-1)^n\langle T, J\gamma\rangle.$$

A current of bidegree (p,p) is symmetric if $JT = (-1)^pT$.

Proposition 9.1.4 (Compatibility with smooth forms)**.** *For every original smooth form ω,*

$$d'[\omega] = [d'\omega], \qquad d''[\omega] = [d''\omega], \qquad J[\omega] = [J\omega].$$

Moreover, for any current and a test form of the appropriate degree,

$$\langle d'd''T, \alpha\rangle = \langle T, d'd''\alpha\rangle. \tag{9.1.1}$$

Proof. Stokes' formula applies because test supports avoid the analytic boundary. If ω has total degree k, integrating $d'(\omega \wedge \alpha) =$

$d'\omega \wedge \alpha + (-1)^k \omega \wedge d'\alpha$ gives the first identity. The second is identical. On top-degree forms J acts by $(-1)^n$, which gives the third identity with the normalization in Definition 9.1.3. The two transpose signs in $d'd''$ multiply to -1; reversing $d''d'$ to $d'd''$ supplies the second minus sign and proves (9.1.1). □

The operations supplied by the definitions have precise domains:

1. A morphism pulls back smooth forms.
2. A proper morphism pushes currents forward by
$$\langle f_* T, \alpha \rangle = \langle T, f^* \alpha \rangle.$$
Properness ensures that the pulled-back test support is admissible.
3. A current can be multiplied by a fixed smooth form, using
$$\langle T \wedge \omega, \alpha \rangle = \langle T, \omega \wedge \alpha \rangle.$$

These formulas do not define a pullback of an arbitrary current or a product of two arbitrary currents. They are the operations in [CLD12, §4.2–§4.4] and [Gubler, §6.4–§6.6].

Definition 9.1.5 (Positive currents)**.** A symmetric current of bidegree (p, p) is weakly positive, positive, or strongly positive if it is nonnegative, respectively, on strongly positive, positive, or weakly positive test forms of bidegree $(n-p, n-p)$.

Symmetry is explicit in this definition. Testing only against symmetric forms must not be used as a substitute for specifying symmetry of the current itself. In bidegree $(1, 1)$ the three positivity conditions agree, because the complementary test degree is $(n-1, n-1)$. In middle degree, Example 7.4.3 prevents importing arguments that require strong positive tests to span all symmetric tests.

9.1.1 Positivity, order zero, and multiplication by a function

The test topology controls derivatives of all orders. Ordinary positivity supplies estimates involving coefficient values alone. We first establish those estimates, and then distinguish them from the stronger scalar-multiplier construction needed for arbitrary continuous functions.

Definition 9.1.6 (Order zero on a presentation)**.** A current T has order zero if, on each fixed finite tropical presentation and fixed compact support B, its value satisfies an estimate

$$|\langle T, \alpha\rangle| \leq C_B \|\alpha\|_{B,0}, \tag{9.1.2}$$

where the seminorm uses the suprema of coefficient values, with quotient seminorms for representatives, and does not use their derivatives. On a real coordinate domain, this is equivalent to the distributional coefficients of T being signed Radon measures.

Proposition 9.1.7 (The usable positive-current estimate)**.** *On a real coordinate domain, an ordinary positive current is of order zero. The same argument on finite tropical presentations gives order zero for ordinary positive currents on the original analytic test sheaf. It also applies to strongly positive currents. Weak positivity alone does not suffice in middle degree.*

Open proof obligation (RC2). Supply the analytic positive-form decomposition and quotient estimate used after passing from the coordinate calculation to the original test sheaf; GJR Lemma 7.12. The real coordinate calculation is retained in historical evidence.

Definition 9.1.8 (Continuous multiplication of an ordinary positive current)**.** Let T be an ordinary positive current and β an ordinary positive smooth test of complementary degree. The positive functional $\phi \mapsto \langle T, \phi\beta\rangle$ on smooth scalar functions satisfies

$$|\langle T, \phi\beta\rangle| \leq \|\phi\|_{\operatorname{supp}\beta} \langle T, \beta\rangle.$$

Uniform density of original smooth scalar functions on compact supports extends this functional to a finite Radon measure $\mu_{T,\beta}$ supported in $\operatorname{supp}\beta$. If a symmetric test is written $\alpha = \beta_1 - \beta_2$ with ordinary positive smooth tests, define

$$(uT)(\alpha) = \int u \, d\mu_{T,\beta_1} - \int u \, d\mu_{T,\beta_2}$$

for a continuous function u, and set its value on antisymmetric tests to zero.

The construction is independent of the decomposition: a linear relation among positive smooth tests gives the same relation among the measures, first on smooth scalar functions and then by uniform density. Finite-presentation

domination proves continuity in the current topology. The density statement is [CLD12, Corollaries 5.4.7–5.4.8]; the ordinary-positive decomposition is [CLD25, Proposition 6.5.2], also used in [GJR, Lemma 7.12]. The scalar-multiplier argument is [CLD25, Lemma 8.5.1]. Thus the definition applies even when u is not a function of the coordinates of one fixed tropical chart. A chartwise order-zero estimate alone would not justify that extension for an arbitrary current; [CLD25, Example 7.2.14] gives an order-zero scalar current on an infinite tropical star which is not a Radon measure.

If $u_j \to u$ uniformly near a test support, then $u_j T \to uT$ there. For $u \geq 0$, the product is positive. It need not be closed, even when T is closed; this distinction is essential in Section 13.1.

9.2 Tests, degrees and symmetry

Fix an open $\Omega \subset \mathbb{R}^n$. For a compact $K \Subset \Omega$, let $A^{p,q}_K$ consist of smooth forms supported in K, with seminorms

$$\|\eta\|_{K,r} = \max_{I,J,\ |\nu|\leq r} \sup_{x\in K} |\partial^\nu \eta_{IJ}(x)| \quad (r = 0, 1, \ldots).$$

The space $A^{p,q}_c$ has the usual test-function inductive-limit topology. A linear functional is a current if its restriction to every $A^{p,q}_K$ is continuous. Equivalently, for each K there are C_K and an integer r_K giving a bound by $C_K \|\eta\|_{K,r_K}$.

Definition 9.2.1. A current of bidimension (q, q) acts on $A^{q,q}_c$; its bidegree is $(n-q, n-q)$. It has order zero if r_K can be chosen to be zero for every K. It is symmetric if

$$T(J\eta) = (-1)^q T(\eta).$$

Put $\eta_s = (\eta + (-1)^q J\eta)/2$. A symmetric current satisfies $T(\eta) = T(\eta_s)$ and vanishes on the complementary antisymmetric part. In matrix notation symmetrization replaces H by $(H + H^t)/2$.

Definition 9.2.2. A symmetric current is weakly positive if it is nonnegative on strongly positive tests; positive if it is nonnegative on positive tests; strongly positive if it is nonnegative on weakly positive tests.

Thus the test cones are reversed: strong positivity of a current is the most restrictive condition. We use positive without an adjective for the middle

condition. Weak convergence $T_j \rightharpoonup T$ means convergence on every fixed smooth compactly supported test. It initially says nothing about continuous or varying tests.

Example 9.2.3. A locally integrable form defines $[\alpha](\eta) = \int \alpha \wedge \eta$. In particular [1] has bidegree $(0,0)$ and tests top-degree forms, while a scalar Radon measure has bidegree (n,n) and tests functions. By wedge duality a smooth positive form gives a positive current.

9.3 Order zero and measure coefficients

The scalar argument below needs no continuity assumption. Positivity itself supplies the required bound.

Lemma 9.3.1. *A linear functional $L : C_c^\infty(\Omega) \to \mathbb{R}$ nonnegative on nonnegative functions extends uniquely to a positive Radon measure.*

Proof. For tests supported in $K \Subset \Omega$, choose $0 \le \chi \in C_c^\infty$ equal to one near K. Then

$$-\|f\|_\infty \chi \le f \le \|f\|_\infty \chi, \qquad |L(f)| \le L(\chi)\,\|f\|_\infty .$$

Every continuous compactly supported function has uniformly converging smooth approximants supported in one larger compact subset: extend by zero and convolve with a smooth compactly supported approximate identity. The bound defines an extension independent of the approximants; compare any two choices on a common compact set. Nonnegative functions admit nonnegative approximants, so the extension is positive. The Riesz representation theorem on $C_c(\Omega)$ gives the unique locally finite Radon measure. □

Theorem 9.3.2 (Positive functionals have order zero)**.** *Let $T : A_c^{q,q}(\Omega) \to \mathbb{R}$ be symmetric and linear, nonnegative on ordinary positive tests. Then T is a current of order zero. There is a positive Radon measure μ_T characterized by*

$$\mu_T(\phi) = T(\phi\beta_q), \qquad \phi \in C_c^\infty(\Omega). \tag{9.3.1}$$

For a symmetric test $\eta = \alpha_H$ supported in K and χ as in Proposition 7.3.2,

$$|T(\eta)| \le \|H\|_{\infty,\mathrm{op}}\ \mu_T(\chi). \tag{9.3.2}$$

Proof. Since β_q is positive, $\phi \mapsto T(\phi\beta_q)$ is a positive scalar functional. Lemma 9.3.1 gives μ_T. Apply T to the two positive forms in (7.3.1); this proves the estimate. Replace an arbitrary test by its symmetric part and use the coefficient norm comparison in Remark 7.3.3. A C^0 bound holds on every compact set, proving both current continuity and order zero. □

The proof uses ordinary-positive domination, not strong-cone spanning. The trace measure depends on coordinates: it is a control measure, not an additional intrinsic volume form.

Theorem 9.3.3 (Matrix of coefficient measures)**.** *Put $m = \binom{n}{q}$. There are unique signed Radon measures $M_{ij} = M_{ji}$ with*

$$T(\alpha_H) = \sum_{i,j=1}^{m} \int H_{ij}\, dM_{ij}, \qquad \mu_T = \sum_i M_{ii}. \tag{9.3.3}$$

There is a measurable symmetric matrix A such that

$$dM_{ij} = A_{ij}\, d\mu_T, \qquad A \geq 0, \quad \operatorname{tr} A = 1 \quad \mu_T\text{-almost everywhere.} \tag{9.3.4}$$

Consequently

$$|T(\alpha_H)| \leq \int \|H(x)\|_{\mathrm{op}}\, d\mu_T(x). \tag{9.3.5}$$

Proof. Use the diagonal matrix units E_{ii} and put $F_{ij} = (E_{ij} + E_{ji})/2$ for $i \neq j$. Define

$$M_{ii}(\phi) = T(\alpha_{\phi E_{ii}}), \qquad M_{ij}(\phi) = T(\alpha_{\phi F_{ij}}).$$

The diagonal functionals are positive measures. The others are signed measures, since

$$F_{ij} = \tfrac{1}{4}\big((e_i + e_j)(e_i + e_j)^t - (e_i - e_j)(e_i - e_j)^t\big),$$

and each square gives a positive measure by the scalar lemma. Expanding H proves (9.3.3). The factor $1/2$ is necessary because the sum includes both ij and ji.

For any constant vector v, the measure $\sum v_i v_j M_{ij}$ is positive. Applying this to $e_i + e_j$ and $e_i - e_j$ gives

$$-(M_{ii} + M_{jj}) \leq 2M_{ij} \leq M_{ii} + M_{jj}.$$

Thus $|M_{ij}| \le (M_{ii} + M_{jj})/2$ and every coefficient measure is absolutely continuous with respect to μ_T. The Radon–Nikodym theorem gives A_{ij}. For each rational vector v, $v^t A v \ge 0$ outside a null set. Remove the union of these countably many null sets; continuity in v then yields $A \ge 0$. The trace identity follows from $\mu_T = \sum_i M_{ii}$. Finally

$$-\|H\|_{\mathrm{op}} \operatorname{Id} \le H \le \|H\|_{\mathrm{op}} \operatorname{Id} \quad \Longrightarrow \quad |\operatorname{tr}(AH)| \le \|H\|_{\mathrm{op}}.$$

Integrating proves the estimate. Testing the matrix units proves uniqueness. □

Corollary 9.3.4. *If both T and $-T$ are positive, then $T = 0$. More generally $\mu_T = 0$ implies $T = 0$.*

Proof. In the first case μ_T and its negative are positive, so $\mu_T = 0$. In either case (9.3.5) makes every test pairing zero. □

Corollary 9.3.5 (Coefficient Cauchy–Schwarz inequality)**.** *For every relatively compact Borel set $E \subset \Omega$,*

$$|M_{ij}|(E) \le \sqrt{M_{ii}(E) M_{jj}(E)}.$$

For any $a, b \ge 0$ there is also the measure inequality

$$ab|M_{ij}| \le \tfrac{1}{2}(a^2 M_{ii} + b^2 M_{jj}).$$

Proof. Positive semidefiniteness of A gives $|A_{ij}|^2 \le A_{ii} A_{jj}$, by taking the determinant of its two-by-two principal minor. Integrate $|A_{ij}| \le \sqrt{A_{ii} A_{jj}}$ over E and apply scalar Cauchy–Schwarz with respect to μ_T. The second assertion follows by integrating $ab|A_{ij}| \le (a^2 A_{ii} + b^2 A_{jj})/2$ on Borel sets. □

The weighted inequality is the real-chart form of [BGJK, Proposition 5.2.6]. Their setting also includes boundary strata, which are not treated here. Conversely, any locally finite positive measure μ and measurable positive semidefinite A with $\operatorname{tr} A = 1$ define a positive current by $T(\alpha_H) = \int \operatorname{tr}(AH)\, d\mu$. The estimate above proves continuity, and the trace measure is μ. Thus the matrix description characterizes positive currents in the present Euclidean setting.

9.4 Why weak positivity is insufficient

Weak positivity can allow derivatives of point masses. Thus it changes more than the constant in an estimate.

Theorem 9.4.1. *There is a nonzero symmetric weakly positive current on $\mathbb{R}^4$ of bidimension $(2,2)$ which is not of order zero. Its negative is also weakly positive.*

Proof. With B from Section 7.4, define on any coefficient matrix H

$$T_B(\alpha_H) = -\partial_{x_1} \operatorname{tr}(BH)(0). \tag{9.4.1}$$

This is a continuous distribution of order at most one. Since B is symmetric, it kills antisymmetric matrices. If α_H is strongly positive pointwise, then $\operatorname{tr}(BH(x)) = 0$ everywhere by Theorem 7.4.2. Hence both T_B and $-T_B$ vanish on all strong tests and are weakly positive.

Choose $\chi \in C_c^\infty(\mathbb{R}^4)$ equal one near zero, and $g \in C_c^\infty(\mathbb{R})$ with $g'(0) = 1$. Set

$$\phi_\varepsilon(x) = \varepsilon g(x_1/\varepsilon)\chi(x), \qquad H_\varepsilon = \phi_\varepsilon B.$$

All supports lie in $\operatorname{supp}\chi$ and $\|H_\varepsilon\|_\infty \to 0$. But $\partial_1\phi_\varepsilon(0) = 1$ and $\operatorname{tr}(B^2) = 6$, whence

$$T_B(\alpha_{H_\varepsilon}) = -6.$$

This contradicts any order-zero estimate on that fixed compact set. □

Also $T_B(\phi\beta_2) = 0$ since $\operatorname{tr} B = 0$. Its formal trace vanishes although the current is nonzero. The trace estimate for ordinary positive currents therefore cannot be applied to weakly positive currents. This is a distributional consequence of the nonpointed cone in [BGJK, Examples 2.3.6 and 5.2.8].

Remark 9.4.2 (The CLD25 order-zero assertion). [CLD25, Proposition 7.2.9] deduces order zero from positivity on strongly positive tests, using strong domination in its proof. On the standard real tropical space $\mathbb{R}^4$, (9.4.1) satisfies its symmetry and positivity assumptions and violates its conclusion. In bidegree $(2,2)$ the symmetric matrix condition agrees in the two conventions. Equip $\mathbb{R}^4$ with its usual affine functions and constant volume calibration in dimension four. Its standard tropical structure has level four; locally one may use the interior of a constantly calibrated four-dimensional cube, as in [CLD25, §6.6.3]. Coordinate functions separate points, hence it is affinely and

differentially separated in the sense of [CLD25, §6.2.3]. The counterexample is in this real tropical setting, not claimed on an analytic Berkovich space. Theorem 9.3.2 provides the ordinary-positive replacement on real charts.

9.5 Multiplication by continuous functions

Proposition 9.5.1. *A positive current has a unique extension to compactly supported continuous coefficient forms, continuous for uniform coefficient convergence on a common compact set. On symmetric tests it is (9.3.3); it vanishes on antisymmetric tests.*

Proof. The coefficient measures are finite on compact sets, so the integrals exist and converge under uniform convergence with fixed compact support. Uniqueness follows by uniformly approximating the finitely many coefficients by smooth functions supported in one larger compact set. Changing coordinates gives the same extension: the extensions agree on smooth forms and the fixed smooth transition matrix preserves uniform convergence on compact sets. □

Definition 9.5.2. For $f \in C^0(\Omega)$ define $(fT)(\eta) = T(f\eta)$ using this extension.

Proposition 9.5.3. *The current fT has order zero, and*

$$|(fT)(\alpha_H)| \le \int |f| \, \|H\|_{\mathrm{op}} \, d\mu_T.$$

If $f \ge 0$, it is positive and $\mu_{fT} = f\mu_T$. Multiplication is associative, commutes with restriction, and satisfies

$$\operatorname{supp}(fT) \subset \operatorname{supp} T \cap \operatorname{supp} f.$$

Proof. The inequality is (9.3.5) applied to fH. If $f, H \ge 0$, then $\operatorname{tr}(AfH) \ge 0$ almost everywhere. Testing $\phi\beta_q$ gives the trace identity. Associativity and restriction follow by multiplying each coefficient measure. On open sets where $T = 0$ its coefficient measures vanish, and on open sets where $f = 0$ the multiplied coefficients vanish. This proves the support statement. □

Remark 9.5.4. Locally bounded Borel functions also multiply the coefficient measures; the relevant equivalence is then equality μ_T-almost everywhere. Continuous multipliers are better suited to limits of varying currents because they admit uniform approximation. For an arbitrary distribution, coefficient distributions need not be measures, so this argument does not define continuous multiplication.

9.6 Weak convergence and varying multipliers

Lemma 9.6.1. *If positive currents of fixed bidimension satisfy $T_j \rightharpoonup T$, then T is positive and for every compact $K \Subset \Omega$,*

$$\sup_j \mu_{T_j}(K) < \infty.$$

Proof. Symmetry and nonnegativity on each positive test pass to the limit. Choose $0 \le \chi \in C_c^\infty$ equal one near K. Then

$$0 \le \mu_{T_j}(K) \le T_j(\chi \beta_q) \longrightarrow T(\chi \beta_q) < \infty.$$

A convergent real sequence, including its initial terms, is bounded. □

Proposition 9.6.2. *Under these hypotheses, $T_j(\eta) \to T(\eta)$ for every fixed continuous compactly supported coefficient form η.*

Proof. Approximate η uniformly by smooth η_ν supported in one compact K'. Theorem 9.3.3 and Lemma 9.6.1 bound $|T_j(\eta - \eta_\nu)|$ uniformly in j by a constant times the coefficient error. The same estimate holds for T. For fixed ν, weak convergence applies to η_ν. First choose ν to control both approximation errors, then let j tend to infinity. □

Theorem 9.6.3 (Joint continuity)**.** *If $T_j \rightharpoonup T$ are positive currents of fixed bidimension and $f_j \to f$ locally uniformly with f_j, f continuous, then*

$$f_j T_j \rightharpoonup fT.$$

Proof. For a symmetric smooth test $\eta = \alpha_H$ supported in K, write

$$T_j(f_j \eta) - T(f\eta) = T_j((f_j - f)\eta) + (T_j - T)(f\eta).$$

The first term is bounded in absolute value by

$$\|f_j - f\|_{K,\infty} \, \|H\|_{\infty,\mathrm{op}} \, \mu_{T_j}(K),$$

which tends to zero by the uniform mass bound. The second tends to zero by Proposition 9.6.2, since $f\eta$ is a fixed continuous test. Antisymmetric components vanish. □

Pointwise convergence of multipliers is insufficient. On $\mathbb{R}$, take $T_j = \delta_{1/j}$ and $f_j(x) = g(jx)$ for $g \in C_c^\infty((1/2, 3/2))$ with $g(1) = 1$. At each fixed x, $f_j(x) \to 0$, and $T_j \rightharpoonup \delta_0$, but $f_j T_j = \delta_{1/j} \rightharpoonup \delta_0$, not zero.

9.7 Differentiation and closedness

For a current S of total degree k, use the distributional convention

$$(d'S)(\eta) = (-1)^{k+1} S(d'\eta), \qquad (d''S)(\eta) = (-1)^{k+1} S(d''\eta).$$

Closed means both derivatives vanish. These signs agree with derivatives of integration currents. Indeed coefficients of a compactly supported top-degree derivative are sums of partial derivatives; Fubini and the one-variable fundamental theorem of calculus make each integral zero.

Lemma 9.7.1. *For a current of diagonal bidegree,*

$$(\mathrm{d}'\mathrm{d}''T)(\eta) = T(\mathrm{d}'\mathrm{d}''\eta). \tag{9.7.1}$$

Differentiation is continuous for weak convergence.

Proof. The total degree k is even. Applying the definitions twice gives

$$(-1)^{k+2}(-1)^{k+1} T(d''d'\eta) = T(d'd''\eta).$$

For continuity, the derivative of a fixed smooth compactly supported test is another fixed test. □

For a smooth form γ and a current S of total degree k, left multiplication is defined by

$$(\gamma \wedge S)(\eta) = (-1)^{k \deg \gamma} S(\gamma \wedge \eta).$$

This convention agrees with left multiplication of locally integrable forms and fixes the signs in the next statement.

Proposition 9.7.2. *If T is closed and f smooth, then*

$$d'(fT) = d'f \wedge T, \qquad d''(fT) = d''f \wedge T, \qquad \mathrm{d'd''}(fT) = \mathrm{d'd''}f \wedge T.$$

Proof. Insert $d'(f\eta) = d'f \wedge \eta + f\, d'\eta$ into $d'T = 0$ to obtain the first formula; exchange primes for the second. In general, the graded Leibniz rules give

$$\begin{aligned}\mathrm{d'd''}(fT) = {} & \mathrm{d'd''}f \wedge T - d''f \wedge d'T \\ & + d'f \wedge d''T + f\,\mathrm{d'd''}T.\end{aligned}$$

Closedness removes the last three terms. This argument needs smoothness of f: derivatives of a continuous multiplier cannot be inserted as ordinary smooth forms. □

Example 9.7.3 (Multiplication can destroy closedness)**.** On $\mathbb{R}$, $T = [1]$ is positive and closed. For $f(x) = e^x > 0$, the current fT is positive, but

$$d'[e^x](\phi\, d''x) = -\int e^x \phi'(x)\, dx = \int e^x \phi(x)\, dx.$$

This is positive for nonzero nonnegative $\phi \in C_c^\infty$, so fT is not closed.

Remark 9.7.4 (CLD25 Corollary 8.6.7). Definition 8.6.2 of [CLD25] requires a Bedford–Taylor current to be positive and closed and to satisfy a curvature-kernel condition. Corollary 8.6.7 asserts preservation under multiplication by an arbitrary positive continuous function. Example 9.7.3 contradicts closedness even for a smooth multiplier. The starting current [1] has the kernel property since $\mathrm{d'd''}(u[1]) = \mathrm{d'd''}[u]$ by definition. The valid replacement here is Proposition 9.5.3: positivity and order zero are preserved. Closedness needs extra assumptions. This does not invalidate the distinct operation $\mathrm{d'd''}(uT)$, whose closedness follows from the differential identities.

9.8 A first curvature product

For positive T and continuous u, $\mathrm{d'd''}(uT)$ is always a distributional current. Positivity requires more. We prove it under a stated approximation hypothesis.

Theorem 9.8.1. *Let T be positive and closed of bidimension (q,q), $q \geq 1$. Suppose u is continuous and every point has a neighbourhood U on which smooth u_j satisfy $\mathrm{d'd''}u_j \geq 0$ and converge to u locally uniformly on the same U. Then $R = \mathrm{d'd''}(uT)$ is positive and closed of bidimension $(q-1,q-1)$, and locally*

$$\mathrm{d'd''}u_j \wedge T \rightharpoonup R.$$

The limit is independent of the approximating sequence.

Proof. Theorem 9.6.3 with fixed T gives $u_j T \rightharpoonup uT$. Lemma 9.7.1 and Proposition 9.7.2 give the displayed convergence. For a positive test η of bidegree $(q-1,q-1)$, Proposition 7.5.2 makes $\mathrm{d'd''}u_j \wedge \eta$ positive. Thus $(\mathrm{d'd''}u_j \wedge T)(\eta) \geq 0$, and positivity and symmetry pass to the limit. A nonnegative smooth partition of unity on a test's compact support transfers local positivity to global positivity. The identities $(d')^2 = (d'')^2 = 0$ and $d'd'' = -d''d'$ give $d'R = d''R = 0$. The limit equals the already defined $\mathrm{d'd''}(uT)$, so it is independent of approximants. □

Proposition 9.8.2. *A continuous convex function on a convex open subset $\Omega \subset \mathbb{R}^n$ satisfies this approximation hypothesis locally.*

Proof. Choose a ball U with compact closure in Ω and a nonnegative smooth kernel ρ supported in the unit ball, of integral one. For sufficiently small ε put

$$u_\varepsilon(x) = \int u(x - \varepsilon y)\rho(y)\,dy, \qquad x \in U.$$

All functions are defined on the same U. Convolution gives smoothness. Apply convexity inside the integral to see that u_ε is convex. Uniform continuity of u on a slightly larger compact neighbourhood gives uniform convergence on $\overline{U}$. Convexity implies a positive semidefinite Hessian by the criterion in Chapter 7. □

Example 9.8.3 (The corner mass of an absolute value)**.** On $\mathbb{R}$, one has $\mathrm{d'd''}[|x|] = 2\delta_0$. For $\phi \in C_c^\infty(\mathbb{R})$, integration by parts on the two half-lines gives

$$\int_{-\infty}^{0} (-x)\phi''(x)\,dx + \int_{0}^{\infty} x\phi''(x)\,dx = 2\phi(0).$$

There is no smooth Hessian density off zero, but the full curvature is nonzero. The smooth convex $u_\varepsilon = \sqrt{x^2 + \varepsilon^2}$ converge locally uniformly to $|x|$, and their second derivatives converge weakly to this mass by Theorem 9.8.1.

Remark 9.8.4. Sequence independence for a fixed u is not curvature-class independence. If $\mathrm{d}'\mathrm{d}''[u] = \mathrm{d}'\mathrm{d}''[v]$, identifying the products still requires

$$\mathrm{d}'\mathrm{d}''((u-v)T) = 0.$$

For smooth $h = u - v$ with $\mathrm{d}'\mathrm{d}''h = 0$ as a form, Proposition 9.7.2 proves this. It does not apply to nonsmooth h. No general kernel assertion follows from Theorem 9.8.1. Symmetry of iterated products is likewise a further theorem, not a consequence of being able to repeat a definition.

9.9 Transfer through charts

The estimates are finite-dimensional in their coefficient directions. They give a transfer statement with explicit hypotheses, but relations among chart presentations must remain visible.

Proposition 9.9.1 (Transfer of order zero)**.** *Let $\mathcal{A}_c$ have a symmetry projection and local linear presentation maps P_D from smooth matrix-valued coefficients on Euclidean chart domains. Assume:*

1. *Tests are finite sums of chart-presented tests after localization.*
2. *For each fixed chart and compact coefficient support there are an actual positive test θ_D and c_D such that, for symmetric H,*

$$c_D \|H\|_\infty \theta_D \pm P_D(H) \quad \text{are actual positive tests.}$$

3. *The topology is the final locally convex topology of these presentation spaces, and presentations respect symmetrization.*

Then a symmetric linear functional S nonnegative on actual positive tests is a current, of order zero on every fixed presentation.

Proof. Applying S to the two tests gives

$$|S(P_D(H))| \le c_D S(\theta_D) \|H\|_\infty .$$

Use symmetrization for the remaining coefficient part. Each composite with a presentation is continuous even in the coefficient C^0 topology. The final topology gives continuity on $\mathcal{A}_c$, and the bound is the asserted order-zero estimate. □

The abstract transfer proposition alone does not define fS for arbitrary continuous f on an analytic space. Such an f need not come from a fixed tropical chart. Nor does separate extension in each presentation show that new continuous relations vanish. The next elementary criterion isolates this issue.

Lemma 9.9.2 (Extension across a quotient)**.** *Let E be a normed space of smooth presentations, $\widehat{E}$ its completion, $N \subset E$ the relation subspace and $\widehat{N} \subset \widehat{E}$ a proposed closed relation space. A bounded functional ℓ vanishing on N extends to $\widehat{E}/\widehat{N}$ if $\widehat{N} = \overline{N}$. In general it extends if and only if its continuous extension vanishes on all of $\widehat{N}$.*

Proof. The functional extends uniquely to $\widehat{E}$ and vanishes on $\overline{N}$ by continuity. A functional factors through a quotient precisely when it vanishes on the relation subspace. □

A chart construction must prove this relation statement, or use an intrinsic extension theorem that already contains it. Positivity provides continuity, not automatically descent through an enlarged relation space. In the algebraic CLD setting, Theorem 8.14.1 supplies a different route: measures attached directly to actual smooth tests.

9.10 Source concordance and subsequent use

The following list records the exact replacements proved in this instalment.

1. [CLD12, Lemma 5.2.3]: Theorem 7.4.2 disproves strong spanning on real charts; Proposition 7.3.2 supplies ordinary-positive domination.
2. [GK19, Remark 1.12(i)]: the weak cone is not pointed. Corollary 9.3.4 is an ordinary-positive statement, not a restoration of its weak analogue.
3. [CLD25, Proposition 7.2.9]: Theorem 9.4.1 gives a real tropical counterexample; Theorems 9.3.2 and 9.3.3 prove the ordinary-positive result.
4. [CLD25, Corollary 8.6.7]: Example 9.7.3 gives the closedness obstruction; Proposition 9.5.3 is the valid multiplier result here.

Chapter 8 constructs intrinsic scalar multiplication, and Chapter 13 treats mixed products in the stated algebraic CLD setting. The next comparison concerns generated potential classes and the curvature kernel, beyond the

admitted approximation class. No general continuous current-psh regularization theorem is claimed.

9.11 Compactness from a uniform trace bound

Order zero makes continuous multiplication possible. A uniform order-zero bound gives a second useful conclusion: compactness for weak convergence. These statements use different quantifiers. Every positive current has a finite trace on a fixed compact set, but a family of positive currents need not have a common bound there.

Theorem 9.11.1 (Local compactness of positive currents)**.** *Let $\Omega \subset \mathbb{R}^n$ be open. For each compact $K \Subset \Omega$, fix a finite number C_K. Let $\mathscr{T}$ be a family of ordinary positive currents of a fixed bidimension, and assume their trace measures in the fixed coordinates satisfy*

$$\sup_{T \in \mathscr{T}} \mu_T(K) \le C_K.$$

Every sequence in $\mathscr{T}$ has a subsequence converging weakly on smooth compactly supported tests to a positive current. If all members are d'-closed, or d''-closed, or both, so is the limit. The same conclusions hold for the closure of $\mathscr{T}$.

Proof. Choose a compact exhaustion $K_j \Subset K_{j+1}^{\circ}$ of Ω. By Theorem 9.3.3, the coefficient measures M_{ab} of every member are bounded in total variation on K_j by a constant controlled by C_{K_j}. Indeed, their densities satisfy $|A_{ab}| \le 1$ relative to μ_T. On the space of continuous functions supported in K_j, choose a countable set dense in the uniform norm. Such a set exists because K_j is compact metrizable; one can equivalently work with $C_0(K_j^{\circ})$ and its separability.

Diagonal extraction over these countable sets, all coefficient pairs and all j gives a subsequence for which every selected coefficient pairing converges. The uniform total-variation bounds extend this convergence to every compactly supported continuous coefficient. For example, if $f_\ell \to f$ uniformly with common compact support, then

$$\left| \int (f - f_\ell)\, dM_{ab,T} \right| \le C_K \|f - f_\ell\|_\infty$$

uniformly in T. Taking first the subsequence limit and then $\ell \to \infty$ gives a well-defined bounded functional on each coefficient space. The resulting current has order zero and the expected compatibility on overlapping compact sets.

For every ordinary positive test η, the limit of $T(\eta) \geq 0$ is nonnegative. Symmetry passes to the limit as well. This proves positivity. Closedness also passes to the limit: for every test ξ, the value on $d'\xi$ or $d''\xi$ is the limit of zero. No continuity of a differential on a space of measures is needed; the differential is applied to the fixed test. The estimates and the same argument remain valid for the weak closure, with the local mass bounds interpreted using compactly supported cutoffs. □

Remark 9.11.2. A weak limit need not satisfy the literal bound $\mu(K) \leq C_K$ for each originally chosen compact K: mass can move into its boundary. What is inherited without ambiguity is the bound on each fixed nonnegative continuous cutoff. For compactness it is enough to retain bounds on slightly larger compact neighbourhoods. This is why the theorem asserts relative compactness and local boundedness, rather than preserving an arbitrary list of sharp compact-set constants.

9.11.1 What changes for an analytic test space

An analytic current is not defined using one ambient Euclidean coordinate space. Its tests are presented in finitely many moment charts, modulo analytic relations. The following formulation isolates the exact functional-analytic input and avoids a countability assumption on the field.

Proposition 9.11.3. *Let E be a real test space with a locally convex final topology from presentation spaces E_a. Suppose a family $\mathscr{T} \subset E'$ satisfies, for every a, a common estimate*

$$|T(\iota_a \eta)| \leq C_a p_a(\eta), \qquad T \in \mathscr{T},$$

where p_a is a continuous seminorm and the images of the E_a span E. Then $\mathscr{T}$ is relatively compact for pointwise convergence on E, in the sense of convergent subnets. Every limit is a continuous functional on E. Positivity on a fixed test cone, vanishing on specified relations, and closedness under fixed continuous test differentials are preserved.

Proof. Each $e \in E$ is a finite sum of presented elements, so the estimates give a finite bound M_e for $|T(e)|$, uniform in T. Embed $\mathscr{T}$ in the compact product $\prod_{e\in E}[-M_e, M_e]$. Every net has a subnet converging in this product. The identities expressing linearity are closed conditions on finitely many coordinates, so the limit is linear. On E_a it still satisfies the displayed estimate, hence is continuous. The defining final topology makes the resulting linear functional continuous on E. Each positivity inequality or differential identity is another closed condition on evaluations. If tests are first defined in a presentation space and then quotiented, the equations annihilating the relation subspace are preserved in exactly the same way. □

A sequential statement requires a countable determining family with uniform approximation control, as in the Euclidean proof. Without such a family, the product compactness theorem gives subnets, not automatically subsequences. Conversely, convergence on a countable family alone need not imply convergence on all analytic tests unless the density and uniform bounds have been established.

9.12 Testing moving coefficients against a convergent current

Proposition 9.12.1. *Suppose $T_i \to T$ on all tests and the currents satisfy a common order-zero bound on each fixed compact presentation: $|T_i(v\eta)| \le C_\eta \|v\|_\infty$ for smooth scalar multipliers v, with C_η independent of i. Let u_i, u be continuous functions on a fixed compact neighbourhood of the support of a test η, with $u_i \to u$ uniformly. Assume the chartwise order-zero extension and continuous approximation for $u\eta$ used in Chapter 9. Then*

$$T_i(u_i\eta) \longrightarrow T(u\eta).$$

Proof. Choose smooth multipliers $v_k \to u$ uniformly on that compact neighbourhood, with a common cutoff where needed. The difference splits as

$$(T_i - T)(v_k\eta) + T_i((u_i - u)\eta) + (T_i - T)((u - v_k)\eta).$$

The first term tends to zero for fixed k. The second is bounded by a fixed constant times $\|u_i - u\|_\infty$. The last is bounded by a fixed constant times $\|u - v_k\|_\infty$, using the uniform order-zero estimates for T_i and T. First let i tend to its limit and then $k \to \infty$. □

Example 9.12.2 (Weak convergence is weaker than variation convergence)**.** On $\mathbb{R}$, $\delta_{1/j} \to \delta_0$ on every continuous compactly supported function, but $\|\delta_{1/j} - \delta_0\|_{\mathrm{TV}} = 2$. Moreover $\delta_j \to 0$ vaguely on $\mathbb{R}$ while every δ_j has total mass one. For a direct moving-test counterexample, take continuous functions u_j supported in small intervals around $1/j$ that avoid zero, with $0 \le u_j \le 1$, $u_j(1/j) = 1$, and interval lengths tending to zero fast enough that $u_j \to 0$ pointwise. Then $\delta_{1/j}(u_j) = 1$ while $\delta_0(0) = 0$. Thus pointwise convergence of moving multipliers does not suffice. The second shows why compactness of the underlying space, or a separate tightness argument, is needed to retain total mass.

The current compactness argument supplies limits, not uniqueness of nonlinear products. In Bedford–Taylor theory, uniqueness comes from the recursion and its estimates; compactness alone could leave several cluster currents. Likewise, positivity and closedness of a limit do not identify its cohomology class unless a class-detecting pairing is continuous and has been retained. These are separate uses of the same weak topology.

9.13 Radial mass monotonicity for closed supercurrents

Closedness imposes a dimension constraint on positive currents. A positive measure can be concentrated at any point, but a positive closed current of positive bidimension cannot place coefficient mass on a set of too small Hausdorff dimension. The real proof uses the convex radial function $|x|$, not the complex logarithmic radial weight. We begin with a regularized formula which avoids multiplying a current by a singular form at the centre.

Fix Euclidean coordinates on $\Omega \subset \mathbb{R}^n$ and put $\beta = \sum_i d'x_i \wedge d''x_i = \frac{1}{2} DD|x|^2$. For a weakly positive current T of bidimension (p,p), its scalar trace measure is

$$\mu_T = T \wedge \frac{\beta^p}{p!}.$$

It is positive because β^p is strongly positive. For weak positivity alone, this scalar measure need not dominate all coefficients of T. Ordinary positivity supplies that additional estimate by Theorem 9.3.3.

Lemma 9.13.1 (The regularized radial identity)**.** *Suppose T is smooth, closed under both differentials, and has bidimension (p,p) with $p \geq 1$. If $\overline{B}(a,r) \subset \Omega$ and $\rho_\varepsilon(x) = (|x-a|^2+\varepsilon^2)^{1/2}$, then*

$$\frac{\mu_T(B(a,r))}{(r^2+\varepsilon^2)^{p/2}} = \frac{1}{p!}\int_{B(a,r)} T \wedge (DD\rho_\varepsilon)^p.$$

Proof. One has $\beta = \rho_\varepsilon DD\rho_\varepsilon + d'\rho_\varepsilon \wedge d''\rho_\varepsilon$. Stokes and closedness give

$$\begin{aligned}\int_{B(a,r)} T \wedge \beta^p &= \int_{\partial B(a,r)} T \wedge d''(\rho_\varepsilon^2/2) \wedge \beta^{p-1} \\ &= \int_{\partial B(a,r)} \rho_\varepsilon^p T \wedge d''\rho_\varepsilon \wedge (DD\rho_\varepsilon)^{p-1} \\ &= (r^2+\varepsilon^2)^{p/2}\int_{B(a,r)} T \wedge (DD\rho_\varepsilon)^p.\end{aligned}$$

In the second line, every other term contains $d''\rho_\varepsilon$ twice and vanishes. In the third line, ρ_ε is constant on the boundary sphere and Stokes is used again. Dividing by $p!$ gives the formula. All forms used here are smooth at a because $\varepsilon > 0$. □

Theorem 9.13.2 (Real mass monotonicity)**.** *If T is weakly positive and d'- and d''-closed of bidimension (p,p), then*

$$r \longmapsto \frac{\mu_T(B(a,r))}{r^p}$$

is nondecreasing for balls compactly contained in Ω. For $p = 0$ this is simply monotonicity of the mass of increasing balls.

Proof. First suppose T smooth and $p \geq 1$. The function ρ_ε is convex, so $(DD\rho_\varepsilon)^p$ is strongly positive. The right side of Lemma 9.13.1 is the mass of a positive measure on the ball and is nondecreasing in r. For $r < s$, let $\varepsilon \downarrow 0$ in the corresponding inequality. This gives the asserted inequality between the two radius ratios. No singular product with $DD|x-a|$ is needed.

For a general current, convolve its coefficient distributions on a slightly smaller domain with a nonnegative smooth approximate identity. The currents T_δ are smooth, weakly positive and closed. Their trace measures converge weakly to μ_T. For radii r, s whose boundary spheres have zero μ_T mass, the ball masses converge, so the inequality passes to the limit. There

are at most countably many exceptional radii on each bounded interval, since the spheres are disjoint and the trace measure is locally finite. For arbitrary $r < s$, approach both radii from below by nonexceptional radii. Continuity from below of a measure on open balls finishes the proof. □

Example 9.13.3 (Closedness cannot be omitted)**.** On $\mathbb{R}$, let T be a nonzero nonnegative smooth scalar function supported in $[-1, 1]$, viewed as a current of bidimension $(1, 1)$. Its trace is $T(x)\,dx$. For $r > 1$, the mass $\mu_T((-r, r))$ is constant, so its ratio to r is strictly decreasing. The current is positive but not closed. Thus the literal statement of Proposition 3.4 in the consulted arXiv v1 of Lagerberg requires a closedness hypothesis; its Stokes proof uses exactly that hypothesis. Corollary 3.5 in that source does include closedness.

9.14 Hausdorff noncharging and support dimension

Corollary 9.14.1. *For a compact $K \Subset \Omega$, there are $R > 0$ and $C_K < \infty$ such that*

$$\mu_T(B(a, r)) \le C_K r^p \qquad (a \in K,\ 0 < r < R).$$

Proof. Choose R so that all closed balls $\overline{B}(a, R)$ with $a \in K$ lie in a fixed compact subset $K' \Subset \Omega$. Monotonicity gives $\mu_T(B(a, r)) \le (r/R)^p \mu_T(K')$. Take $C_K = R^{-p}\mu_T(K')$. □

Theorem 9.14.2. *Let T be an ordinary positive closed current of bidimension (p, p) on Ω. If a Borel set $E \subset \Omega$ has zero p-dimensional Hausdorff measure, then every coefficient measure of T has zero total variation on E. In particular, if the support of T has zero p-dimensional Hausdorff measure, then $T = 0$.*

Proof. Work first with E in a fixed compact subset K. For every $\varepsilon > 0$, the Hausdorff assumption provides a countable ball cover $E \subset \bigcup_j B(a_j, r_j)$ with centres in K, radii below the R of Corollary 9.14.1, and $\sum_j r_j^p < \varepsilon$ after adjusting an inessential dimensional constant. Therefore

$$\mu_T(E) \le \sum_j \mu_T(B(a_j, r_j)) \le C_K \sum_j r_j^p < C_K \varepsilon.$$

Letting $\varepsilon \downarrow 0$ gives zero trace mass. Ordinary positivity gives the coefficient total-variation bounds by the trace measure, so every coefficient vanishes on E. Exhaustion by compact subsets proves the general assertion. If all coefficients are supported on such an E, they are zero. □

The last step is exactly where ordinary positivity is used. The monotonicity of a scalar trace alone cannot recover coefficients invisible to that trace. Lagerberg's Remark 3.3 already records this real-versus-complex distinction. It is the same distinction behind the strong-cone correction in Chapter 7.

9.14.1 Lelong numbers and the metric normalization

If ω_p is the volume of the Euclidean unit ball in $\mathbb{R}^p$, the limit

$$\nu(T, a) = \lim_{r \downarrow 0} \frac{\mu_T(B(a, r))}{\omega_p r^p}$$

exists and is finite by monotonicity and local finiteness. For a smooth current of positive codimension, its trace has locally bounded density in n dimensions and $p < n$, so $\nu(T, a) = 0$. A coordinate p-plane with multiplicity m has $\nu = m$ in the standard coordinates.

Example 9.14.3. In $\mathbb{R}^2$, let $f(x, y) = \max(0, x + 2y)$. Its Hessian matrix current is $aa^{\mathsf{t}}\delta(\langle a, (x, y)\rangle)$ with $a = (1, 2)$. The trace is $5\delta(x + 2y)\, dx\, dy = \sqrt{5}\, ds$ on the line, where ds is Euclidean arclength. Hence $\nu(DDf, 0) = \sqrt{5}$. The tropical divisor has lattice weight one. There is no contradiction: Euclidean radial density and lattice multiplicity use different normalizations.

To obtain a support theorem on an analytic space, one must relate these real trace estimates to the measures attached to every actual analytic test. A single tropical pushforward may lose directions and even vanish when the map has insufficient rank. The analytic calibration and chart-detection arguments in CLD25 are therefore substantive extra steps. Section 19.14 uses the resulting all-test noncharging property, while the theorem above supplies its real measure-theoretic model.

References. [Lag12, Definition 3.1, Remark 3.3, Proposition 3.4 and Corollary 3.5]; compare [CLD25, Section 16.8]. Closedness and the distinction between weak and ordinary positivity have been retained explicitly.

9.15 Local equality, gluing and the full test space

A current identity is local because tests can be localized by a smooth partition of unity. This is different from checking the identity on a smaller chosen family of tests. Localization keeps the test category fixed. The distinction is particularly useful when a delta-form identity is proved in different local presentations.

Proposition 9.15.1. *Let X have a test-form sheaf admitting smooth partitions of unity, with continuous multiplication by fixed smooth functions. Suppose T_i are currents of one degree on an open cover U_i, and their restrictions agree on overlaps. Then they glue uniquely to a current T on X. Closedness is local. Positivity is local for a test cone stable under restriction and multiplication by nonnegative smooth functions.*

Proof. Choose a locally finite nonnegative smooth partition ρ_i subordinate to the cover and set

$$T(\eta) = \sum_i T_i(\rho_i \eta).$$

Only finitely many summands meet the compact support of a test. Each product is supported compactly inside U_i. If σ_j is another partition, insert $\sum_j \sigma_j = 1$ and use agreement on overlaps:

$$\sum_i T_i(\rho_i \eta) = \sum_{i,j} T_i(\rho_i \sigma_j \eta) = \sum_{i,j} T_j(\rho_i \sigma_j \eta) = \sum_j T_j(\sigma_j \eta).$$

Thus the definition is independent of the partition. The same calculation for a test supported in one U_i shows $T|_{U_i} = T_i$. On each fixed presentation space, the sum is finite and multiplication by each ρ_i is continuous after a common refinement, so the resulting functional is continuous in the final test topology. Uniqueness follows by applying any proposed global current to the partitioned test.

Multiplication by a nonnegative scalar preserves the chosen positive cone, so local positivity implies global positivity. Differentiation commutes with restriction, hence $d'T$ and $d''T$ restrict to the corresponding local derivatives. If these vanish on the cover, uniqueness of gluing makes them zero globally. The converse implications are immediate by restriction. □

The proposition applies to the original CLD test theory on its usual paracompact domains. It also applies to an enlarged test theory when that theory

is a module over the smooth scalar functions and has the stated topology. To prove an identity on all actual delta-tests, one still needs the local identity on every localized actual delta-test. A partition of unity does not turn an arbitrary delta-test into an external product or an original smooth test.

9.16 Zero extension is not automatic closed extension

An order-zero current on $X \setminus E$ may extend by zero if its coefficient measures have finite local mass near E. Positivity survives this operation when the coefficient cone is preserved, but closedness can fail because differentiation detects a boundary term. A simple real example is the scalar current $1_{(0,\infty)}$ on $\mathbb{R}\setminus\{0\}$. It is closed on that open set; its zero extension to $\mathbb{R}$ has derivative $\delta_0 d'x$.

The following sufficient criterion exhibits the estimate needed for a removable set. It is an elementary consequence of coefficient domination and a Hausdorff covering argument. Its growth hypothesis is explicit; closedness only on the complement does not supply that hypothesis at centres lying in the removed set.

Theorem 9.16.1 (An elementary removal criterion)**.** *Let E be relatively closed in $\Omega \subset \mathbb{R}^n$, and let T be an ordinary positive closed current of bidimension (p,p) on $\Omega \setminus E$, where $p \geq 2$. Assume its trace has finite mass on compact subsets up to E. Assume also that on each fixed compact neighbourhood there is a uniform estimate*

$$\mu_T(B(a,r) \setminus E) \leq Cr^p \quad (a \in E,\ 0 < r < r_0).$$

If $\mathcal{H}^{p-1}(E) = 0$, the zero extension $\widetilde{T}$ is positive and closed on Ω.

Proof. The coefficient total variations are bounded by a fixed multiple of the trace locally. Their finite-mass zero extensions therefore define an order-zero current, and integration against positive tests remains nonnegative. Fix a smooth test η with compact support, and work in a slightly larger compact neighbourhood. For arbitrary small $\varepsilon, \delta > 0$, cover the portion of E there by finitely many balls $B(a_j, r_j)$ centred on E, with $r_j < \delta$ and $\sum_j r_j^{p-1} < \varepsilon$. Compactness allows a finite subcover of a Hausdorff cover.

Choose smooth bumps χ_j, equal to one on $B(a_j, r_j)$, supported in $B(a_j, 2r_j)$, with $|\nabla \chi_j| \leq C_0/r_j$. Apply a fixed smooth truncation to $\sum_j \chi_j$

to obtain $0 \le \chi \le 1$, equal to one near the relevant part of E, supported in the union of the doubled balls, and satisfying $|\nabla\chi| \le C_1 \sum_j r_j^{-1} 1_{B(a_j,2r_j)}$. Choose radii small enough that all doubled balls remain in the fixed neighbourhood.

The test $(1-\chi)\eta$ is supported away from E, so closedness of T applies. Up to the harmless transpose sign, the pairing of $d'\widetilde{T}$ with η is bounded by

$$\begin{aligned} |\widetilde{T}(d'\eta)| &\le |\widetilde{T}(\chi d'\eta)| + |\widetilde{T}(d'\chi \wedge \eta)| \\ &\le C_\eta \sum_j \bigl(r_j^{p} + r_j^{p-1}\bigr) \le C_\eta(1+\delta)\varepsilon. \end{aligned}$$

The constants absorb the doubled radii and the coefficient estimate. Letting $\varepsilon \downarrow 0$ gives $d'\widetilde{T} = 0$. The same argument with the double-primed differential gives $d''\widetilde{T} = 0$. □

The threshold is dictated by the derivative of the cutoff: a ball mass of order r^p loses one power of r under differentiation. This explains why the noncharging theorem of Section 9.14 and the removal criterion have different Hausdorff exponents. Noncharging concerns the current itself; removable closedness concerns its first derivative. Stronger extension theorems, such as the toric Skoda–El Mir comparison, use additional geometry and should be cited with their own hypotheses.

References. The gluing construction is the standard duality argument for the CLD test sheaf, [CLD12, Section 4]. The removal estimate combines the coefficient control and ball-growth bounds developed above; it does not replace [BGJK, Theorem 7.2.4].

Chapter 10

Poincaré–Lelong and corner formulas

10.1 Cycles, logarithmic singularities, and the divisor formula

10.1.1 An integration current retains cycle multiplicities

For a closed analytic subspace Z of pure codimension r in a pure n-dimensional space, its integration current acts on a complementary test by integration over the associated cycle:

$$\langle \delta_Z, \eta \rangle = \int_{Z^{\mathrm{an}}} \eta, \qquad \eta \in A_c^{n-r,n-r}(X).$$

Here the notation includes the generic multiplicities of Z. For a nonreduced hypersurface defined by f^m, the integration current is $m\delta_{\mathrm{div}(f)}$ when the usual Cartier-divisor hypotheses hold. This is the analytic counterpart of the doubled tropical hypersurface in Chapter 5.

The current is closed on the boundaryless locus by Stokes. This does not mean every current supported on the same analytic set equals a scalar multiple of δ_Z. Support and degree constrain a current, but the coefficient structure and differential conditions still matter. The stronger support theorems in CLD25 have additional hypotheses.

10.1.2 The sign and the content of Poincaré–Lelong

For a nonzero meromorphic function under the divisor hypotheses of CLD, the formula is

$$\mathrm{d}'\mathrm{d}''[\log|f|] = \delta_{\mathrm{div}(f)}.$$

Equivalently, the logarithmic Green function $g = -\log|f|$ satisfies

$$\mathrm{d}'\mathrm{d}''[g] + \delta_{\mathrm{div}(f)} = 0.$$

There are two assertions here. First, $\log|f|$ is locally integrable in the sense needed to define a current. Second, its distributional Hessian is the cycle with the correct multiplicities. A computation away from the zero and pole set proves only that the Hessian vanishes there; it does not determine the singular term.

The proof reduces local analytic geometry to finite maps and one-dimensional slope calculations, while retaining the degree normalization. The zeros and poles contribute precisely their orders. Compatibility with tropical refinements then turns the local computation into an identity on every actual test form. This is why the divisor theorem requires more than the observation that $\log|f|$ is affine wherever f is a unit.

10.1.3 A projective-line check

On $\mathbb{P}^{1,\mathrm{an}}$ with coordinate z, let ξ_G be the Gauss point and give $\mathcal{O}(1)$ its standard model metric. On the torus put $t = -\log|z|$. The Green functions of 0 and ∞ can be written

$$g_0 = \max(0, t), \qquad g_\infty = \max(0, -t).$$

Their current identities are

$$\mathrm{d}'\mathrm{d}''[g_0] = \delta_{\xi_G} - \delta_0, \qquad \mathrm{d}'\mathrm{d}''[g_\infty] = \delta_{\xi_G} - \delta_\infty.$$

On the finite tropical line, one sees the positive corner at $t = 0$. The missing negative term lies at the appropriate analytic endpoint of the compactification. This is an effective sign check: on a compact boundaryless curve, a global distributional Hessian has total mass zero, whereas the Chern measure of $\mathcal{O}(1)$ has total mass one.

10.1.4 Weak convergence: fixed tests and varying tests

For currents, $T_j \rightharpoonup T$ means $\langle T_j, \eta\rangle \to \langle T, \eta\rangle$ for each fixed test η. It does not by itself permit replacing η by an arbitrary sequence η_j. If T_j are positive, the coefficient estimates proved above often provide the missing uniform bound for continuous scalar multipliers.

For example, if $u_j \to u$ uniformly on a compact neighbourhood of a fixed test support, then

$$\langle \mathrm{d}'\mathrm{d}''[u_j] - \mathrm{d}'\mathrm{d}''[u], \eta\rangle = \int (u_j - u)\mathrm{d}'\mathrm{d}''\eta \longrightarrow 0.$$

The estimate uses the total variation of the signed measure represented by $\mathrm{d}'\mathrm{d}''\eta$. No derivatives of u_j need converge. Conversely, weak convergence of positive measures does not imply convergence in total variation: on a real interval, $\delta_{1/j} \rightharpoonup \delta_0$, while $\|\delta_{1/j} - \delta_0\|_{\mathrm{TV}} = 2$ for every j.

10.1.5 Curvature currents and top-degree measures

On a real two-dimensional chart, consider the positive $(1,1)$-forms

$$\alpha = d'x_1 \wedge d''x_1, \qquad \beta = d'x_2 \wedge d''x_2.$$

They are different, but their squares both vanish. Thus even the self-top-degree measure need not determine a positive lower-degree current. More refined uniqueness statements, such as uniqueness of a normalized global solution of a Monge–Ampère equation in an ample class, use global geometry and a specified class of potentials. They cannot be inferred from the notation $T \mapsto T^n$ alone.

References. [CLD12, §§4.3–4.6]; [Gubler, Proposition 6.10].

10.1.6 Logarithmic clipping on bounded ordinary tests

The finite localization estimate uses the signed top-form measure of Proposition NAG-002970, the native topology of NAG-002472/002473, and the top-degree vanishing of NAG-002806. The clipping argument below is an application under the native fixed-test Poincaré–Lelong and current hypotheses of NAG-003103 and NAG-003106. Its setting is a specified compact support and a finite ordinary Cartier cover.

Test topology. Let k be a complete non-Archimedean field with its given absolute value, X a good Hausdorff pure n-dimensional k-analytic space, $n \geq 1$, and U an ordinary open in $\mathrm{Int}(X/k)$. Use real ordinary smooth moment forms, the structure-sheaf integral, and ordinary compact supports. Write $E = \mathcal{A}_c^{n-1,n-1}(U)$. For an affinoid domain $V \subset U$, a finite tuple g of units on V, an open $\Omega \supset t_g(V)$ with $t_g = -\log|g|$, and an ordinary smooth χ compactly supported in the topological interior of V in U, put

$$Q_i\alpha = \mathrm{ext}_0(\chi\, t_g^*\alpha), \qquad p_{L,m}(\alpha) = \max_{I,J,|\gamma|\leq m} \sup_{v\in L} |\partial^\gamma \alpha_{IJ}(v)| \quad (L \Subset \Omega).$$

An empty coefficient space has zero seminorms. NAG-002472 defines τ_{cut} by all seminorms P for which PQ_i is continuous for every i. The ordinary stages instead glue finitely many ambient representatives agreeing on pairwise intersections of the ordinary chart interiors and vanishing on each interior outside a fixed compact contained in their union. Each coefficient subspace has the induced finite product topology and is divided by the kernel of gluing with its quotient topology. Their final locally convex topology τ_{ord} equals τ_{cut} by NAG-002473. A set $B \subset E$ is bounded if $\sup_{\eta\in B} P(\eta) < \infty$ for every continuous seminorm P. The proof uses this definition directly on E.

Finite localization lemma. Fix a compact $S \subset U$ and a finite ordinary open cover $O_1, \dots, O_r$ of S in U. On each O_j fix analytic a_j, b_j which are non-zero-divisors at every stalk. Write $Z_j = V(a_j) \cup V(b_j)$. Choose ordinary smooth nonnegative ρ_j on U with compact support in O_j and $\sum_j \rho_j = 1$ near S (NAG-002428). Define four compact top forms on O_j, restricting all products there, by

$$T_{j0}\eta = \rho_j d'd''\eta, \qquad T_{j1}\eta = d'\rho_j \wedge d''\eta,$$
$$T_{j2}\eta = -d''\rho_j \wedge d'\eta, \quad T_{j3}\eta = d'd''\rho_j \wedge \eta.$$

Let $\mu_{jt}(\eta)$ be their respective signed native Radon measures (NAG-002970). For every bounded family $B \subset E$ whose tests are supported in S, there are $C, H < \infty$ such that for all $\eta \in B$,

$$\sum_{j,t} |\mu_{jt}(\eta)|(O_j) \leq C, \qquad |\mu_{jt}(\eta)|\big(\{\min(|a_j|,|b_j|) < e^{-H}\}\big) = 0 \quad \text{for every } j,t.$$

Hence clipping either logarithm by any Borel profile equal to the identity above $-H$, including at $-H$, leaves each weighted signed measure unchanged on the complement of Z_j; extend it by zero on Z_j. The same holds for the difference of the two weighted measures. These are assertions about variation of localized top-form measures. The original tests can meet the divisor.

Proof. Every output and every derivative used in its definition is local. In particular the support of $T_{jt}\eta$ is contained in $\operatorname{supp}\rho_j \cap \operatorname{supp}\eta$. By NAG-002806 a compact ordinary top form on O_j vanishes on an ordinary neighbourhood of the zeros of each regular factor. Thus its compact support is disjoint from Z_j. This assertion so far is per form.

Fix an incoming cutoff stage i and an index j. The compact set $D = \operatorname{supp}\chi \cap \operatorname{supp}\rho_j$ is contained in $\operatorname{Int}_{\mathrm{top}}(V,U) \cap O_j$. Cover D by finitely many ordinary interiors of affinoid neighbourhoods in that intersection on which χ, ρ_j have fixed ordinary moment representatives. Adjoin the restricted tuple g to their coordinates. Use NAG-002428 on O_j for a compactly supported partition subordinate to these interiors, summing to one near D. Apply that partition *after* differentiating. NAG-002424 and the coefficient product rule then give, for each t, a finite expansion with terms

$$((\partial^{\gamma_\lambda}\alpha_{I_\lambda J_\lambda}) \circ t_g)\,\beta_{ijt\lambda}, \qquad |\gamma_\lambda| \le 2.$$

Indeed the undifferentiated variable form is a sum of coefficients times wedges of coordinate differentials. Each differentiation of a variable coefficient inserts a coordinate differential and an ambient partial derivative. Differentiations of the fixed cutoffs only change fixed factors. All those factors, signs, coordinate wedges and the partition element belong to the fixed compact ordinary top form $\beta_{ijt\lambda}$, extended by zero in O_j. If D is empty take the empty sum. The expansion uses one fixed cover for the whole incoming coefficient space. The tangential relations are preserved by the ordinary operations on the forms.

For a smooth scalar h defined near $\operatorname{supp}\beta$, $\mu_{h\beta} = h\mu_\beta$. Indeed cut h off by a fixed ordinary function equal to one near the compact support, using NAG-002428 there (include the complementary open away from the support if needed). The two measures give the same values on every smooth scalar test, by multiplication and uniqueness in NAG-002970. Multiplication by a bounded continuous scalar on a compact carrier preserves Radon regularity, since errors on Borel differences are bounded by its supremum times the old variation error. The finite-partition definition of variation gives $|h\mu| \le \|h\|_{\infty,\operatorname{supp}\mu}|\mu|$ by integrating on each piece and summing, and gives the triangle inequality for sums. Consequently, with $L_i = t_g(V)$,

$$|\mu_{jt}(Q_i\alpha)| \le p_{L_i,2}(\alpha)\,\nu_{ijt}, \qquad \nu_{ijt} = \sum_\lambda |\mu_{\beta_{ijt\lambda}}|.$$

The carrier $C_{ijt} = \bigcup_\lambda \operatorname{supp}\beta_{ijt\lambda}$ is compact in $O_j \setminus Z_j$ by NAG-002806 separately on these finitely many fixed forms. This fixed carrier is the extra input needed for the passage to bounded families.

Take nonnegative locally bounded Borel weights w_j on $O_j \setminus Z_j$. The expression

$$P_w(\eta) = \sum_{j,t} \int_{O_j \setminus Z_j} w_j \, d|\mu_{jt}(\eta)|$$

is finite on all of E by the per-form support assertion, and subadditive and absolutely homogeneous by variation. The stage bound is

$$P_w(Q_i\alpha) \le p_{L_i,2}(\alpha) \sum_{j,t} \big(\sup_{C_{ijt}} w_j\big)\nu_{ijt}(O_j),$$

with zero for an empty carrier. The coefficient is finite for each i. Hence P_w is continuous in the original topology and is bounded on B, without a common presentation of B. The choice $w_j = 1$ proves the bound C.

On $O_j \setminus Z_j$ set $s_j = \max(0, -\log|a_j|, -\log|b_j|)$. If no common H worked, for every integer $k \ge 1$ we could choose $\eta_k \in B, j_k, t_k$ with $m_k = |\mu_{j_k t_k}(\eta_k)|(\{s_{j_k} > k\}) > 0$. Then put

$$w_j = \sum_{k:\, j_k = j} (k/m_k)\mathbf{1}_{\{s_j > k\}}.$$

These weights are locally bounded Borel functions since s_j is finite and continuous off Z_j. But $P_w(\eta_k) \ge k$, a contradiction. Together with the individual zero mass on Z_j this gives H; the upper logarithms are bounded on the fixed compact supports of the cutoffs. Clipping is therefore stationary in each measure separately. The auxiliary Borel weights occur only in integrals against the already constructed Radon variations.

Finally the graded Leibniz rule gives $d'd''(\rho_j\eta) = \sum_t T_{jt}\eta$ on O_j. After zero extension, summing in j gives $d'd''\eta$ for $\operatorname{supp}\eta \subset S$, since the partition sums to one near S. Thus all four summands in localizing a Cartier potential can be estimated before either the partition cancellation or numerator and denominator subtraction. This does not assert that local clipped potentials glue. The bound concerns the native structure-sheaf measure of these ordinary top tests only.

Exact consumer. NAG-003103, proof lines 240–254 of F8NM, applies scalar Poincaré–Lelong to $\rho_j\eta$ for each regular factor. Its left side before subtraction is $L_{c_j}(\mathrm{d}'\mathrm{d}''(\rho_j\eta))$, where $c_j = a_j$ or b_j. NAG-003106, lines 372–381, uses the positive transpose sign $(\mathrm{d}'\mathrm{d}''T)(\eta) = T(\mathrm{d}'\mathrm{d}''\eta)$ for a degree-zero

current in the native topology. We apply the reviewed cutoff lemma precisely to these operations.

Let k be complete non-Archimedean with its given absolute value, X good Hausdorff pure of dimension $n \geq 1$, and $U \subseteq \mathrm{Int}(X/k)$ ordinary open. Use the native structure-cycle integral, ordinary real smooth moment tests, and $\tau_a = \tau_{\mathrm{cut}} = \tau_{\mathrm{ord}}$ of NAG-002472/002473. Assume the native fixed-test PL inputs of NAG-003103, with their full structure and Cartier multiplicities. For an ambient regular meromorphic f, fix the finite localization of that proof near a specified compact $S \subset U$. Thus $f = a_j/b_j$ on ordinary opens O_j covering S, in the true interiors of the chosen affinoid neighborhoods as in lines 240–245. Each factor is an ambient non-zero-divisor. The fixed smooth ρ_j have compact support in O_j and sum to one near S. Let E_S be the $(n-1,n-1)$-tests on U supported in S, with the topology induced by τ_a.

The actual operation. Use the smooth profile of NAG-002480. For $M \geq 0$ set $\lambda_M(t) = -M + (t+M)\theta(t+M+1)$, where θ is smooth, between zero and one, zero on $(-\infty, 0]$ and one on $[1, \infty)$. Write $\ell_M(c) = \lambda_M(\log|c|)$ off its zero set and $-M$ on it. This is ordinary smooth, locally constant near the zeros, and equals $\log|c|$ wherever $\log|c| \geq -M$. Put $u_{j,M} = \ell_M(a_j) - \ell_M(b_j)$. Consider the two continuous linear functionals

$$A_M(\eta) = \sum_j \int_{O_j} u_{j,M}\, \mathrm{d}'\mathrm{d}''(\rho_j \eta), \qquad P_M(\eta) = \sum_j \int_{O_j} u_{j,M}\, \rho_j \mathrm{d}'\mathrm{d}''\eta.$$

Here A_M regularizes the local proof terms. The other operation is $P_M = (\mathrm{d}'\mathrm{d}''T_{v_M})|_{E_S}$, where $v_M = \sum_j \mathrm{ext}_0(\rho_j u_{j,M})$ and $T_v(\alpha) = \int_U v\alpha$. This is the derivative of a specified partition-dependent smooth potential. Raw local clips need not agree on overlaps. For every bounded $B \subset E_S$ there is H_B such that for every real $M \geq H_B$ and every $\eta \in B$,

$$A_M(\eta) = P_M(\eta) = L_f(\mathrm{d}'\mathrm{d}''\eta) = \delta_{\mathrm{div}\, f}(\eta).$$

In particular both sequences of functionals (or real-parameter families) converge on bounded sets of the indicated supported space.

Proof. Let $\mu_{jt}(\eta)$, $t = 0,1,2,3$, represent the top forms $\rho_j \mathrm{d}'\mathrm{d}''\eta$, $d'\rho_j \wedge d''\eta$, $-d''\rho_j \wedge d'\eta$, $\mathrm{d}'\mathrm{d}''\rho_j \wedge \eta$, respectively. Their sum represents $\mathrm{d}'\mathrm{d}''(\rho_j\eta)$ on O_j. Boundedness in E_S implies boundedness under its inclusion in the full test space. The independently reviewed finite cutoff lemma supplies

$C_B, H_B \geq 0$, with total variation summed over j, t at most C_B, and zero variation for each measure where either factor has absolute value $< e^{-H_B}$. The original lower-degree test can have support meeting the divisor.

Choose $L \geq 0$ so both factors on every $\operatorname{supp} \rho_j$ have absolute value at most e^L, using compactness and finiteness. For either factor separately the logarithm lies in $[-H_B, L]$ almost everywhere for every indicated variation (values on the zero set are immaterial). Thus with $D = \max(H_B, L)$, the sum of the absolute logarithmic integrals for one chosen factor per chart is at most DC_B; the absolute-log tails at levels $R > D$ are zero, uniformly. In particular for every $M \geq H_B$,

$$\sum_{j,t} \sum_{c \in (a_j, b_j)} \int_{O_j \setminus (V(a_j) \cup V(b_j))} \big|\ell_M(c) - \log|c|\big| \, d|\mu_{jt}(\eta)| = 0.$$

The inner sum counts the two factors with repetition. This proves the required uniform integrability in the varying test measures before any signed cancellation. For each native integral this is indeed its Radon realization: the fixed top test vanishes near both zero loci by NAG-002806, so the genuine logarithm on its compact support can be cut off smoothly within the common unit locus. NAG-002970 identifies its smooth-multiplier pairing with the Radon integral. No Borel extension of the native coefficient integral enters.

For fixed M, the reviewed stage estimate bounds each clipped term by the order-two input coefficient seminorm times the finite mass of a fixed stage measure times the supremum of the fixed multiplier on its compact carrier. The same works for the true logarithm since that carrier avoids the zero loci. Finality gives continuity, hence continuity on E_S by restriction. For the limit of A_M, all four true-log terms sum to $L_f(\sum_j \mathrm{d}'\mathrm{d}''(\rho_j \eta))$, by linearity and the ordinary restriction of the meromorphic pairing. The inner sum equals $\mathrm{d}'\mathrm{d}''\eta$. For P_M only term zero occurs and $\sum_j \rho_j \mathrm{d}'\mathrm{d}''\eta = \mathrm{d}'\mathrm{d}''\eta$. NAG-003103 now identifies the common value with the full Cartier functional. Unit transition factors, if different representatives of the same quotient are used, leave the true pairing unchanged. No equality of these two localized expressions at shallow clipping depth is required.

For the smooth-metric clause of the same consumer take ordinary frames, $s = f_j e_j$, $h_j = -\log \|e_j\|$. Replace both multipliers $u_{j,M}$ by $h_j - u_{j,M}$. The h_j terms are unchanged throughout the limit. Both resulting functionals eventually equal $G_s(\mathrm{d}'\mathrm{d}''\eta) = (T_{c_1} - \delta_{D_s})(\eta)$ on B, by the frame gluing and Stokes calculation in NAG-003103, lines 259–285. The sign is also fixed by the norm-one trivial frame.

10.1.7 Native fixed-test identities and the current transfer

The following native proof excerpts use the stated hypotheses on the actual regular factors, on the compact interior tests and on the ordinary smooth metric. The closed-immersion pullback uses the native cutoff topology. The current identities require the fixed-test inputs as stated. Their transitive prerequisite cone is still under review. References to the detached quotient comparison and its two formulae are printed by their permanent identifiers.

Let K be a complete non-Archimedean field with its specified absolute value, including trivial valuation. Generalized affinoids are allowed. Let X be good, Hausdorff and pure of analytic dimension $n \geq 1$, and fix an ordinary open $U \subseteq \mathrm{Int}(X/K)$. There is no ambient S_1 assumption. All test supports are ordinary compact subsets of U. Use the frozen ordinary moment sheaf, native integration and positive interleaved convention of `NAG-002424`, `002425` and `002388`. Thus the scalar logarithm has the positive sign $L_a(\mathrm{d}'\mathrm{d}''\eta) = \delta_{\mathrm{div}(a)}(\eta)$, without an extra constant.

A function is *ambient regular* when multiplication on $\mathcal{O}_{U_G}$ is injective; on actual affinoid restrictions this is regularity in their coordinate rings. A regular meromorphic function is a unit of the local total quotient sheaf in the ordinary good-space scope, represented locally by a quotient of ambient regular functions. A line bundle has ordinary local analytic frames, a smooth metric has ordinary smooth weights, and a regular meromorphic section is given data. No existence theorem for such a section is asserted.

The proof inputs are distinguished as follows.

(1) The exact component source has SHA-256

`34cea90b0be25d9bcbc565721888844e328453d64137a13c9bf79097495005af`.

F8CR-S gives reduced-component S_1, compact analytic-interior pullback and differential compatibility. F8CR-N/I give weighted native integration and absolute logarithmic integration. F8CR-C gives full Cartier comparison under its written $\mathrm{ZP}_{\mathrm{loc}}$ premise; F8CR-P gives the analytic scalar identity under $\mathrm{ZP}_{\mathrm{loc}}$ and RPL. The separate nonauthor interface-fit receipt discharges those premises on the actual pure affinoids and reduced components used there. These are reviewed applications, still separate from canonical admission.

(2) Frozen `NAG-002772/002778` retain their actual quotient and pure-zero-space scopes. Their effective length comparison and regular-quotient

construction do not require ambient S_1. The reviewed ZP input supplies empty-or-pure dimension $n-1$ on all actual common refinements, including regular cross-products.

(3) Frozen `NAG-002806` gives neighbourhood vanishing of ordinary top-degree tests near zeros of an ambient regular function. Frozen `NAG-002577` supplies restricted Stokes for genuine analytic-interior compact supports. Neither is replaced by a component boundary argument.

(4) The exact reviewed meromorphic source has SHA-256

`b211ebdb9ad232a3f66d7e80feac6be31857f66a1415c91a034b599ca615aa2b`.

Its F8MG-O/T continuity results will be used only on the actual reduced components, where their stated S_1 hypothesis holds. The new ambient extension is proved below rather than read into those bytes.

For an affinoid $V = \mathcal{M}(A)$ pure of dimension n, set

$$\operatorname{Min} A = \{\mathfrak{q}_i\}_{i=1}^{r}, \qquad V_i = \mathcal{M}(A/\mathfrak{q}_i), \quad j_i : V_i \hookrightarrow V, \qquad m_i = \operatorname{length}_{A_{\mathfrak{q}_i}} A_{\mathfrak{q}_i}.$$

All m_i are positive integers. They are not replaced by one. A general X is treated on finitely many such neighbourhoods for each compact localization, not by an assumed finite global component list.

Theorem NAG-003103 (Non-S_1 fixed-test identities; F8NM-G)**.** *Under the exact reviewed component/scalar and ZP inputs above, every ambient regular meromorphic f on U satisfies*

$$L_f(\mathrm{d}'\mathrm{d}''\eta) = \delta_{\operatorname{div}(f)}(\eta) \qquad (\eta \in \mathcal{A}_c^{n-1,n-1}(U)). \tag{10.1.1}$$

Let $\overline{\mathcal{L}}$ have ordinary smooth metric weights and a given ambient regular meromorphic section s. Its potential pairing G_s, full Cartier divisor D_s, and ordinary curvature satisfy

$$G_s(\mathrm{d}'\mathrm{d}''\eta) + \delta_{D_s}(\eta) = \int_U c_1(\overline{\mathcal{L}}) \wedge \eta. \tag{10.1.2}$$

These are fixed-test statements before any topology is invoked.

Proof. Choose a finite ordinary quotient atlas near $\operatorname{Supp}\eta$ and a compact smooth partition ρ_j subordinate to it. Each $\eta_j = \rho_j\eta$ is supported in

the true analytic interior of a chosen affinoid neighbourhood: use $O_j \subset \mathrm{Int}_{\mathrm{top}}(V_j, X) \cap \mathrm{Int}(X/K)$ and frozen NAG-001630/001704, exactly as in reviewed F8CR-P. Apply that reviewed scalar implication to a_j and b_j, then subtract. Proposition NAG-003100 identifies the full Cartier right side. Since $\eta = \sum_j \rho_j \eta$, their mixed derivatives sum to $\mathrm{d}'\mathrm{d}''\eta$. In particular all four terms

$$\mathrm{d}'\mathrm{d}''(\rho_j\eta) = \rho_j \mathrm{d}'\mathrm{d}''\eta + d'\rho_j \wedge d''\eta - d''\rho_j \wedge d'\eta + \mathrm{d}'\mathrm{d}''\rho_j \wedge \eta$$

are retained. The finite sum proves (10.1.1). The component tests are admissible by reviewed F8CR-S, and its pullback commutes with the ordered $d'd''$. This supplies exactly the use of the reduced scalar input; ambient S_1 is never inferred.

For the metric identity, choose frames e_i with $e_j = u_{ij}e_i$, put $h_i = -\log\|e_i\|$, and write $s = f_i e_i$. Then

$$h_j = h_i - \log|u_{ij}|, \qquad f_j = f_i/u_{ij}.$$

The unit logarithm is a linear moment coordinate, so its $d'd''$ is zero without using PL. Consequently $c_1|_{U_i} = \mathrm{d}'\mathrm{d}''h_i$ glues, as do $D_s|_{U_i} = \mathrm{div}(f_i)$ and

$$G_{s,i}(\alpha) = \int h_i\alpha - L_{f_i}(\alpha).$$

The displayed transition equalities cancel on every top test; finite product partitions again prove independence.

For a compact interior test in one frame, frozen restricted Stokes applies to $h_i d''\eta$ and $d'h_i \wedge \eta$. Writing $A = \int d'h_i \wedge d''\eta$, its two equations are

$$0 = A + \int h_i \mathrm{d}'\mathrm{d}''\eta, \qquad 0 = -\int \mathrm{d}'\mathrm{d}''h_i \wedge \eta - A.$$

Thus $\int h_i \mathrm{d}'\mathrm{d}''\eta = \int \mathrm{d}'\mathrm{d}''h_i \wedge \eta$, with the positive sign. Subtract (10.1.1) for f_i and use a finite partition to obtain (10.1.2). The support and all boundary hypotheses of Stokes remain in force. The norm-one trivial frame gives $G_s = -L_f$, independently checking the divisor sign. □

Write $\tau_a = \tau_{\mathrm{cut}} = \tau_{\mathrm{ord}}$ for exactly the frozen final topology of NAG-002472/002473. No intrinsic or external topology is identified here.

Proposition NAG-003106 (Closed pullback and non-S_1 current transfer; F8NM-T)**.** *For a closed immersion $j : Y \hookrightarrow X$ of good Hausdorff spaces, pullback is continuous on native ordinary compact test spaces with τ_a, including after restriction to an ordinary open $U \subseteq \mathrm{Int}(X/K)$ and its inverse image. It preserves compact interior support and commutes with d' and d''.*

Under the reviewed inputs of Theorem NAG-003103, L_f, G_s, $\delta_{\mathrm{div}(f)}$, δ_{D_s} and the smooth curvature pairing are continuous for this topology on U. The fixed-test identities are therefore native current identities

$$\mathrm{d}'\mathrm{d}''L_f = \delta_{\mathrm{div}(f)}, \qquad \mathrm{d}'\mathrm{d}''G_s + \delta_{D_s} = T_{c_1(\overline{\mathcal{L}})}.$$

This extends ambient scope without enlarging the written S_1 statements of the reviewed meromorphic source.

Proof. For a cutoff stage $Q = (V, f, \Omega, \chi)$ on X, its inverse image $W = Y \times_X V$ is the actual affinoid closed subspace of V. The pulled-back tuple is a unit tuple. Closedness of the immersion makes $j^{-1}\operatorname{Supp}\chi$ compact, and continuity gives

$$j^{-1}\operatorname{Int}_{\mathrm{top}}(V, X) \subseteq \operatorname{Int}_{\mathrm{top}}(W, Y).$$

Hence $j^*\chi$ is an admissible cutoff on Y, and

$$j^*Q\eta = Q_{(W, f|_W, \Omega, j^*\chi)}\eta.$$

The empty inverse image gives zero. This is a continuous single-stage factorization, so finality proves pullback continuity. Reviewed F8CR-S gives the analytic-interior support and differential statements. Applying this argument to the base-changed closed immersion $j^{-1}U \hookrightarrow U$ gives the restricted assertion.

First suppose U is an ordinary open in a pure affinoid V. Its finitely many reduced components restrict to closed immersions $j_i^{-1}U \to U$, each in the exact S_1 scope of F8CR-S. The reviewed F8MG-O/T are therefore applicable to their logarithmic, Cartier and metric pairings. Formulae (`NAG-003101`) and (`NAG-003102`) express the ambient logarithmic and Cartier pairings as finite sums $\sum_i m_i (j_i)_* T_i$. Each summand is continuous by the pullback factorization just proved. The same decomposition for G_s follows locally from F8CR-N for $h_i\alpha$ and (`NAG-003101`), then from a finite frame partition. Smooth scalar and curvature pairings also have their direct fixed-chart coefficient bounds from the frozen native integrator.

For a general U, test continuity on a fixed cutoff stage. Its support has a fixed finite cover by ordinary opens contained in the interiors of pure affinoid neighbourhoods and by quotient/frame opens. Choose a fixed compact partition there. Multiplying this stage by each partition member and regarding it as a test in its smaller open is continuous: cover its compact support by affinoids inside that open, adjoin the fixed cutoff moments to the original unit tuple, and write the variable coefficient as a fixed smooth coefficient times its pullback by a fixed projection. The product and chain rules give the coefficient bounds. This is precisely the finite-stage factorization used in frozen `NAG-002473`, without an S_1 assumption. On each such open the preceding finite-component argument applies. Their finite sum proves continuity on the original stage, and finality proves continuity on U. No global finite component decomposition or common presentation for all bounded sets is asserted.

For completeness, the native test differentials are continuous in this same non-S_1 category. On a cutoff image use $d'(\chi t_f^*\eta) = d'\chi \wedge t_f^*\eta + \chi t_f^* d'\eta$. The first term has the fixed finite joint-chart factorization just used; the second uses one extra ambient derivative. The identical argument applies to d''. It uses only the frozen ordinary sheaf. With the usual dual sign $(-1)^{p+q+1}$, their composition on a degree-zero current is $\mathrm{d}'\mathrm{d}''T(\eta) = T(\mathrm{d}'\mathrm{d}''\eta)$. The equalities on every test from Theorem NAG-003103 now give exactly the displayed current identities. □

10.2 The distributional calculation on an interval

A corner formula is an integration-by-parts identity. Keeping its endpoint terms visible settles the signs and explains why convexity on individual faces is insufficient. We use the normalization $\int a(t)d't \wedge d''t = \int a(t)dt$.

Theorem 10.2.1. *Let $I \subset \mathbb{R}$ be open and let u be continuous, with a locally finite subdivision into intervals on whose closures it is C^2 from each side. Then*

$$\mathrm{d}'\mathrm{d}''[u] = u''(t)\,dt + \sum_p \big(u'_+(p) - u'_-(p)\big)\delta_p.$$

The density is taken off the subdivision vertices. The current is positive if and only if the density is nonnegative on every open interval and every displayed jump is nonnegative.

Proof. A compact test support meets finitely many pieces. On one piece $[a, b]$ two integrations by parts give

$$\int_a^b u\phi'' \, dt = \int_a^b u''\phi \, dt + [u\phi' - u'\phi]_a^b.$$

At an internal vertex p, continuity of u cancels the two terms containing $\phi'(p)$. The remaining contribution is $(u'_+(p) - u'_-(p))\phi(p)$. The outer endpoints lie off the test support. This proves the formula. For positivity, tests supported inside a single interval detect its density. Shrinking nonnegative tests around one vertex detect its atomic coefficient, because the integral of the locally bounded density tends to zero. Conversely both kinds of coefficients nonnegative make the displayed Radon measure positive. □

Example 10.2.2. The function $u = -|t|$ is affine on both half-lines, so every facewise Hessian is zero. Its derivative jump is -2, and $\mathrm{d}'\mathrm{d}''[u] = -2\delta_0$. The function $v = -t^2$ has no corners and $\mathrm{d}'\mathrm{d}''[v] = -2dt$. Thus a criterion using only facewise convexity misses the first obstruction, and one using only slope sums at vertices misses the second.

10.3 Balanced graphs and endpoint conventions

Let C be a locally finite rational polyhedral curve in $N_{\mathbb{R}}$, with constant positive edge weights m_e. An edge coordinate is measured in its primitive lattice direction, not Euclidean arclength. Assume balancing at all vertices where tests may meet the curve. Tests are restrictions of ambient smooth functions; their directional derivatives at a vertex therefore come from one ambient differential.

Theorem 10.3.1. *For a continuous edgewise C^2 function u with one-sided derivatives at vertices, one has*

$$\mathrm{d}'\mathrm{d}''[u] = \sum_e m_e u''_e \, dt_e + \sum_v \left(\sum_{e \ni v} m_e \partial_e u(v) \right) \delta_v.$$

Here ∂_e is the outgoing primitive derivative. The identity is on tests supported away from any designated graph boundary.

Proof. Apply the interval calculation on each edge. At a vertex the endpoint contribution is

$$-u(v)\sum_{e\ni v} m_e\partial_e\phi(v) + \phi(v)\sum_{e\ni v} m_e\partial_e u(v).$$

The first sum is $d\phi_v(\sum_e m_e n_{e,v}) = 0$ by balancing. This leaves exactly the asserted mass. Local finiteness reduces the calculation to finitely many edges for each test. □

If balancing is absent at an endpoint and tests are allowed to reach it, the term involving the derivative of the test remains. One must then formulate a boundary-current identity or impose a boundary test convention. It is incorrect to omit this term merely because the underlying graph is compact. In the analytic theory the relevant support condition is avoidance of the analytic boundary.

Corollary 10.3.2. *On a compact connected metric graph without boundary, equipped with the usual Kirchhoff test condition, an edgewise C^2 continuous function with nonnegative Laplacian is constant.*

Proof. Pair the Laplacian with the constant function one. Its total mass is zero. Positivity implies that the measure is zero, hence $u'' = 0$ on edges and every outgoing slope sum vanishes. Edgewise integration by parts now gives

$$\sum_e m_e\int_e (u_e')^2 dt_e = -\sum_e m_e\int_e u_e u_e'' dt_e - \sum_v u(v)\sum_{e\ni v} m_e\partial_e u(v) = 0.$$

All derivatives vanish, and connectedness identifies the constants. □

10.4 An annulus as a sign check

On an annulus use $t = -\log|T|$. For a real number a in its skeletal interval and a function pulled back from that interval,

$$\mathrm{d}'\mathrm{d}''\max(0, t-a) = \delta_a, \qquad \mathrm{d}'\mathrm{d}''\min(0, t-a) = -\delta_a$$

in the interval calculation. The analytic interpretation uses the annular tropicalization and its calibration. At this stage the formulas describe the tropical measure; identifying it with an analytic current on every analytic test additionally uses the comparison theorem.

For a meromorphic function f, the analytic Poincaré–Lelong normalization in this book is

$$\mathrm{d}'\mathrm{d}''[\log|f|] = \delta_{\mathrm{div}(f)}, \qquad \mathrm{d}'\mathrm{d}''[-\log|f|] = -\delta_{\mathrm{div}(f)}.$$

Consequently, for a meromorphic section $s = fe$ and a metric weight $\varphi_e = -\log\|e\|$,

$$-\log\|s\| = \varphi_e - \log|f|, \qquad \mathrm{d}'\mathrm{d}''[-\log\|s\|] + \delta_{\mathrm{div}(s)} = c_1(L, \|\cdot\|).$$

This calculation checks the sign of the Green identity. It uses the analytic divisor theorem; the graph calculation alone is not a proof of Poincaré–Lelong in higher dimension.

10.5 Subdivision and normal lifts

The higher-dimensional corner weight has two terms because a primitive normal is a class modulo tangent directions. Let C be balanced with constant weights and let u be continuous and affine on its cells. For a facet τ, write ℓ_σ and ℓ_τ for the linear parts. Then

$$c_\tau(u) = \sum_{\sigma \supset \tau} m_\sigma \ell_\sigma(n_{\sigma,\tau}) - \ell_\tau\left(\sum_{\sigma \supset \tau} m_\sigma n_{\sigma,\tau}\right).$$

Proposition 10.5.1. *This expression is independent of all normal lifts, vanishes for an ambient affine function, and gives zero on a new facet introduced inside a cell where u was already affine.*

Proof. Balancing puts the argument of ℓ_τ in its domain. Changing a lift by $a \in N_\tau$ changes the first term by $m_\sigma \ell_\sigma(a)$ and the second by $m_\sigma \ell_\tau(a)$. Continuity gives equality of these restrictions, so the changes cancel. For an ambient affine function all linear parts are restrictions of one functional, and cancellation is immediate. At a subdivision facet inside one cell the two normal classes are opposite, the weights agree, and the linear parts are the same. Choose opposite lifts; both sums then vanish. □

This proves the elementary independence statements used in calculations. Balancing of the resulting codimension-one cycle does not follow from lift independence alone. Theorem 15.5.2 supplies the missing argument in the constant-weight PL setting, using the current identity and the Stokes characterization of balancing.

10.6 The two positive parts of a piecewise smooth Hessian

A piecewise smooth function has an interior Hessian and a corner contribution. Positivity of their sum can be separated because these two measures live in different dimensions. This is stronger than merely testing the Hessian on the interiors of maximal cells. It is the first step in the maximum principle of Gubler–Rabinoff.

Proposition 10.6.1. *Let C be a pure d-dimensional rational tropical cycle with positive constant weights, and let f be continuous and smooth on the cells of a locally finite subdivision. Then*

$$DD(f\delta_C) = [d'_P d''_P f] \wedge \delta_C + \delta_{f\cdot C}.$$

This current is positive if and only if the cellwise Hessian is positive on every maximal cell and every smooth weight of the corner cycle $f \cdot C$ is nonnegative.

Proof. The identity is the piecewise smooth Poincaré–Lelong formula: twice integrating by parts leaves the interior second derivatives and the normal slope jumps, with the tangential correction at each facet. This is the same computation as the PL formula, with the cellwise second derivative retained.

The sufficiency of the two positivity conditions follows by summing positive pairings. For necessity, positivity against tests supported in the interior of one maximal cell gives its Hessian positivity. To isolate the corner, fix a positive compactly supported test η and let Z be the union of the facets meeting its support. Choose smooth cutoffs $0 \le \chi_j \le 1$, equal to one on those facets near the support and tending to zero away from them. Then

$$0 \le DD(f\delta_C)(\chi_j\eta) = ([d'_P d''_P f] \wedge \delta_C)(\chi_j\eta) + \delta_{f\cdot C}(\eta).$$

The first term tends to zero. Indeed, it is integration against a signed measure with smooth densities on the d-cells, and its total variation gives zero mass to their lower-dimensional faces. Dominated convergence for that total variation applies. This argument does not require applying monotone convergence directly to a signed measure. Thus the corner current is positive. Tests near the relative interior of a facet detect its scalar weight, proving nonnegativity of every weight; continuity extends the conclusion to facet boundaries. □

10.7 The tropical strong maximum principle

Theorem 10.7.1. *In the setting of Proposition 10.6.1, if $DD(f\delta_C) \geq 0$ and f has a local maximum at an interior point x of the cycle, then f is constant in a neighbourhood of x in C.*

Proof. Translate x to zero and restrict to a small ball. The local cycle is the intersection of a rational fan with the ball, and we may assume $f \leq f(0)$ throughout it. We prove the stronger claim that f is constant on this entire small fan neighbourhood, and argue by induction on d. Dimension zero is immediate. In dimension one, write s_e for the outgoing derivative on a ray and $m_e > 0$ for its weight. The maximum gives $s_e \leq 0$, while positivity of the corner gives $\sum_e m_e s_e \geq 0$. Hence every $s_e = 0$. The nonnegative second derivative on each ray makes its derivative nondecreasing from zero. Thus $f \geq f(0)$ on each ray, while the maximum gives the reverse inequality. The function is constant.

Suppose $d \geq 2$ and f is not constant. By continuity and density of rational points in the rational fan, choose a rational point y with $f(y) < f(0)$, in the relative interior of a maximal cone and away from the finitely many unwanted face spans. Choose a rational linear hyperplane H through 0 and y, otherwise generic for the fan. The stable intersection $C' = C \cdot H$ is an effective cycle of pure dimension $d-1$, with support equal to $C \cap H$ near these points. This is the proper-intersection case of the tropical displacement theorem.

The restricted cellwise Hessian stays positive. The divisor-intersection identity gives

$$(f|_{C'}) \cdot C' = (f \cdot C) \cdot H.$$

The right side has nonnegative weights: the corner cycle is effective and the intersection coefficients with the linear hyperplane are nonnegative lattice indices. Proposition 10.6.1 therefore shows that $f|_{C'}$ is weakly tropically psh. The induction hypothesis, applied on the same fan neighbourhood, makes it constant there. This contradicts $f(y) < f(0)$ and proves the result. □

The positive weights and balancing have different jobs. Positive weights force each outgoing derivative to vanish in dimension one. Balancing makes the corner formula and the restriction by a tropical hyperplane compatible. A collection of convex functions on separate cells, without the corner inequalities, need not satisfy this maximum principle.

10.8 Separating an analytic point from the boundary

To apply the tropical theorem to an analytic function, it is not enough that the chosen analytic point is interior. Its tropical value could also be attained at a boundary point. Additional coordinates remove this overlap.

Lemma 10.8.1. *Let X be a strict affinoid space and let $x \in \mathrm{Int}(X)$. There are a strict affinoid neighbourhood U of x and analytic units $g_1, \dots, g_s$ on U such that the tropicalization $b = (-\log|g_i|)_i$ satisfies*

$$b(x) \notin b(\partial U).$$

Proof. The affinoid boundary lemma of CLD12 supplies finitely many analytic functions g_i on X with $|g_i| \le 1$, $|g_i(x)| < 1$, and with at least one $|g_i(y)| = 1$ at every $y \in \partial X$. If $g_i(x) = 0$, add a nonzero constant of norm less than one; this preserves all three properties and makes the value at x nonzero. This boundary lemma is the geometric input.

Choose r in the positive value group, larger than every $-\log|g_i(x)|$, and set $U = \bigcap_i \{|g_i| \ge e^{-r}\}$. It is a strict Laurent domain and a neighbourhood of x. The functions g_i are units on U, and $b(U) \subset [0, r]^s$. Points inherited from ∂X have at least one coordinate zero. Any new boundary point of the Laurent domain has at least one coordinate r, by the relative-boundary formula. Hence $b(\partial U)$ lies in the boundary of the box, while $b(x) \in (0, r)^s$. □

Theorem 10.8.2 (The analytic maximum principle in the piecewise smooth class)**.** *Let X be a good strict analytic space of pure dimension over a complete nontrivially valued field. If a piecewise smooth function h is current-psh for the original CLD tests and has a local maximum at an interior point x, then it is locally constant at x.*

Proof. Choose a strict affinoid neighbourhood on which $h = F \circ a$ for a moment tropicalization a and a piecewise smooth F, and shrink so that $h \le h(x)$. Adjoin the boundary-separating coordinates of Lemma 10.8.1; the new chart is $a' = (a, b)$, and F is pulled back from the first factor. Write $\omega = a'(x)$. Then $\omega \notin a'(\partial U)$.

By Theorem 6.10.2, the image has pure dimension $\dim X$ near ω. The analytic calibration and balancing theorem equips it there with positive tropical multiplicities. For a positive compactly supported superform η on this image, with support avoiding the tropicalized boundary, its pullback is an admissible positive CLD test. The integration formula gives

$$DD(F\delta_{a'(U)})(\eta) = DD[h]((a')^*\eta) \geq 0.$$

The tropical function has a maximum at ω, because $h \leq h(x)$ on all of U. Theorem 10.7.1 makes F constant near ω in the tropical image. Pulling back proves the assertion. □

The proof uses neither a converse from current positivity to model semipositivity nor a general smooth regularization theorem. It applies directly to the piecewise smooth class. On a compact connected boundaryless space in this setting, every such psh function is constant: its maximum set is nonempty and closed, and the local theorem makes that set open. This conclusion concerns scalar functions; a semipositive metric on a nontrivial line bundle has transition functions and is not a single global psh scalar.

References. [GRPL, Section 7, Proposition 7.4 and Theorem 7.7]; the boundary-separating input is [CLD12, Lemma 3.4.3]. The pure-dimensional analytic case is stated here so that no restriction-to-components step is implicit.

Part III

Potential theory and products

Chapter 11

Psh functions and generated classes

All continuity and local-uniform approximation in this chapter use the ordinary Berkovich topology, not the path metric on a skeleton. Example 4.2.1 shows why these topologies cannot be interchanged. A neighborhood on which an approximating family is defined is fixed before taking its limit; restricting to an analytic domain is not a substitute for proving such a neighborhood exists.

11.1 Continuous potentials, smooth approximation, and curvature

Assume for this section that X has no analytic boundary. A function is locally integrable in the current formalism if it is locally integrable against the measures represented by smooth top-degree test forms. There is no unspecified ambient Lebesgue measure on X in this definition. For a continuous real function u, the current

$$\langle [u], \alpha \rangle = \int_X u\alpha$$

is well-defined and has bidegree $(0, 0)$.

Definition 11.1.1 (The continuous psh condition in CLD 2012)**.** A continuous real function u is psh in the sense of [CLD12, Definition 5.5.1] if $d'd''[u]$ is a positive current. It is locally smoothly psh-approximable if each point has a neighborhood on which u is a uniform limit of original smooth psh functions.

The second condition is Definition 5.6.3 of the same source. It has an existential approximation requirement that does not occur in the first condition.

Proposition 11.1.2 (Stability under locally uniform limits)**.** *Let u_j be continuous current-psh functions converging locally uniformly to a finite continuous function u. Then u is current-psh. In particular, local smooth psh approximation implies the continuous psh condition of Definition 11.1.1.*

Proof. Let α be a positive smooth test form of bidegree $(n-1, n-1)$, and choose a compact neighborhood C of its support. The smooth top-degree form $d'd''\alpha$ represents a signed measure μ_α of finite total variation on C. Hence

$$\left|\langle d'd''[u_j - u], \alpha\rangle\right| = \left|\int_C (u_j - u)\, d\mu_\alpha\right| \leq \|u_j - u\|_C\, |\mu_\alpha|(C) \longrightarrow 0.$$

Each $\langle d'd''[u_j], \alpha\rangle$ is nonnegative, so its limit is nonnegative. Positivity is local and the test form was arbitrary. □

Remark 11.1.3 (What the 2012 construction does not establish). The converse to Proposition 11.1.2 is not proved in CLD 2012; [CLD12, Remark 5.6.4] explicitly records this difficulty. Consequently, a theorem whose hypotheses require local smooth psh approximation cannot be invoked merely because a continuous function has positive $d'd''$-current.

The sentence following [CLD12, Definition 5.5.1] also asserts functoriality for all continuous current-psh functions. Later work distinguishes current-psh from functorial psh and does not supply that general assertion as an automatic consequence of the current definition. It must therefore be cited with a separately verified hypothesis, rather than proved by an undefined pullback of currents. Smooth potentials and local uniform limits of smooth psh potentials are legitimate settings for the corresponding pullback argument; the smooth comparison is also covered by [GK19, Corollary 8.9].

Example 11.1.4 (A corner contributes to the current)**.** On an interval around 0, set $u(t) = -|t|$. Both restrictions to $t < 0$ and $t > 0$ are affine, hence convex. Nevertheless, for a smooth compactly supported test function χ,

$$\langle d'd''[u], \chi\rangle = \int_{\mathbb{R}} -|t|\,\chi''(t)\,dt = -2\chi(0).$$

Thus $d'd''[u] = -2\delta_0$ and u is not psh. The identical calculation applies in a tropical coordinate on an annulus. The facewise Hessians vanish; the negative contribution lies at the corner.

For a tropical curve with three outgoing primitive directions $(1,0)$, $(0,1)$, $(-1,-1)$, a continuous piecewise affine potential with outgoing slopes a, b, c has vertex mass $a+b+c$. Choosing $a+b+c<0$ gives the counterexample in [GK19, Example 3.3] to the continuous version of [CLD12, Lemma 5.5.3]. The smooth restriction of that criterion is the one retained in [GK19, Remark 3.2].

Theorem 11.1.5 (The mixed product constructed in CLD 2012)**.** *Let $u_1, \dots, u_m$ be locally smoothly psh-approximable continuous functions, where $0 \le m \le n$. There is a positive current of bidegree (m,m) denoted by*

$$d'd''u_1 \wedge \cdots \wedge d'd''u_m.$$

On an open subset where $u_{i,j}$ are smooth psh functions converging uniformly to u_i, its value on a test form α is

$$\lim_{j\to\infty} \int_X d'd''u_{1,j} \wedge \cdots \wedge d'd''u_{m,j} \wedge \alpha.$$

The limit is independent of the approximating sequences and is compatible with restriction. If $m = n$, it is a positive measure.

Open proof obligation (RC2). Prove the native mixed-current assertion under its local uniform approximation hypothesis. CLD12 Corollary 5.6.5 is supplied here; the described internal route also has open multiplier convergence.

Definition 11.1.6 (Metric weights and curvature)**.** Let L be a line bundle with a finite continuous metric. For a local nonvanishing frame e, write

$$\varphi_e = -\log\|e\|, \qquad c_1(L, \|\cdot\|)|_U = d'd''[\varphi_e].$$

The metric is current-psh if its local weights satisfy Definition 11.1.1.

Proposition 11.1.7 (Frame independence and the Poincaré–Lelong sign)**.** *The local curvature currents in Definition 11.1.6 agree on overlaps. If Z is an algebraic variety and s a nonzero meromorphic section of L, then*

$$c_1(L, \|\cdot\|) = d'd''[-\log\|s\|] + \delta_{\mathrm{div}(s)}.$$

Open proof obligation (RC2). Prove the scalar divisor/current identity with the stated sign and scope; CLD12 Theorem 4.6.5 or the cited Gubler alternative is the premise.

A local smooth approximation of each weight, a global smooth approximation of a metric on a fixed line bundle, and an approximation by relatively nef algebraic models are three different requirements. The first two are already separated in [CLD12, §6.3.1]; the third belongs to model positivity. The weak convergence of curvature currents proved in Proposition 11.1.2 does not identify these approximation categories. Likewise, adding a constant to every local weight leaves the curvature unchanged but changes the metric. Curvature comparison alone does not identify metrized line bundles.

11.2 The change of psh definition from 2012 to 2025

We work on a good Hausdorff boundaryless analytic space of pure dimension n and use the original smooth-form sheaf. An original smooth function is called psh when the smooth $(1,1)$-form $d'd''u$ is positive. The smooth-form/current comparison identifies this with positivity of $d'd''[u]$ in this regularity class; see [CLD25, Corollary 7.3.10 and Theorem 12.11.1]. The issue in this section is the passage to nonsmooth functions.

11.2.1 The classes that must remain separate

Definition 11.2.1 (Local approximation classes)**.** For an open set U, let $\mathcal{U}(U)$ be the continuous real functions u such that every $x \in U$ has an open neighbourhood $V \subset U$ on which u is the locally uniform limit of a sequence of original smooth psh functions defined on that same V. Let $\mathcal{M}(U)$ be the finite continuous functions which, locally on one fixed open neighbourhood, are decreasing limits of sequences of original smooth psh functions. Write $\mathrm{Psh}_{12}^{\mathrm{cont}}(U)$ for the continuous current-psh functions of Definition 11.1.1.

The neighbourhood in the definition is fixed for the whole approximating sequence. Neither definition is satisfied merely by finding, for every accuracy parameter, a function which is psh on a different shrinking neighbourhood of the point.

Definition 11.2.2 (The two generated sheaves in CLD25)**.** The sheaf $\mathcal{P}_{25}$ is the smallest subsheaf of functions with values in $\mathbb{R} \cup \{-\infty\}$ which contains the original smooth psh functions and is stable under decreasing limits of sequences on every open set. The sheaf $\mathcal{C}_{25}$ is the smallest subsheaf of finite continuous functions which contains the same smooth functions and is stable under uniform limits. These are [CLD25, Definitions 8.1.1 and 8.1.7].

The ordinal stages of the first construction are defined by

$$\mathcal{P}_{25,0} = \{\text{original smooth psh functions}\},$$

with $\mathcal{P}_{25,\alpha+1}$ consisting of local decreasing limits of sequences from $\mathcal{P}_{25,\alpha}$; at a limit ordinal one takes the sheaf of functions which locally belong to an earlier stage. In particular, the first stage $\mathcal{P}_{25,1}$ has an explicit local decreasing smooth approximation. The generated sheaf includes the later stages as well.

The word "smallest" refers to intersection among subsheaves satisfying the two defining properties. It is an exact definition and does not assert that every resulting section is a one-step limit of smooth functions. The transfinite description in [CLD25, Lemma 8.1.4] makes this distinction visible.

Proposition 11.2.3 (The continuous first stage)**.** *As sheaves of finite continuous functions,*

$$\mathcal{M} = \mathcal{U} = C^0 \cap \mathcal{P}_{25,1}. \tag{11.2.1}$$

Proof. If $u_j \downarrow u$ on a fixed neighbourhood and u_j, u are continuous, Dini's theorem gives uniform convergence on every compact subset. This proves $\mathcal{M} \subset \mathcal{U}$.

Conversely, fix a smaller open neighbourhood V with compact closure inside a common approximation neighbourhood. Choose smooth psh functions v_j such that

$$\|v_j - u\|_{\overline{V}} \leq 4^{-j}.$$

Put $w_j = v_j + 2 \cdot 4^{-j}$. Addition of a constant preserves smooth psh. On V,

$$u + 4^{-j} \leq w_j \leq u + 3 \cdot 4^{-j}, \qquad w_{j+1} \leq u + \tfrac{3}{4}\, 4^{-j} < w_j.$$

Hence $w_j \downarrow u$ on V. This proves the reverse inclusion. The last equality is the definition of the first generated stage, with the continuous endpoint required explicitly. □

Proposition 11.2.4 (Implications obtained without identifying the higher stages)**.** *In the setting above one has*

$$\mathcal{U} \subseteq \mathcal{C}_{25} \subseteq C^0 \cap \mathcal{P}_{25} \subseteq \mathrm{Psh}_{12}^{\mathrm{cont}}. \tag{11.2.2}$$

More generally, a locally integrable section u of $\mathcal{P}_{25}$ has positive original current $d'd''[u]$. None of the reverse inclusions for general analytic spaces is inferred here from the definitions.

Proof. The first inclusion follows by restricting to relatively compact neighbourhoods and applying the uniform-limit closure property of $\mathcal{C}_{25}$. The generated psh sheaf is a cone, is stable under addition of constants, and is local. A locally uniform limit of finite members can therefore be replaced, on a smaller relatively compact neighbourhood, by a decreasing subsequence after adding positive constants, exactly as in Proposition 11.2.3. Thus $C^0 \cap \mathcal{P}_{25}$ contains smooth psh functions and is stable under uniform limits; the minimality of $\mathcal{C}_{25}$ proves the second inclusion.

For the last assertion, use transfinite induction on the decreasing-limit construction. Suppose $u_j \downarrow u$, where u is locally integrable and each u_j belongs to an earlier stage. All generated functions are upper semicontinuous, so u_j is bounded above on compact sets. The inequalities $u \le u_j \le u_1$ imply local integrability of u_j; Proposition 11.6.7 records this inheritance at every ordinal. If α is a positive top-degree test form, monotone convergence applied after subtracting a local upper bound gives

$$\int u_j \alpha \longrightarrow \int u\alpha.$$

A general top-degree test is a difference of positive tests. Hence $[u_j] \to [u]$, and

$$d'd''[u_j] \longrightarrow d'd''[u].$$

Positivity is preserved under this convergence because each positive test has a nonnegative value at every stage. Locality treats sheafification and limit ordinals. The smooth initial stage follows from integration of positive smooth forms. This supplies the usable argument for [CLD25, Proposition 8.3.1(a)] without invoking Proposition 8.1.11 or the false weak-positive order-zero statement. □

Remark 11.2.5 (The equality printed in Proposition 8.1.11). CLD25 states the stronger equality

$$\mathcal{C}_{25} = C^0 \cap \mathcal{P}_{25}$$

and an equality at every ordinal stage. Its printed successor-stage argument starts with approximants in the continuous stage, whereas the decreasing-limit definition provides approximants in the possibly discontinuous stage. The missing replacement is discussed in Remark A.1.4. We use (11.2.2) and the proved first-stage equality (11.2.1); no argument in this book requires the stronger printed equality. This is a limitation of the available argument, not a counterexample to that equality. Sections 11.6.1–11.6.3 prove the compact-domain barrier theorem, the indexed forward inclusion and the locally integrable comparison, and isolate the additional domain requirement. A projective route, using Wu's comparison and envelope inputs, is given in Section 11.7. Theorem 11.7.5 proves that bounded first-stage decreasing stability is sufficient for the full continuous-stage equality.

Remark 11.2.6 (Translation of the word *approchable*). In [CLD12, Definition 5.6.3], "locally psh-approachable" is the positive approximation condition represented here by $\mathcal{U}$, whereas "locally approachable" denotes a difference of two such functions. In [CLD25, Definition 8.1.13], a psh function is "locally approachable" when it belongs to $\mathcal{P}_{25,1}$. Thus the latter expression is on the positive side of the theory. For finite continuous endpoints, Proposition 11.2.3 compares the positive classes; it does not identify the old difference class with the new positive class.

11.2.2 Pulling back functions and pulling back currents

Proposition 11.2.7 (Pullback for generated and approximable psh functions)**.** *Let $f : Y \to X$ be an analytic morphism in the preceding category. Pullback of functions preserves $\mathcal{P}_{25}$ and $\mathcal{U}$. In the generated class it preserves each ordinal stage.*

Proof. Pullback of an original smooth function is original smooth, and pullback of its positive $(1,1)$-form is positive. It commutes with composition and with pointwise decreasing limits. Transfinite induction, followed by locality, proves the assertion for $\mathcal{P}_{25}$, as in [CLD25, Proposition 8.1.5]. For $\mathcal{U}$, pull back the smooth approximants on the inverse image of a common neighbourhood. A compact subset of that inverse image has compact image, so local uniform convergence is preserved. □

The proof constructs $u \circ f$ and, whenever this function is locally integrable, its curvature current. Local integrability holds for continuous u; a singular psh pullback may instead be identically $-\infty$. The proof never defines a pullback of an arbitrary current. In particular, the notation

$$d'd''[u \circ f]$$

does not by itself justify an operation $f^*(d'd''[u])$ on the whole current space. The general pullback assertion following [CLD12, Definition 5.5.1] cannot be used as a proof of this operation or as a comparison with all current-psh functions; see Section A.1 and the functorial conditions in the delta-form section.

11.2.3 A complete comparison on real convex domains

Proposition 11.2.8 (Continuous distributional convexity)**.** *Let $\Omega \subset \mathbb{R}^r$ be open and convex, and let $u : \Omega \to \mathbb{R}$ be continuous. The following are equivalent:*

1. *u is convex;*
2. *$d'd''[u]$ is a positive supercurrent;*
3. *u is locally a uniform limit of smooth convex functions;*
4. *u is locally a decreasing limit of smooth convex functions.*

Proof. Convolution on a slightly larger relatively compact domain preserves convexity and gives smooth functions converging uniformly on smaller compact sets. Thus (1) implies (3). The shift construction in Proposition 11.2.3 proves (3) implies (4), and local uniform convergence of the corresponding distributions gives (3) implies (2).

If (2) holds, convolve the distributional Hessian with a nonnegative smooth kernel. The resulting matrix is positive semidefinite, so each regularization u_ε is convex by Proposition 7.2.4. Continuity gives $u_\varepsilon \to u$ uniformly on compact subsets. Passing to the limit in the convexity inequality proves local convexity. Restricting to a line segment in Ω then gives global convexity on the convex domain. Finally, (4) implies (3) by Dini's theorem. □

Remark 11.2.9 (Why continuity cannot be omitted from a pointwise statement). On $(-1,1)$ define $u(0)=1$ and $u(t)=0$ for $t\neq 0$. Then u is locally integrable and even upper semicontinuous, and $[u]=[0]$. Thus $d'd''[u]=0$, but u is not convex:

$$u(0)=1>\tfrac{1}{2}u(-a)+\tfrac{1}{2}u(a)=0 \qquad (0<a<1).$$

The implication from the locally integrable current condition to pointwise convexity in [CLD25, Proposition 8.3.2] is therefore false literally. A distribution determines an almost-everywhere class; a convex representative must be specified, or continuity must be assumed as in Proposition 11.2.8. Upper semicontinuity alone does not repair this example.

11.3 Positive distributional Hessians and convex representatives

A current defined by a locally integrable function only remembers its almost-everywhere class. To repair a pointwise convexity assertion, one must first construct the canonical representative of that class. The continuous comparison in Section 11.2 is a special case of the result below; the proof also explains precisely why changing one point can invalidate the unrepaired statement.

Let $\Omega\subset\mathbb{R}^n$ be a nonempty convex open set. For $u\in L^1_{\mathrm{loc}}(\Omega)$, say that its distributional Hessian is positive if

$$\sum_{i,j}\xi_i\xi_j\,\partial_i\partial_j u\geq 0 \quad \text{as a distribution for every } \xi\in\mathbb{R}^n.$$

This is equivalent to ordinary positivity of $DD[u]$ in the real superform convention. It is a condition on a distribution, so it is unchanged by modifications on Lebesgue-null sets.

Lemma 11.3.1 (An interior bound from an L^1 bound)**.** *Let v be a smooth convex function on $B(0,4r)$ and put $M=\int_{B(0,4r)}|v|\,dx$. With $V_r=\mathrm{vol}(B(0,r))$, one has*

$$-3M/V_r\leq v(x)\leq M/V_r \quad (x\in B(0,r)).$$

The functions with a common M bound are uniformly Lipschitz on $B(0,r/2)$, with a constant depending only on M,r,n.

Proof. For $z \in B(0,3r)$, the average of points in $B(z,r)$ is z. Jensen's inequality gives $v(z) \le M/V_r =: A$. For $x \in B(0,r)$ and $y \in B(x,r)$, the point $2y - x$ lies in $B(0,3r)$; convexity gives

$$v(y) \le \tfrac{1}{2}v(x) + \tfrac{1}{2}v(2y - x) \le \tfrac{1}{2}(v(x) + A).$$

If $v(x) \ge -A$ there is nothing to prove. Otherwise the right side is negative throughout that ball, and integration of $|v|$ yields $M \ge V_r(-v(x) - A)/2$. Thus $v(x) \ge -3A$. For $x \in B(0,r/2)$ and a unit vector e, the two points $x \pm (r/2)e$ lie in $B(0,r)$ after an arbitrarily small inward adjustment. The tangent-line inequality for a convex function bounds $|\partial_e v(x)|$ by $8A/r$. This gives a uniform gradient bound and the Lipschitz assertion. □

Theorem 11.3.2 (The convex representative theorem)**.** *A function $u \in L^1_{\mathrm{loc}}(\Omega)$ has positive distributional Hessian if and only if its almost-everywhere class contains a finite convex function v. Such a representative is unique. Every standard compactly supported nonnegative smooth approximate identity ρ_ε gives*

$$u * \rho_\varepsilon \longrightarrow v \quad \textit{locally uniformly on } \Omega.$$

Proof. Assume first that the Hessian is positive. On the inner domain where convolution is defined, $u_\varepsilon = u * \rho_\varepsilon$ is smooth and its Hessian is positive semidefinite: for each vector ξ, its quadratic Hessian coefficient is the convolution of the nonnegative distribution $\partial_\xi^2 u$ with a nonnegative kernel. Thus u_ε is convex on every convex inner subdomain.

The convolutions converge to u in L^1 on every relatively compact open subset. Their L^1 norms are therefore uniformly bounded there for sufficiently small ε. Cover a given compact subset by finitely many balls whose fourfold enlargements remain in Ω. Lemma 11.3.1 gives uniform bounds and equicontinuity on the compact subset. Arzelà–Ascoli and a diagonal argument over an exhaustion give a subsequence converging locally uniformly to a finite continuous function v. The convex inequality passes to the limit on each compact line segment, so v is convex. Its L^1 limit is also u, hence $v = u$ almost everywhere.

Two finite convex representatives are continuous. If they differed at one point, they would differ on a nonempty open set, which has positive Lebesgue measure. Hence they coincide. This uniqueness and the same local compactness argument show convergence of the whole family u_ε, not just the selected

subsequence: any sequence violating uniform convergence on a compact set would have a locally uniformly convergent subsequence with the same unique limit.

Conversely, if $u = v$ almost everywhere for a finite convex v, its convolutions are smooth convex functions and converge locally uniformly to v. Their positive Hessian distributions converge to the Hessian distribution of u. Positivity is closed under convergence on tests, proving the converse. □

11.3.1 Which pointwise representative is admissible

Corollary 11.3.3. *The representative in Theorem 11.3.2 is characterized by*

$$v(x) = \lim_{r\downarrow 0} \frac{1}{\operatorname{vol} B(x,r)} \int_{B(x,r)} u(y)\, dy = \lim_{r\downarrow 0} \operatorname*{ess\,sup}_{B(x,r)} u.$$

If the chosen pointwise function u is strongly upper semicontinuous, in the sense that $u(x) = \limsup_{y\to x,\, y\notin E} u(y)$ for every Lebesgue-null set E, then $u = v$ everywhere. Ordinary upper semicontinuity alone does not suffice.

Proof. The integral and essential supremum are unchanged by replacing u with v. Continuity of v makes both limits equal to $v(x)$. For the last assertion take $E = \{u \neq v\}$, which is null. Its complement is dense in every open ball. Strong upper semicontinuity and continuity of v therefore give $u(x) = v(x)$. To see the failure for ordinary upper semicontinuity, put $u(0) = 1$ and $u = 0$ elsewhere on a ball containing zero. This function is upper semicontinuous and defines the zero distribution, but is not convex. □

This gives two precise replacements for the pointwise claim in CLD25 Proposition 8.3.2: either work with a continuous function from the outset, or work with an L^1 class and its unique convex representative. Strong upper semicontinuity selects that representative. The approximation converges uniformly to the representative, not to an arbitrarily modified pointwise version.

11.4 The Hessian kernel and potential independence on a real domain

Proposition 11.4.1. *If a distribution w on a connected open subset of $\mathbb{R}^n$ satisfies $\partial_i \partial_j w = 0$ for all i, j, then w is the distribution of an affine function. Consequently two finite convex functions on a convex open set with the same Hessian current differ by an affine function.*

Proof. On any ball compactly contained in the domain, small convolutions w_ε have zero Hessian, hence are affine on a smaller concentric ball. The finite-dimensional space of affine distributions on that smaller ball is closed in the distribution topology. To see this directly, choose $n+1$ test functions whose integrals against $1, x_1, \dots, x_n$ form an invertible matrix; convergence on these tests forces convergence of all affine coefficients. Since $w_\varepsilon \to w$ as distributions, w is affine on the smaller ball. On overlapping balls the affine polynomials agree as distributions and hence as functions on an open set, so their coefficients agree. Connectedness glues them to one affine function. Apply this to the difference of the two functions and then use their continuity. □

Corollary 11.4.2. *Let S be an ordinary positive current closed under both differentials on a convex real domain. If finite convex functions u, v have $DD[u] = DD[v]$, then*

$$DD(uS) = DD(vS).$$

Proof. Both functions are continuous, so multiplication is defined by the order-zero theorem. Their difference $a = u - v$ is affine by Proposition 11.4.1. The smooth Leibniz formula and closedness give $DD(aS) = (DDa) \wedge S = 0$. Subtracting the two products proves the result. □

On a singular tropical support, the kernel of the current Hessian can be larger than the affine functions inherited from the ambient space. The cross example in Chapter 14 exploits exactly that enlargement. Thus the Euclidean argument proves potential independence on its own domain and simultaneously identifies the step that cannot simply be carried over to an arbitrary quotient of charts.

References. This section supplies the representative-sensitive repair of [CLD25, Proposition 8.3.2]. The distinction between strong upper semicontinuity and a mere distributional class is also used in [BGJK25, Section 3.1].

11.5 A convex potential for a positive closed real current

On a convex real domain, every positive closed $(1,1)$ supercurrent has a convex potential. The assertion concerns an ambient Euclidean domain. It is a useful comparison theorem for the local analytic problem, but its proof uses linear coordinates and cannot be transferred to a singular tropical quotient without checking those operations. We include the distributional step so that regularizing the current does not conceal a missing convergence argument for its potentials.

Lemma 11.5.1 (Positive Laplacian gives local integrability)**.** *Let u be a distribution on an open subset of $\mathbb{R}^n$. If Δu is a positive distribution, then u is represented by a locally integrable function.*

Proof. A positive distribution is a positive Radon measure; write $\mu = \Delta u$. Choose a compactly supported smooth cutoff χ equal to one on a smaller open set. A fundamental solution E_n for Δ is

$$E_1(x) = \tfrac{1}{2}|x|, \qquad E_2(x) = \tfrac{1}{2\pi}\log|x|,$$
$$E_n(x) = -\frac{|x|^{2-n}}{(n-2)\ \mathrm{area}(S^{n-1})} \quad (n \geq 3).$$

Each kernel is locally integrable. The convolution $v = E_n * (\chi\mu)$ is locally integrable by Fubini: on a compact set, the integral of $|E_n(x-y)|$ in x is uniformly bounded for y in the compact support of $\chi\mu$. In distributions, $\Delta v = \chi\mu$. Thus $u - v$ is a harmonic distribution on the smaller open set.

For completeness, a harmonic distribution is smooth. Its small convolutions are smooth harmonic functions. Fix a smooth radial averaging kernel supported in a ball small enough for the harmonic mean-value identity. Every such convolution equals its convolution with this fixed kernel on a smaller ball. Passing to distributions shows that the original distribution equals its convolution with the fixed kernel there, which is smooth. This is the distributional Weyl lemma. Consequently $u = v + (u - v)$ is locally integrable. □

Corollary 11.5.2. *A distribution whose Hessian is positive semidefinite in the distributional sense is represented by a unique finite convex function on a convex domain.*

Proof. Its Laplacian is a sum of positive distributions, hence positive. Lemma 11.5.1 gives a locally integrable representative, and Theorem 11.3.2 gives the unique finite convex representative. □

Theorem 11.5.3 (The real DD potential theorem)**.** *Let $\Omega \subset \mathbb{R}^n$ be convex and open. A symmetric ordinary positive $(1,1)$ supercurrent T with $d'T = d''T = 0$ has a finite convex potential u satisfying $DD[u] = T$. The potential is unique up to addition of an affine function.*

Proof. Write $T = \sum_{i,j} T_{ij}\, d'x_i \wedge d''x_j$. Symmetry gives $T_{ij} = T_{ji}$, and closedness gives

$$\partial_k T_{ij} = \partial_i T_{kj}.$$

The trace $\mu = \sum_i T_{ii}$ is a positive Radon measure. Commuting distributional derivatives and using symmetry gives

$$\Delta T_{ij} = \sum_k \partial_k \partial_i T_{kj} = \partial_i \partial_j \sum_k T_{kk} = \partial_i \partial_j \mu.$$

First work on a relatively compact convex subdomain $U \Subset \Omega$. Choose $\chi = 1$ near its closure and form $v = E_n * (\chi\mu)$. The preceding lemma's argument makes v locally integrable. On U, the distributions

$$S_{ij} = T_{ij} - \partial_i \partial_j v$$

are harmonic, hence smooth. They remain symmetric and satisfy $\partial_k S_{ij} = \partial_i S_{kj}$. Translate an interior base point of U to zero and define

$$a_j(x) = \int_0^1 \sum_i x_i S_{ij}(tx)\, dt.$$

Differentiating and using the closed-column identity gives

$$\partial_k a_j(x) = \int_0^1 \left(S_{kj}(tx) + t \sum_i x_i \partial_i S_{kj}(tx) \right) dt = S_{kj}(x).$$

Symmetry now says that the smooth one-form $\sum_j a_j dx_j$ is closed. A second radial integration,

$$b(x) = \int_0^1 \sum_j x_j a_j(tx)\, dt,$$

gives $\partial_j b = a_j$ and $D^2 b = S$. Hence the locally integrable function $v + b$ has Hessian T on U. Positivity and Theorem 11.3.2 replace it by a finite convex representative u_U.

Exhaust Ω by nested relatively compact convex open subdomains U_j. Such an exhaustion is obtained by intersecting large balls with inner parallel convex domains. On U_j, the difference $u_{U_{j+1}} - u_{U_j}$ has zero Hessian, hence is affine by Proposition 11.4.1. Subtract this affine function from $u_{U_{j+1}}$ and proceed inductively. Affine subtraction preserves convexity, and the adjusted potentials agree on overlaps. They glue to the required finite convex function on Ω. The same Hessian-kernel proposition gives uniqueness modulo affine functions. □

This proof makes two uses of the ambient real structure explicit. Coordinate derivatives commute as distributions, allowing the Laplacian calculation; and straight segments remain in the convex domain, allowing the two radial integrations. The equation $DD[u] = T$ on a tropical support is an equality modulo tangential relations. It need not furnish an ambient matrix T_{ij} satisfying these unrestricted coordinate identities. This is the precise obstruction to treating the real potential theorem as a local-potential theorem on every Berkovich chart.

Corollary 11.5.4. *For a positive closed* $(1,1)$ *current on all of* $\mathbb{R}^n$*, every connected component of the complement of its support is convex.*

Proof. Let u be its global convex potential and let V be such a component. The potential agrees there with one affine function a. At any point of V, that affine function is a supporting plane for u, so $u \geq a$ globally. The zero set of the convex nonnegative function $u - a$ is convex. It contains V, hence its convex hull. Since V is open, its convex hull is open as well; u is affine on that open hull, so the current vanishes there. Connectedness and maximality of the component then imply $\mathrm{conv}(V) = V$. □

References. The potential theorem and the support-complement consequence occur in [Lag12, Propositions 1.13–1.14]. The proof here supplies the distributional

integrability and gluing steps explicitly, using the representative theorem of Section 11.3.

11.6 Which approximation statement is available

The first-stage theorem and the generated-sheaf comparison serve different purposes. The former constructs a single smooth sequence on a fixed neighbourhood and is the input for Theorem 13.6.3. The latter allows repeated local limiting operations. A section obtained after several such operations must not be used as a first-stage section without an additional argument.

Lemma 11.6.1 (The upper-semicontinuous form of Dini's argument)**.** *Let K be compact, let u_j be finite upper semicontinuous functions decreasing to a continuous finite function u. Then $u_j \to u$ uniformly on K.*

Proof. For $\epsilon > 0$, the sets $O_j = \{u_j - u < \epsilon\}$ are open, increase with j, and cover K. Compactness gives $K = O_N$ for some N. Thus $0 \le u_j - u < \epsilon$ on K for all $j \ge N$. □

This observation locates the difficulty in CLD25 Proposition 8.1.11 more precisely. The obstacle is not the uniformity of a decreasing limit with continuous endpoint: upper semicontinuity already suffices for that. It is the replacement of the possibly discontinuous predecessors in $\mathcal{P}_{25,\alpha}$ by members of $\mathcal{C}_{25,\alpha}$. Uniform convergence of discontinuous predecessors does not make those predecessors continuous. Proposition 11.2.3 avoids this issue because its predecessors are smooth.

Assertion	Usable justification
$\mathcal{U} = \mathcal{M} = C^0 \cap \mathcal{P}_{25,1}$	Proposition 11.2.3, with fixed local approximation domain.
$\mathcal{U} \subseteq \mathcal{C}_{25} \subseteq C^0 \cap \mathcal{P}_{25}$	Proposition 11.2.4; no reverse inclusion is used.
$\mathcal{C}_{25} = C^0 \cap \mathcal{P}_{25}$	Stronger source assertion; the predecessor replacement remains unproved here.
$R_X(u_1, \dots, u_k; T)$	Theorem 13.6.3 for $u_i \in \mathcal{U}_X$ and the stated ordinary positive closed T.

The kernel question is independent of this existence statement. The cross calculation in Proposition 14.2.2 refutes its unrestricted abstract version. A

positive result on an analytic space must specify the harmonic kernel, the test quotient and the permitted background currents.

References. CLD25 Definitions 8.1.1, 8.1.7 and Proposition 8.1.11; the compactness argument above is elementary.

11.6.1 A continuous upper barrier on a fixed compact set

To understand the missing step in Proposition 8.1.11, we first remove one difficulty from the problem. Repeated decreasing limits on a fixed compact set can be handled without making every predecessor continuous. A continuous upper barrier allows us to select one predecessor at a time. The distinction between this construction and a sheaf construction will then be explicit.

Definition 11.6.2 (The decreasing hierarchy on a fixed compact set)**.** Let K be a compact Hausdorff space and let $\mathscr{S} \subset C(K, \mathbf{R})$ be nonempty. Define classes of actual functions $K \to \mathbf{R} \cup \{-\infty\}$ by

$$\begin{aligned} D_0(\mathscr{S}) &= \mathscr{S}, \\ D_{\alpha+1}(\mathscr{S}) &= \{f : \text{there are } f_j \in D_\alpha(\mathscr{S}) \text{ with } f_j \downarrow f \text{ on } K\}, \\ D_\lambda(\mathscr{S}) &= \bigcup_{\beta<\lambda} D_\beta(\mathscr{S}) \quad (\lambda \text{ a limit ordinal}). \end{aligned}$$

Write $D(\mathscr{S})$ for the class obtained after stabilization. All functions at all stages have domain K. There is no sheafification or passage to a smaller domain in this definition.

The classes increase because constant sequences are allowed. They stabilize since they are subsets of the fixed set of all functions on K. Every member is upper semicontinuous: this is preserved by a decreasing limit and is unchanged by taking a union of classes. These observations alone do not give first-stage stabilization for discontinuous functions. Corollary 11.24.6 below proves it by a separate compact diagonal argument.

Lemma 11.6.3 (Selection below a continuous barrier)**.** *If $f \in D(\mathscr{S})$ and $b \in C(K, \mathbf{R})$ satisfy $f < b$ everywhere on K, then there is $s \in \mathscr{S}$ such that*

$$f \le s < b \quad \text{on } K. \tag{11.6.1}$$

Proof. We prove the assertion by induction on the stage containing f. At stage zero, take $s = f$. At a successor stage, write $f_j \downarrow f$ with all f_j in the preceding stage. The sets

$$O_j = \{z \in K : f_j(z) < b(z)\}$$

are open, increase with j, and cover K. Openness uses upper semicontinuity of $f_j - b$, and the covering property uses $f < b$. By compactness, $O_N = K$ for some N. Apply the induction hypothesis to f_N and the same barrier b. It gives $f \le f_N \le s < b$. At a limit ordinal, f already belongs to one earlier stage by definition, so the induction hypothesis applies directly. □

Only one predecessor is retained at each successor step. The selected predecessor may be discontinuous; its upper semicontinuity is enough for the next selection. All selections use the same compact set and the same barrier. This is the point that a direct appeal to continuity of the predecessors would miss.

Theorem 11.6.4 (Continuous endpoints of the compact hierarchy)**.** *Suppose $\mathscr{S}$ is stable under addition of real constants. Then*

$$C(K, \mathbf{R}) \cap D(\mathscr{S}) = \overline{\mathscr{S}}^{\|\cdot\|_\infty} = C(K, \mathbf{R}) \cap D_1(\mathscr{S}). \tag{11.6.2}$$

Consequently, the continuous parts of $D_\alpha(\mathscr{S})$ agree for every $\alpha \ge 1$.

Proof. Let u be a finite continuous member of $D(\mathscr{S})$. Apply Lemma 11.6.3 with $b = u + \epsilon$. For every $\epsilon > 0$ it gives $s_\epsilon \in \mathscr{S}$ with $0 \le s_\epsilon - u < \epsilon$ on all of K. Thus u is in the uniform closure of $\mathscr{S}$.

Conversely, let u be in that uniform closure. Choose $s_j \in \mathscr{S}$ with $\|s_j - u\|_\infty \le \delta_j$, where $\delta_j = 4^{-j}$, and set $t_j = s_j + 2\delta_j$. Then $t_j \in \mathscr{S}$ and

$$u + \delta_j \le t_j \le u + 3\delta_j, \qquad t_{j+1} \le u + \tfrac{3}{4}\delta_j < t_j.$$

Hence $t_j \downarrow u$ uniformly on K, so $u \in D_1(\mathscr{S})$. The remaining inclusion follows from $D_1 \subset D$. The assertion for every positive ordinal follows by inserting $D_1 \subset D_\alpha \subset D$ into (11.6.2). □

This is an elementary statement about monotone closure on a fixed compact domain. It does not use positivity, tropical charts or a regularization theorem. Its application to the generated psh sheaf requires an additional representation property, stated next.

11.6.2 The remaining domain requirement

Corollary 11.6.5 (A compact representation gives first-stage approximation)**.** *Let K be a compact neighbourhood of x in a Hausdorff locally compact analytic space X. Let $\mathscr{S}_K$ consist of the restrictions to K of original smooth psh functions defined on open neighbourhoods of K. These neighbourhoods may depend on the function. Let u be finite and continuous near K. If*

$$u|_K \in D(\mathscr{S}_K), \tag{11.6.3}$$

then u has a decreasing original smooth psh approximation on the single open neighbourhood $\mathrm{Int}_X(K)$ of x, uniformly on compact subsets there. In particular, u is locally in $\mathcal{U}_X$ near x.

Proof. Theorem 11.6.4 gives a decreasing sequence $t_j \in \mathscr{S}_K$ converging uniformly to $u|_K$. Choose smooth psh representatives near K. Every representative is defined on $\mathrm{Int}_X(K)$, even though their larger neighbourhoods may differ. Their restrictions to this fixed interior therefore give the required sequence. The inequalities and the uniform bounds on K remain valid there. □

Condition (11.6.3) is the substantive hypothesis. Membership in $\mathcal{P}_{25,\alpha}$ allows local representations at every successor stage and sheafification at limit stages. Restricting one section to K does not by itself give a representation in $D_\alpha(\mathscr{S}_K)$: the lower-stage sections may only have representations on a cover of K, and their smooth predecessors need not extend across that cover. The compact hierarchy has no such local operation.

In particular, approximation on a neighbourhood depending on the error is insufficient. On the real tropical line, the function $u(t) = -t^2$ is not psh on any interval, since $u'' = -2$. Nevertheless, for every $\epsilon > 0$, the smooth psh constant zero satisfies

$$|0 - u(t)| < \epsilon \quad \text{for } |t| < \sqrt{\epsilon}.$$

Indeed, every continuous function admits such shrinking-domain constant approximations at a point. Thus this condition carries no psh information. In Corollary 11.6.5, the compact neighbourhood is fixed before the error tends to zero.

The conclusion of the corollary is stronger than the unindexed equality asserted in CLD25 Proposition 8.1.11: it gives first-stage approximation. Consequently, constructing compact representations for every continuous generated psh function would settle more than that equality. Failure to construct them does not refute the weaker equality. For that weaker target, continuous replacements already in $\mathcal{C}_{25}$ on one fixed domain would suffice; their ordinal need not match the ordinal of the original predecessor. The same-ordinal assertion in the source imposes this further constraint.

11.6.3 What survives at every ordinal

We record the valid direction of the continuous comparison with its ordinal intact. Define $\mathcal{C}_{25,0} = \mathcal{P}_{25,0}$, let $\mathcal{C}_{25,\alpha+1}$ be the sheaf of local uniform limits of sections of $\mathcal{C}_{25,\alpha}$, and at a limit ordinal take the sheaf of functions locally in an earlier continuous stage. All its sections are finite and continuous.

Proposition 11.6.6 (The indexed inclusion)**.** *For every ordinal α,*

$$\mathcal{C}_{25,\alpha} \subset C^0 \cap \mathcal{P}_{25,\alpha}.$$

Equality holds for $\alpha = 0, 1$. No reverse inclusion at later stages is asserted here.

Proof. First, addition of a constant preserves every $\mathcal{C}_{25,\alpha}$: prove this by induction, using the assertion for smooth psh functions, compatibility of translation with uniform limits, and locality at limit ordinals. Now argue by induction for the displayed inclusion. The zero stage is immediate. At a successor stage, work on an open set where $u_j \in \mathcal{C}_{25,\alpha}$ converges uniformly to u. After passing to a subsequence, assume $\|u_j - u\| \leq 4^{-j}$. The functions $u_j + 2 \cdot 4^{-j}$ remain in $\mathcal{C}_{25,\alpha}$ and decrease to u, by the estimate in Proposition 11.2.3. By induction they lie in $\mathcal{P}_{25,\alpha}$; hence $u \in \mathcal{P}_{25,\alpha+1}$. If the convergence is only locally uniform, first restrict to a relatively compact open neighbourhood. Sheafification and limit ordinals are treated by restriction to the corresponding local representations. Equality at stage one is Proposition 11.2.3. □

Local integrability behaves differently under the order relation defining a decreasing limit. If u is locally integrable, v is upper semicontinuous, and $u \leq v$, then on a compact set where $v \leq M$ one has

$$|v| \leq |u| + \max(M, 0) \quad \text{almost everywhere.} \tag{11.6.4}$$

Thus v is integrable for each locally finite measure used in the definition. In CLD25 paragraph 5.7.2 this can be checked on skeletal cells with their Lebesgue measures, or against the specified locally bounded volume forms. It does not mean integrability against every arbitrary background current.

Proposition 11.6.7 (The locally integrable hierarchy)**.** *Let $\mathcal{I}_{25,\alpha}$ be the hierarchy obtained from the original smooth psh functions by the same local decreasing-limit and limit-ordinal operations as $\mathcal{P}_{25,\alpha}$, but retaining only locally integrable functions and requiring locally integrable endpoints. Then, for every ordinal α,*

$$\mathcal{I}_{25,\alpha} = L^1_{\mathrm{loc}} \cap \mathcal{P}_{25,\alpha}. \tag{11.6.5}$$

These are classes of actual functions; the order and limits are pointwise, not operations on equivalence classes modulo null sets. Moreover, if $u_j \downarrow u$ are generated psh functions and u is locally integrable, then every u_j is locally integrable and $u_j \to u$ in local L^1 for each of the measures in that definition.

Proof. This is the argument of CLD25 Proposition 8.1.12, with the inherited integrability made explicit. The inclusion from left to right in (11.6.5) follows from the construction. For the reverse inclusion, use induction on α. At a successor stage, write a locally integrable u locally as $u_j \downarrow u$ with $u_j \in \mathcal{P}_{25,\alpha}$. The functions u_j are upper semicontinuous and bounded above on compact sets. Since $u \le u_j$, estimate (11.6.4) shows that each u_j is locally integrable. The induction hypothesis puts them in $\mathcal{I}_{25,\alpha}$, so their locally integrable endpoint belongs to $\mathcal{I}_{25,\alpha+1}$. The zero and limit stages follow directly from the definitions and locality.

For the convergence assertion, work on a compact set for one of the defining measures. The nonnegative integrable function $u_1 - u$ dominates $u_j - u$, which decreases to zero almost everywhere. Dominated convergence gives

$$\int |u_j - u| \, d\mu \longrightarrow 0.$$

Apply this on the local cells or to each required volume measure. Thus the currents $[u_j]$ converge to $[u]$ against the original smooth tests wherever these currents are defined, as used in Proposition 11.2.4. No continuous predecessor replacement is needed. □

Remark 11.6.8 (Consequences for the approximation audit). The compact barrier theorem resolves the transfinite selection problem when one common compact representation is supplied. It does not prove that sheaf-generated sections admit such a representation. The indexed inclusion and the locally integrable equality above are valid without that representation. Consequently, the gap identified in Proposition 8.1.11 does not invalidate Proposition 8.1.12 or the locally integrable current-positivity argument. Neither local L^1 convergence nor membership in a generated class alone defines products of unbounded potentials with arbitrary currents. Such products require their own integrability and continuity statements.

References. CLD25 v2, paragraph 5.7.2, Definitions 8.1.1 and 8.1.7, Lemmas 8.1.4, 8.1.8 and 8.1.10, Propositions 8.1.11–8.1.12. The compact hierarchy and its barrier proof are elementary deductions stated separately from the source's sheaf hierarchy. The indexed forward inclusion and the L^1 equality expand valid portions of the source argument; no counterexample to its continuous equality is asserted.

11.7 Envelope methods and bounded localization

The compact argument of Section 11.6.1 leaves a geometric question: how can approximants on different local domains be compared on one neighbourhood? A projective ambient space provides another route. One first extends bounded local potentials to a common global background, uses an envelope comparison there, and then restricts back. This section gives the order estimates needed for that route and identifies the additional theorems it uses.

11.7.1 Three classes in the recent local theory

We fix the preprint [Wu26], arXiv version 1 of 23 September 2026. Its local theory is formulated on opens in algebraic analytifications over a complete discretely or trivially valued field. Write $\mathcal{P}_W$ for its class of decreasing limits of tropically convex PL functions, and $\mathcal{R}_W$ for its smooth-approximable class. These are first-stage local approximation conditions. They must be distinguished from the sheaf $\mathcal{P}_{25}$ obtained by iterating decreasing limits and localization.

For the comparisons below we use locally bounded functions. They are finite, so the exclusion of functions identically $-\infty$ on a component causes no ambiguity. The smooth generators are the original CLD generators; re-

placing them by weakly smooth or harmonic-chart generators would change the comparison.

Class	Local requirement	Relevant source
$\mathcal{P}_W$	One decreasing PL sequence on one open neighbourhood	[Wu26], Definition 3.8
$\mathcal{R}_W$	One decreasing original s-mooth convex sequence	[Wu26], Definition A.1
$\mathcal{P}_{25}$	The generated sheaf, includ-ing further decreasing limits	[CLD25], Definition 8.1.1

Theorem A.3 of [Wu26] asserts $\mathcal{P}_W = \mathcal{R}_W$. Corollary 4.18(1) supplies decreasing-limit stability of $\mathcal{P}_W$ when the projective ambient variety has the envelope property. Remark A.2 explicitly retains this hypothesis in the comparison with the generated CLD definition. These are substantial source inputs, not consequences of the terminology "psh". Their implication for continuous generated functions is proved in Section 11.7.4.

In the convex terminology here, the supporting affine function touches the function at the point. Example A.8.1 records a defect in the source's displayed definition and its repair. For the explicit rational-generator class of Section 11.9.1, Theorem 11.9.5 supplies one direction of approximation independently of Theorem A.3, over a nontrivially valued field.

11.7.2 Continuous obstacles on a compact space

An envelope argument needs continuous majorants of a local potential. Compactness alone does not make every upper semicontinuous function a decreasing limit of a sequence of continuous functions on an arbitrary Hausdorff space. The local approximation hypothesis supplies precisely the missing information here.

Lemma 11.7.1 (Continuous majorants from local sequences)**.** *Let X be compact Hausdorff and let $u : X \to \mathbf{R}$. Suppose every point has an open neighbourhood on which u is a decreasing limit of finite continuous functions. Then there are $F_j \in C(X, \mathbf{R})$ with $F_j \downarrow u$ pointwise on X. No metrizability assumption is needed.*

Proof. Choose a finite open cover $U_1, \dots, U_r$ with continuous sequences $u_{i,j} \downarrow u|_{U_i}$. By normality of a compact Hausdorff space, choose a continuous par-

tition of unity ρ_i with $\operatorname{supp}\rho_i \subset U_i$. Extend $\rho_i u_{i,j}$ by zero outside U_i and put

$$F_j = \sum_{i=1}^{r} \rho_i u_{i,j}.$$

Each summand is continuous: its support stays inside its defining open set. Nonnegative coefficients give $F_{j+1} \le F_j$. At every point only finitely many terms occur, and their limit is $\sum_i \rho_i u = u$. □

The functions F_j are continuous obstacles; the proof does not assert that they are psh. Applying a partition of unity directly to psh potentials would introduce uncontrolled derivatives of the coefficients. Positivity is recovered by an envelope, under the following explicit hypotheses.

Proposition 11.7.2 (The bounded envelope comparison)**.** *Fix a projective ambient space and an ample semipositive model background ω. Let $\mathscr{G}_\omega$ and $\mathscr{L}_\omega$ be respectively its global and local classes of bounded ω-psh potentials, with $\mathscr{G}_\omega \subset \mathscr{L}_\omega$. Assume the following inputs:*

1. *Every $u \in \mathscr{L}_\omega$ is locally a decreasing limit of continuous functions.*
2. *For $F \in C(X^{\mathrm{an}}, \mathbf{R})$, the envelope $P_\omega F$ is a continuous member of $\mathscr{G}_\omega$, satisfies $P_\omega F \le F$, and its Monge–Ampère measure is supported on $\{P_\omega F = F\}$.*
3. *Domination holds: for $u \in \mathscr{L}_\omega$ and $v \in \mathscr{G}_\omega$, the inequality $u \le v$ almost everywhere for $\mathrm{MA}_\omega(v)$ implies $u \le v$ everywhere.*
4. *$\mathscr{G}_\omega$ is closed under decreasing limits with bounded endpoints.*

Then $\mathscr{L}_\omega = \mathscr{G}_\omega$.

Proof. Take $u \in \mathscr{L}_\omega$. Lemma 11.7.1 gives $F_j \downarrow u$ with F_j continuous. Put $p_j = P_\omega F_j$. The definition of an envelope is order preserving, so $p_{j+1} \le p_j$. On the support of $\mathrm{MA}_\omega(p_j)$ one has $u \le F_j = p_j$. Domination gives $u \le p_j$ on the whole space. Thus

$$u \le p_j \le F_j, \qquad p_j \downarrow u.$$

The endpoint is bounded, so the last hypothesis gives $u \in \mathscr{G}_\omega$. □

This is the bounded part of the mechanism in [Wu26], Theorem 4.17. Envelope continuity, orthogonality, and domination remain imported inputs;

none follows from Lemma 11.7.1. The lemma makes the continuous-obstacle construction independent of a countable dense subfield. It does not remove countability hypotheses from other theorems in that paper.

11.7.3 An order-preserving extension on a fixed neighbourhood

The next construction explains why the global comparison is relevant to a local decreasing sequence. The extensions must preserve order; choosing an unrelated global extension for every term would not suffice. We use a local potential class closed under finite maxima, positive scaling and addition of constants. Model backgrounds in this subsection are curvature classes of metrics, not automatically original smooth CLD forms.

Proposition 11.7.3 (A fixed bounded extension formula)**.** *Let X be projective. Let ω, θ be semipositive model backgrounds on the same $\mathbf{Q}$-line bundle, admitting local psh potentials in the chosen class, and choose a global continuous PL function b with $\theta = \omega + d'd''b$. On an open $Y \subset X^{\mathrm{an}}$ let v be a continuous psh potential of θ. Assume*

$$Q = \{v \le 0\} \Subset Y \cap U, \qquad P = \{v \le -\epsilon\}, \qquad x \in \mathrm{Int}(P), \qquad \epsilon > 0,$$

where U is an open set on which the local potentials will be given. Fix $M > 0$ and a positive rational number A with $A\epsilon > 2M + 1$, and set $h = Av + M + 1$. For any psh u on U with $|u| \le M$ on Q, define

$$\Psi(u) = \begin{cases} \max\{u - h, 0\}, & \text{on } Q, \\ 0, & \text{on } X^{\mathrm{an}} \setminus Q, \end{cases} \qquad \Phi(u) = A^{-1}\Psi(u) + b. \quad (11.7.1)$$

Then $\Phi(u)$ is a bounded local ω-psh potential. On the same open neighbourhood $V = \mathrm{Int}(P)$ of x, for all such u,

$$\Phi(u) + g = A^{-1}u, \qquad g = v - b + A^{-1}(M + 1). \quad (11.7.2)$$

The map Φ preserves order and decreasing pointwise limits within this bounded family. Moreover,

$$\|\Phi(u) - \Phi(w)\|_{X^{\mathrm{an}}} \le A^{-1}\|u - w\|_Q. \quad (11.7.3)$$

Proof. On P one has $h < -M \le u$. On the compact collar $C = \{-1/(2A) \le v \le 0\}$ one has $h \ge M + 1/2 > u$. Consequently $\Psi(u)$ vanishes on a neighbourhood of the boundary of Q, and the piecewise formula is well defined without a boundary jump. On $\mathrm{Int}(Q)$,

$$\Psi(u) + h = \max\{u, h\}$$

is psh. Outside a smaller compact sublevel set, $\Psi(u) = 0$. Since θ is semi-positive with admitted local potentials, these statements show that $\Psi(u)$ is locally $A\theta$-psh. After scaling and changing the background,

$$\omega + d'd''\Phi(u) = \theta + A^{-1}d'd''\Psi(u) \ge 0$$

in the local-potential sense. Boundedness follows from the bounds on u, continuity of h on Q, and continuity of b on the compact space. On P the maximum selects $u - h$, which proves (11.7.2). Finally, the scalar map $t \mapsto \max(t - h, 0)$ is increasing, continuous, and 1-Lipschitz. This proves the order, limit, and norm assertions using the same A, h, b throughout. □

Lemma 11.7.4 (One collar for a whole decreasing tail)**.** *In the preceding setting, suppose u_j are finite upper semicontinuous functions on U with $u_j \downarrow u$ and $|u| \le M$ on Q. Then, for all sufficiently large j, $u_j < h$ on the fixed collar C. If the u_j are continuous, their extensions by (11.7.1) are continuous for this entire tail. On P the identity (11.7.2) holds for every j.*

Proof. The open sets $\{u_j < M + 1/4\}$ increase and cover the compact set C, since $u \le M$. One index therefore works on all of C, and every later index works as well. There $u_j < M + 1/4 < h$. On P, the inequalities $u_j \ge u \ge -M > h$ give the claimed identity. □

These formulas reconstruct the bounded localization mechanism of [Wu26], Proposition 3.28, while recording the background change and the common collar. The existence of the projective barrier data is a separate geometric input, constructed for integral projective varieties in Theorem 11.8.9. In a weighted Fubini–Study presentation its local shape can be

$$v = \max\{-a, \ell_1, \dots, \ell_r\}, \qquad a > \epsilon > 0, \quad \ell_i(x) < -\epsilon. \tag{11.7.4}$$

Here the ℓ_i are normalized logarithmic section ratios with their weights, and the outer sublevel set must be chosen compactly inside U. The negative

constant branch is essential. A formula $\max\{0, \ell_1, \dots, \ell_r\}$ is nonnegative and cannot satisfy $v(x) < 0$. Also, equality of underlying line bundles does not identify their model backgrounds; the term b in (11.7.1) performs the required conversion.

11.7.4 What bounded decreasing stability would settle

We now isolate a sufficient input that is weaker than constructing the raw compact representation of Corollary 11.6.5. Let $\mathcal{R} = \mathcal{P}_{25,1}$ denote the original first-stage sheaf, allowing discontinuous functions.

Theorem 11.7.5 (Bounded stability implies collapse of continuous stages)**.** *Assume that on every open set a decreasing sequence of locally bounded sections of $\mathcal{R}$, whose endpoint is locally bounded, again has its endpoint in $\mathcal{R}$. Then*

$$\mathcal{P}_{25} \cap L^{\infty}_{\mathrm{loc}} = \mathcal{R} \cap L^{\infty}_{\mathrm{loc}}. \tag{11.7.5}$$

For every ordinal $\alpha \geq 1$, one moreover has

$$\mathcal{C}_{25,\alpha} = C^0 \cap \mathcal{P}_{25,\alpha} = \mathcal{U}. \tag{11.7.6}$$

All boundedness conditions here concern actual pointwise functions.

Proof. We prove by induction on α that each locally bounded section of $\mathcal{P}_{25,\alpha}$ belongs to $\mathcal{R}$. This holds at stage zero. At a successor stage, work on an open set where $u_j \downarrow u$, with $u_j \in \mathcal{P}_{25,\alpha}$ and u locally bounded. Since $u_j \geq u$ and u_j is upper semicontinuous with no value $+\infty$, every u_j is locally bounded. The induction hypothesis puts every predecessor in $\mathcal{R}$. The assumed bounded decreasing stability now applies on this open set. At a limit ordinal use the local earlier-stage representations and the sheaf property of $\mathcal{R}$. This proves (11.7.5).

A finite continuous $u \in \mathcal{P}_{25,\alpha}$ is locally bounded, hence belongs to $\mathcal{R}$. Dini's argument on a smaller relatively compact neighbourhood turns its decreasing smooth approximation into local uniform approximation. Thus $u \in \mathcal{U}$. Conversely, $\mathcal{U} = \mathcal{C}_{25,1}$ by Proposition 11.2.3, and the continuous hierarchy is increasing. Combine these inclusions with Proposition 11.6.6 to obtain (11.7.6). □

The hypothesis is a genuine stability statement on a common open set. It does not follow merely by choosing a separate regularization neighbourhood

for each predecessor. Once it is known, no additional ordinal estimate is needed for continuous functions: all positive stages already coincide. This strengthens the earlier repair plan, which treated ordinal control as a further possible task.

11.7.5 The projective scope and its source dependencies

Corollary 11.7.6 (Application of the envelope comparison inputs)**.** *Let K be complete and discretely or trivially valued, let X be projective over K, and suppose X has the envelope property over K in the sense of [Wu26]. Import Theorem A.3 and Corollary 4.18(1) of that source, with its comparison of analytic and algebraic smooth generators. Then on opens of X^{an}, the conclusions* (11.7.5) *and* (11.7.6) *hold.*

Proof. For locally bounded functions, Theorem A.3 identifies $\mathcal{R}$ with $\mathcal{P}_W$. A locally bounded decreasing endpoint is generically finite, so Corollary 4.18(1) gives the bounded stability assumed in Theorem 11.7.5. Apply that theorem. □

Wu's Theorem 7.1 supplies the envelope property for projective geometrically unibranch varieties over discretely or trivially valued fields of equicharacteristic zero; normal projective varieties are included. Accordingly, this is a source-dependent route to the continuous-stage comparison in that category. The paper's Fornæss–Narasimhan step, Theorem 6.5, includes a countable-dense-subfield hypothesis; the proof of Theorem 7.1 contains a further descent argument to remove it. Neither hypothesis nor descent step should be suppressed when reconstructing that proof.

Remark 11.7.7 (What has been proved here and what is imported). The continuous-majorant lemma, the fixed extension estimates, and the transfinite bounded-stability implication have complete proofs above. The projective corollary uses the indicated preprint theorems. It is not an independent reconstruction of the full proof of Theorem A.3, the domination principle, or the envelope theorem. In particular, Appendix A of [Wu26] invokes two Amini–Piquerez–Wu preprints and passes from approximation of generators to approximation classes. Section 11.8 matches the localization and PL-approximation locators, corrects a false whole-domain inequality, and proves fixed-domain estimates. The general generator-to-class passage and the separate mixed-calculus input remain to be verified.

The general analytic question from Proposition 8.1.11 remains separate. The cited envelope theorem does not cover arbitrary complete fields or arbitrary Berkovich spaces; in particular, its equicharacteristic-zero statement is not a theorem for every finite extension of $\mathbf{Q}_p$. Nor does a comparison of functions establish an arbitrary-background-current Bedford–Taylor calculus. The next task is to verify the source comparison chain in the projective category, while retaining bounded first-stage stability as the precise remaining input outside it.

References. Wu, arXiv:2609.27610v1, Definitions 3.8 and A.1, Proposition 3.28, Theorem 4.17, Corollary 4.18, Theorems 6.5 and 7.1, Remark A.2 and Theorem A.3. The present bounded extension is a corrected reconstruction of the localization mechanism; the continuous-majorant and transfinite arguments are elementary deductions. The external comparison theorems remain attributed inputs.

11.8 Common domains in local approximation

A comparison of generators becomes a comparison of first-stage classes only when the approximations can be made on one neighbourhood. We first give the required diagonal argument. We then reconstruct two localization procedures that produce such neighbourhoods: one on a tropical compactification and one on a projective analytic space. The tropical argument also identifies an incorrect extra inequality in the printed source. The local conclusion survives after a precise restriction of its domain.

11.8.1 A diagonal sequence on a prescribed domain

Lemma 11.8.1. *Let V be a fixed set, let $u_j : V \to \mathbb{R}$ decrease pointwise to $u : V \to \mathbb{R} \cup \{-\infty\}$, and let $\mathcal{D}(V)$ be a class stable under addition of rational constants. Suppose that, for every $j \geq 1$, there is $a_j \in \mathcal{D}(V)$ with*

$$\|a_j - u_j\|_V \leq \epsilon_j, \qquad \epsilon_j = 4^{-j}.$$

Then $b_j = a_j + 2\epsilon_j$ belongs to $\mathcal{D}(V)$ and decreases pointwise to u on this same V.

Proof. The errors give

$$u_j + \epsilon_j \leq b_j \leq u_j + 3\epsilon_j, \qquad b_{j+1} \leq u_{j+1} + 3\epsilon_{j+1} \leq u_j + \epsilon_j \leq b_j.$$

The first pair of inequalities gives the pointwise limit, including at points where $u = -\infty$. No boundedness of u and no continuity of the endpoint are required. □

Proposition 11.8.2 (A sufficient criterion for transferring first-stage classes)**.** *Let $\mathcal{A}$ and $\mathcal{B}$ be classes of finite continuous functions on ordinary open sets of a locally compact Hausdorff space, stable under restriction, and suppose $\mathcal{B}$ is stable under addition of rational constants. Assume that whenever $V \Subset U$ are open and $a \in \mathcal{A}(U)$, then for every $\delta > 0$ there exists $b \in \mathcal{B}(V)$ with $\|a - b\|_V < \delta$. Every function locally given by a decreasing sequence of $\mathcal{A}$-functions is then locally given by a decreasing sequence of $\mathcal{B}$-functions. Any separate endpoint condition, such as generic finiteness, is unchanged.*

Proof. At a point x, choose a representation $u_j \downarrow u$ on one open U. Choose $x \in V \Subset U$ once. The hypothesis gives an approximation to $u_j|_V$ with error at most 4^{-j} for every j, without changing V. Lemma 11.8.1 applies. □

The hypothesis is stronger than approximation near each point of each individual generator. From statements with domains V_j depending on j, one cannot simply form $\bigcap_j V_j$ and call it a neighbourhood. For example, the neighbourhoods $(-1/j, 1/j)$ of zero have intersection $\{0\}$. This logical distinction identifies a missing justification; it is not by itself a counterexample to equality of the two function classes.

Corollary 11.8.3 (Decreasing finite logarithmic maxima)**.** *Let V be an ordinary open set of a good analytic space in the original CLD category. Suppose u_j decreases pointwise on V and each term has a finite presentation*

$$u_j = \max\{c_j,\ a_{j1} \log |f_{j1}| + d_{j1}, \dots, a_{jr_j} \log |f_{jr_j}| + d_{jr_j}\}, \quad a_{ji} > 0,$$

where f_{ji} are analytic on all of V and c_j, d_{ji} are real constants. There is one decreasing sequence of original smooth psh functions on V with the same pointwise limit. Different terms may use different analytic functions; these functions may have zeros.

Proof. For each j, regularize its finite maximum by the compactly supported regularized maximum used in Theorem 20.8.1. The constant branch makes u_j finite and continuous. At a zero of one of the f_{ji}, its logarithmic branch tends to $-\infty$ and is strictly below the constant branch on a neighbourhood. Exact deletion of inactive coordinates makes the regularization smooth there. At

other points the surviving functions are analytic units, and convexity of the regularized maximum gives a positive Hessian in a moment chart. The local formulas agree by exact deletion. Thus they define a smooth psh function on all of V, with a uniform error bounded by the regularization parameter. Choose that parameter at most 4^{-j} and apply Lemma 11.8.1. □

This is a common-domain result for the displayed presentations. It does not assert that an arbitrary locally tropically convex PL function has one such presentation on an arbitrarily prescribed open set. Log-sum-exp alone would not justify smoothness at zeros; the exact-deletion property is the reason for using this regularization. The unit-only formula in Theorem 19.18.15 has no such zero issue.

11.8.2 The local affine support calculation

Lemma 11.8.4. *Let Π be a locally finite polyhedral complex in a finite-dimensional real vector space E, let $t \in |\Pi|$, and let W be an open neighbourhood of t. There is $r > 0$, depending only on Π, W, t, such that every cell meeting $B(t,r)$ contains t and $B(t,r) \subset W$. If $F \in C^1(W)$ is convex on $\sigma \cap B(t,r)$ for every cell σ, then*

$$F(z) \geq \ell_t(z), \qquad \ell_t(z) = F(t) + dF_t(z-t), \qquad z \in B(t,r) \cap |\Pi|. \quad (11.8.1)$$

In particular, the same radius works for any family satisfying these hypotheses for the same complex and open set.

Proof. Local finiteness gives a neighbourhood meeting only finitely many cells. Each of those not containing t is closed and has positive distance from t. A sufficiently small ball avoids all of them and lies in W. If z is in the remaining ball and in a cell σ, then $t, z \in \sigma$ and their segment lies in $\sigma \cap B(t,r)$. Apply the supporting-line inequality to the convex function $s \mapsto F(t + s(z-t))$ on $[0,1]$. Its right derivative at zero is $dF_t(z-t)$. □

The affine expression must be centred at t. Interpreting dF_t as a linear functional on E, the expression $dF_t(z) + F(t)$ generally fails to take the value $F(t)$ at $z = t$. Also, the cells here contain the tropical point $t = \mathrm{Trop}(x)$, not the analytic point x. These observations correct the notation in the supporting-affine-function step of Wu's Appendix A. They prove local support for a fixed polyhedral presentation, not ambient convexity on all of W.

11.8.3 A false global inequality and the local replacement

We fix [APW26], arXiv:2610.25602v1. Its Proposition 5.19 contains both a local extension assertion and the additional inequality $\varphi + g \geq Cf$ on the whole original open set U. Only the latter is contradicted by the following example.

Example 11.8.5 (Failure of majorization on all of U)**.** For every $n \geq 1$, take the projective tropical toric variety $X = (\mathbb{TP}^1)^n$, with dense stratum $X^\circ = \mathbb{R}^n$ and product fan. Set

$$g(t) = \sum_{i=1}^{n} |t_i|, \qquad U = (-1, 1)^n, \qquad f(t) = \frac{1}{1 - t_1} + \sum_{i=2}^{n} t_i^2.$$

The function g satisfies the positivity and conewise-linearity assumptions in that proposition, and f is smooth and strictly convex on U. Nevertheless, for $\omega = \partial\bar{\partial} g$, there are no $C > 0$ and $\varphi \in \mathrm{CPSH}_\omega(X)$ satisfying $\varphi + g \geq Cf$ throughout U.

Proof. The function g is convex, homogeneous, linear on each orthant, and positive away from zero. The Hessian of f is diagonal with entries $2/(1 - t_1)^3, 2, \ldots, 2$, hence positive definite. By Definition 4.3 of the source, every member of $\mathrm{CPSH}_\omega(X)$ is bounded. Since $g \leq n$ on U, the left-hand side of the proposed inequality is bounded above there. The right-hand side tends to $+\infty$ along $(t_1, 0, \ldots, 0)$ as $t_1 \uparrow 1$. This is impossible for $C > 0$. □

The printed proof first bounds f on an inner compact neighbourhood U' but then uses that bound to control the set where a global barrier lies below f on all of U. The example shows why that enlargement of the domain is invalid. The construction can instead be carried out on the inner neighbourhood alone. The following formulation makes the domain and all constants uniform for a bounded family.

Proposition 11.8.6 (Uniform tropical localization on an inner domain)**.** *Use the projective tropical toric setting and the bounded-growth correspondence of [APW26, Example 4.9]. Write $Y = X^\circ \subset E = \mathbb{R}^N$, let g be convex homogeneous PL with $g > 0$ away from zero, put $h = g|_Y$, and let $\omega = \partial\bar{\partial} h$. Fix $x \in Y$, an open $U \subset Y$, and $r > 0$ such that*

$$Q = Y \cap \overline{B}(x, r) \Subset U.$$

Fix $M > 0$. There are one neighbourhood V of x in Q and one $\lambda > 0$ such that every $f \in \mathrm{LConv}(U)$ with $|f| \le M$ on Q admits $\Phi_f \in \mathrm{CPSH}_\omega(X)$ satisfying

$$\Phi_f + h = \lambda^{-1} f \text{ on } V, \qquad \Phi_f + h \ge \lambda^{-1} f \text{ on } Q. \tag{11.8.2}$$

The assignment preserves order and is λ^{-1}-Lipschitz for the uniform norms on Q and X. If f is PL, the extension is PL in the source's category. No inequality is asserted on $U \setminus Q$.

Proof. Continuity on the unit sphere gives $c > 0$ with $g(z) \ge c\|z\|$. Choose λ with $\lambda cr > 2M + 2$ and put

$$g_x(y) = g(y - x), \qquad H = \lambda g_x - M - 1,$$
$$F_f(y) = \begin{cases} \max\{f(y), H(y)\}, & y \in Q, \\ H(y), & y \in Y \setminus Q. \end{cases}$$

On a fixed inner collar of ∂Q, the inequality $H > M$ holds, so the two formulas agree on a neighbourhood of that boundary. Thus F_f is continuous and locally convex on Y: use the maximum of locally convex functions inside, and H outside. On the fixed neighbourhood

$$V = Y \cap \{g_x < 1/(2\lambda)\} \subset \mathrm{Int}_Y Q$$

one has $H < -M - 1/2 < f$, so $F_f = f$. Set $\Phi_f = \lambda^{-1} F_f - h$ on Y. Outside Q this is $g_x - g - (M + 1)/\lambda$. A finite convex homogeneous PL function is globally Lipschitz, hence $|g_x - g| \le L\|x\|$. On Q boundedness follows from the hypotheses. Example 4.9 of the source therefore gives the bounded ω-psh extension to X. In the PL case, the translated background extends as a PL potential difference as in the proof of its Proposition 5.19; the modification has compact support in Y and is locally a maximum of PL functions. This preserves PL.

The two identities follow directly from the maximum. On Q, this maximum is increasing and 1-Lipschitz as a function of f; outside Q the extension is independent of f. The norm bound follows on Y, hence on X by continuity and density. These observations prove order preservation as well. If a decreasing family stays within the stated bounded class, the same formulas also commute with its pointwise limit. □

This proves the uniformity needed to localize a sequence already uniformly bounded on a prescribed compact tropical domain. Combined with the

source's uniform PL density theorem, it repairs the localization input in Proposition 5.21. That proof uses the local identity, not majorization on all of U. The correction consequently does not refute its local PL approximation conclusion. Neither the tropical extension nor uniform PL density, however, supplies the analytic pullback comparison invoked separately in Wu's Appendix A.

11.8.4 Projective Fubini–Study barriers

We now supply the geometric data assumed in Proposition 11.7.3, first as an explicit construction of weighted metrics. Let K be any complete non-Archimedean field, let X be an integral projective K-variety, and let L be ample. A $\mathbf{Q}$-line bundle is handled by first taking an actual tensor power. All topological neighbourhoods below are ordinary neighbourhoods in X^{an}.

Lemma 11.8.7 (An affine compact buffer)**.** *For $x \in U \subset X^{\mathrm{an}}$ with U open, there are $d > 0$, a nonzero $s \in H^0(X, L^d)$, the affine open $Y = D(s)$ containing x, finitely many $f_i \in K[Y]$, and rational constants c_i, such that*

$$\begin{aligned} K_0 = \{y \in Y^{\mathrm{an}} : |f_i(y)| \le e^{-c_i} \text{ for all } i\} \Subset U \cap Y^{\mathrm{an}}, \\ |f_i(x)| < e^{-c_i} \qquad \text{for all } i. \end{aligned} \tag{11.8.3}$$

Proof. A globally generated power of L has a section s_0 nonvanishing at x; its principal open $Y_0 = D(s_0)$ is affine. The topology of its analytification is generated by absolute values of regular functions, as in Section 2.10. Thus a finite intersection of strict inequalities $|p_i| < R_i$ and $|q_j| > r_j > 0$ contains x and is contained in $U \cap Y_0^{\mathrm{an}}$. On $Y = Y_0 \setminus \bigcup_j Z(q_j)$ the lower inequalities become upper inequalities for q_j^{-1}. This is again a principal affine open of the required type: clear the denominators of the finite product of the q_j using a power of s_0, then multiply its extending section by s_0 to ensure nonvanishing only inside Y_0. The resulting nonzero section of a power of L defines exactly Y.

Replace each strict upper bound by a closed bound strictly between the value at x and that upper bound. These bounds may be chosen in $\exp(\mathbf{Q})$, which is dense in $\mathbb{R}_{>0}$. Add bounds, again strict at x, for a finite set of algebra generators of $K[Y]$. Those latter bounds cut out the intersection of a closed polydisc with a closed affine embedding of Y, hence a compact affinoid domain; arbitrary positive radii are allowed. Intersecting with the other closed inequalities gives a compact subset K_0 of it. All original strict

inequalities hold on K_0, so $K_0 \subset U$. Their strictness at x supplies its ordinary interior neighbourhood. This argument applies also to a trivially valued field and to non-strict affinoid radii. □

Lemma 11.8.8 (One denominator for finitely many functions)**.** *Let s be a nonzero section of L^d on an integral projective variety, and let $f_1, \dots, f_m$ be regular on $Y = D(s)$. For every sufficiently large N, each $f_i s^N$ extends to a section of L^{dN} on X.*

Proof. Cover X by finitely many affine opens trivializing L^d. On such an open $\operatorname{Spec} A$, the section s is a nonzero element $a \in A$, and $f_i|_{D(a)} \in A_a$. Clearing the finitely many denominators gives a common exponent for every i and every open in the cover. The resulting local sections agree on the dense open $D(s)$ and hence on overlaps, since X is integral. They glue. A larger exponent is obtained by multiplication by a further power of s. This also justifies the denominator-clearing step in Lemma 11.8.7. □

Theorem 11.8.9 (A negative Fubini–Study barrier)**.** *In the projective setting above, given $x \in U$ there exist a rational-weighted finite Fubini–Study metric θ on L, an affine open $Y = D(s)$ containing x, and a continuous local weight v for θ on Y^{an} such that, for some $\epsilon > 0$,*

$$Q = \{v \le 0\} \Subset Y^{\mathrm{an}} \cap U, \qquad x \in \operatorname{Int}_{X^{\mathrm{an}}}\{v \le -\epsilon\}. \tag{11.8.4}$$

The weight is locally tropically convex and is locally uniformly approximable by original smooth psh functions. These assertions concern a metric and its local weights. Identifying its curvature with a model background in a narrower source category requires that category's Fubini–Study/model comparison.

Proof. Take Y, s, f_i, c_i, K_0 from Lemma 11.8.7. By Lemma 11.8.8, choose one N such that all $t_i = f_i s^N$ extend to sections of L^{dN} and that line bundle is globally generated. Choose a finite globally generating list $r_1, \dots, r_a$ of its sections. Every r_k/s^N is regular on Y. Choose rational b_k so negative that $\log|r_k/s^N|(x) + b_k < 0$, with $\log 0 = -\infty$. Choose also a rational constant $c_0 < 0$. On Y^{an} put

$$v = \frac{1}{dN} \max\left\{c_0,\ (\log|f_i| + c_i)_i, (\log|r_k/s^N| + b_k)_k\right\}. \tag{11.8.5}$$

This is the weight, relative to the nonvanishing section s^N of L^{dN}, of the metric

$$\theta = \frac{1}{dN} \max \left\{ \log |s^N| + c_0,\ (\log |t_i| + c_i)_i, (\log |r_k| + b_k)_k \right\}.$$

The last group of sections has no common zero, so this formula defines a continuous metric globally. Every branch of (11.8.5) is strictly negative at x, and the maximum is finite because of c_0. Hence $v(x) < 0$ and v is continuous. Choose $0 < \epsilon < -v(x)$; a neighbourhood of x then lies in $\{v < -\epsilon\}$. Moreover, $v \leq 0$ implies all inequalities defining K_0, so $Q \subset K_0$. The set Q is closed in Y^{an} and therefore closed in the compact set K_0. This proves the required compact containment.

Locally, branches vanishing at a point can be deleted because the constant branch dominates them nearby. The remaining branches are logarithms of analytic units with constants; their maximum is a convex PL function of moment coordinates. This proves local tropical convexity. Theorem 20.8.1, or its local exact-deletion argument, supplies the original smooth psh approximations. The construction uses rational weights but does not require those weights to belong to the value group, nor does it change the field. □

In the normalized discrete/trivial framework of [Wu26], Definition 2.3 admits these rational-weighted metrics; Proposition 2.4 is the cited model identification. Thus the theorem reconstructs the barrier geometry for integral projective varieties in that framework. If ω is the initial model background on L, let b be the difference of the constructed metric and the initial metric. It is a global continuous PL function there, and $\theta = \omega + d'd''b$. Inserting this b and (11.8.4) into Proposition 11.7.3 gives its extension formula on a fixed neighbourhood, with the required background correction. The geometric construction is proved here; the model identification is an explicitly attributed input. Reducible varieties and more general analytic spaces have not been added to this statement.

11.8.5 The remaining comparison input

The preceding results settle the quantitative diagonal step, bounded-family tropical localization and projective barrier geometry. Section 11.9 now assembles these with model approximation to obtain the PL-to-smooth direction on one ordinary neighbourhood, for its explicitly stated nontrivially valued rational-generator category. Proposition 11.22.14 supplies the smooth-to-PL

direction for one original smooth psh input in this projective setting. The common-domain passage for arbitrary sequences, identification of the full source generator class and extension to trivial valuation remain separate.

There is also a source dependency that cannot be replaced by the elementary constructions above. Wu invokes Theorem 6.13 of Amini–Piquerez–Wu, *Mixed differential calculus and Monge–Ampère equations on tropical varieties*. Both inspected bibliographies list it as a 2026 preprint without an identifier. A targeted search of the title and the authors' publication pages did not locate its primary full text in this revision. Accordingly, the analytic comparison assigned to that theorem is recorded as an unverified imported input. This is an access limitation, not evidence that the paper or theorem does not exist. Corollary 11.7.6 retains its explicit source-dependent status.

References. Wu26, Definitions 2.3 and A.1, Propositions 2.4, 2.11 and 3.28, and Appendix A, pp. 52–54; APW26, Definition 4.3, Example 4.9 and Propositions 5.19 and 5.21, fixed October v1. The counterexample and the common-domain estimates are proved here. Tropical bounded-growth extension and the indicated model comparison remain cited framework inputs.

11.9 From PL sequences to smooth sequences on one neighbourhood

The projective barrier of Section 11.8.4 can be chosen before the functions to be approximated. The bound of an individual function then affects only a scalar in the construction, not the final neighbourhood. Combining this observation with the known approximation of nef model metrics gives one direction of the local comparison without an envelope hypothesis. We state the coefficient and model conventions explicitly: arbitrary real PL weights cannot be identified with rational model metrics without a further argument.

11.9.1 The model-compatible class of generators

Throughout this section K is complete and nontrivially valued, its absolute value is fixed, and X is an integral projective K-variety of dimension at least one. Put $\Gamma = -\log|K^\times|$ and $\Gamma_{\mathbf{Q}} = \mathbf{Q}\Gamma$. For an ordinary open $U \subset X^{\mathrm{an}}$, write $\mathcal{G}(U)$ for the finite continuous functions which locally have the form

$$u = \max_{1\le a\le r}\left\{ c_a + \sum_{i=1}^{m} q_{ai}\log|f_i| \right\}, \qquad c_a \in \Gamma_{\mathbf{Q}}, \quad q_{ai} \in \mathbf{Q}, \tag{11.9.1}$$

where the f_i are analytic units on the neighbourhood in question. Presentations and neighbourhoods may vary with the point. This is the local convex rational PL class used below. It is stable under finite maxima, positive rational scaling, and addition of constants in $\Gamma_{\mathbf{Q}}$. Products of the finite lists of units give common moment charts for these operations.

Every such local presentation is uniformly approximable by original smooth psh functions on that neighbourhood: apply the regularized maximum to its affine branches. This assertion concerns a single presentation. It does not yet give a common approximation domain for a sequence of functions, each with its own covering by presentations. A finite convex PL function on an ordinary real open set has the displayed form after shrinking to a convex neighbourhood. At a boundary point of an extended tropical space, the reduction to finite coordinates is supplied for ambient convex PL functions in Section 11.10.1. The present theorem assumes (11.9.1); the relative-image class is discussed separately in Remark 11.10.10.

Lemma 11.9.1 (Positivity at a continuous endpoint)**.** *On an ordinary open set, suppose $u_j \in \mathcal{G}(U)$ decreases to a finite continuous function u. Then $d'd''[u]$ is positive against the original CLD compactly supported smooth tests.*

Proof. Local regularization of (11.9.1) gives positivity of $d'd''[u_j]$. For a fixed test η, Dini's lemma gives uniform convergence on its compact support. The smooth top-degree form $d'd''\eta$ defines a signed measure of finite total variation there, so

$$\langle d'd''[u_j], \eta\rangle = \langle [u_j], d'd''\eta\rangle \longrightarrow \langle [u], d'd''\eta\rangle.$$

Nonnegativity on positive tests passes to the limit. No smooth approximating sequence on a common neighbourhood has been used. □

We use two model-theoretic inputs. First, on a proper algebraic analytification, integral PL metrics are formal/model metrics; rational versions follow by taking a common tensor power on a finite cover. The model/formal/PL comparison is [GM, Theorem 1.1]. Constants in $\Gamma_{\mathbf{Q}}$ cause no extension of K: after a tensor power they are logarithms of absolute values of elements of K. Second, a model metric whose curvature current is positive on the whole projective analytification is nef. This is the model criterion in [CLD25, Corollary 18.8.8], with the residual mechanism recorded in Theorem 19.18.12 and Section 19.18.13. These are named geometric inputs. For the specific maximum weights below, Proposition 11.10.7 also supplies a route through Gubler–Künnemann functorial positivity and Gubler–Martin descent; its proof uses

the displayed generators and does not depend on the present approximation theorem.

11.9.2 A fixed barrier with variable scales

Lemma 11.9.2. *For $x \in U$, the data L, Y, v, Q, ϵ of Theorem 11.8.9 can be chosen so that all weights of the Fubini–Study metric θ lie in $\Gamma_{\mathbf{Q}}$. In particular θ is a rational model metric and $v \in \mathcal{G}(Y^{\mathrm{an}})$.*

Open proof obligation (RC2). Prove the value-group barrier in the stated scope; BE21 Theorem 5.14 is invoked.

Proposition 11.9.3 (Localization with a domain independent of the bound)**.** *Fix the preceding barrier, put $P = \{v \le -\epsilon\}$ and $V = \mathrm{Int}_{X^{\mathrm{an}}} P$, and let $u \in \mathcal{G}(U)$. Choose $M, \tau \in \Gamma_{\mathbf{Q}}$ with $M > 0$, $\tau > 0$, $|u| \le M$ on Q, and a rational $A > 0$ with $A\epsilon > 2M + \tau$. Then there is a nef rational model metric m_u on the fixed line bundle L whose weight w_u relative to the same power-section frame as v satisfies*

$$Aw_u + M + \tau = u \quad \text{on } V. \tag{11.9.2}$$

The neighbourhood V depends only on x, U, L and the chosen barrier. The numbers M, A may depend on u.

Proof. Define a global function by

$$\phi_u = \begin{cases} A^{-1}\max\{u - Av - M - \tau, 0\}, & \text{on } Q, \\ 0, & \text{on } X^{\mathrm{an}} \setminus Q. \end{cases} \qquad m_u = \theta + \phi_u. \tag{11.9.3}$$

Every boundary point of Q lies in $Y^{\mathrm{an}} \cap U$ and has $v = 0$. There $u - Av - M - \tau \le -\tau$. Continuity gives an open collar on which the maximum vanishes, so the formulas glue. The collar may depend on u, A, which is harmless: it is used only to construct this one global metric. Since u, v are locally rational PL with constants in $\Gamma_{\mathbf{Q}}$, the glued function is rational PL. The model/PL comparison stated above makes m_u a rational model metric.

On the interior of Q, its local weight is

$$w_u = v + \phi_u = \max\{A^{-1}(u - M - \tau), v\}.$$

Both branches, and their maximum on a common moment chart, are in $\mathcal{G}$. Outside the modification the metric is θ. Hence its curvature current

is positive everywhere. The quoted current/model criterion gives nefness; alternatively apply Proposition 11.10.7 directly to these weights. Finally, on P,

$$Av + M + \tau \leq -A\epsilon + M + \tau < -M \leq u,$$

so the first branch is active and (11.9.2) follows. □

Unlike Proposition 11.7.3, this proposition does not claim that the global extensions preserve the order of an entire family. Different scales usually destroy that order. Order is restored only after restricting the approximants to the fixed V. This is why a uniform bound for the whole family is unnecessary.

11.9.3 Global approximation and the fixed-domain diagonal

Proposition 11.9.4 (A known global approximation input)**.** *A nef rational model metric m on an ample line bundle over a projective K-scheme is a uniform limit of pure Fubini–Study metrics. Consequently, for every $\delta > 0$ it admits a global original smooth semipositive metric $\widetilde{m}$ with $\|\widetilde{m} - m\|_{X^{\mathrm{an}}} < \delta$. Here K is complete and nontrivially valued.*

Open proof obligation (RC2). Prove the required FS density for the nef classes and its exact hypotheses; BE21 Theorem 7.8 is invoked.

This approximation theorem is already in the literature. Its role here is to supply functions on all of Y^{an}, so that the local domains no longer depend on the generator being approximated. No envelope continuity theorem is used in this step.

Theorem 11.9.5 (One neighbourhood for a decreasing PL sequence)**.** *Let $u_j \in \mathcal{G}(U)$ decrease pointwise to $u : U \to \mathbf{R} \cup \{-\infty\}$. For every $x \in U$ there is one ordinary open neighbourhood V of x and original smooth psh functions b_j on V such that $b_j \downarrow u|_V$. Neither a uniform bound on the family (u_j) nor local boundedness or continuity of u is required. Any generic-finiteness condition imposed in the definition of the endpoint class is preserved.*

Proof. Choose the barrier and V once by Lemma 11.9.2. Fix $\tau > 0$ in $\Gamma_{\mathbf{Q}}$. Each u_j is continuous on the compact set Q, so choose its own $M_j \in \Gamma_{\mathbf{Q}}$ and rational $A_j > 0$ as in Proposition 11.9.3. This gives nef model metrics m_j on the same ample L, with weights w_j satisfying

$$u_j = A_j w_j + M_j + \tau \quad \text{on } V.$$

Put $\epsilon_j = 4^{-j}$. Apply Proposition 11.9.4 to m_j with error less than ϵ_j/A_j. Let $\widetilde{w}_j$ be the resulting smooth weight in the same power-section frame on Y^{an}. The function

$$a_j = A_j\widetilde{w}_j + M_j + \tau \quad \text{satisfies} \quad \|a_j - u_j\|_V < \epsilon_j.$$

It is original smooth and psh because $A_j > 0$. A power-section frame defines a normalized weight by dividing by its tensor exponent; it does not require a root of that section over K. Finally set $b_j = a_j + 2\epsilon_j$. Lemma 11.8.1 proves $b_j \downarrow u$ on this same V. □

Corollary 11.9.6. *Under the hypotheses of Theorem 11.9.5, if u is finite continuous, then u is locally uniformly approximable by original smooth psh functions. Thus the continuous endpoints of this PL first-stage class belong to $\mathcal{U}$.*

Proof. Shrink to a relatively compact neighbourhood inside V and apply Dini's lemma to the decreasing continuous functions b_j and their continuous limit. □

Remark 11.9.7. This combines Wu's localization mechanism, a model semi-positivity criterion, Gubler–Martin's PL/model comparison and Boucksom–Eriksson's approximation theorem. The explicit choices are a fixed neighbourhood and errors ϵ_j/A_j; no priority claim is made. Wu's convention $\mathbf{Z} \subseteq \Gamma_K$ places his rational constants in $\Gamma_{\mathbf{Q}}$. The ambient analytic generators are identified in Theorem 11.10.3; the relative finite-selection presentation is supplied in Theorem 11.12.5, with its explicit convention. Arbitrary real PL weights and trivial valuation are not covered.

11.9.4 First-stage comparison and further stability

Let $\mathcal{P}_{\mathcal{G}}$ be the local decreasing class generated by $\mathcal{G}$, with the same endpoint convention as the original smooth first-stage class $\mathcal{R}$. Theorem 11.9.5 proves $\mathcal{P}_{\mathcal{G}} \subseteq \mathcal{R}$. Corollary 11.24.4 now supplies the reverse inclusion in the same nontrivially valued integral-projective category, by rational replacement on a fixed affinoid. Thus $\mathcal{P}_{\mathcal{G}} = \mathcal{R}$ in this precisely specified first-stage sense.

The following sufficient criterion is retained for its stability implication. Generator membership and first-stage equality are no longer the missing steps in this setting. Closure under decreasing limits of arbitrary sections of

the resulting sheaf remains additional: their row domains may vary. Lemma 11.24.5 handles common-domain rows, but does not provide a common domain from termwise germ membership.

Proposition 11.9.8 (A sufficient stability criterion)**.** *Suppose every original smooth psh function locally belongs to $\mathcal{P}_{\mathcal{G}}$, and $\mathcal{P}_{\mathcal{G}}$ is closed under decreasing limits of its sections on ordinary open sets whenever the endpoint is allowed. Then $\mathcal{R} = \mathcal{P}_{\mathcal{G}}$. In particular, its bounded decreasing stability implies the continuous-stage equalities of Theorem 11.7.5.*

Proof. On a neighbourhood representing a section of $\mathcal{R}$, each smooth predecessor is a section of the sheaf $\mathcal{P}_{\mathcal{G}}$ by the first hypothesis. The second hypothesis places their decreasing limit there on that same open set. This proves the reverse inclusion; combine it with Theorem 11.9.5. Apply Theorem 11.7.5 for the last assertion. □

11.10 Convex PL generators at the extended tropical boundary

The logarithms in the presentation of $\mathcal{G}$ are logarithms of units. An analytic tropicalization, however, may be defined by functions with zeros, so its image meets the boundary of $\mathbb{T}^k$, where $\mathbb{T} = \mathbf{R} \cup \{+\infty\}$. We explain why this distinction disappears locally for finite ambient convex PL functions. The argument expands [Wu26, Remark 3.2]; it also makes precise the absolute-value estimate used in Remark 3.9 of that paper. The word ambient is essential: the defining function is given on an open subset of $\mathbb{T}^k$, not merely on a tropical image.

11.10.1 Finite affine selections and boundary factorization

We use the finite-valued convention of [Wu26, Definition 3.1(1)–(2)]. On an ambient open $\Omega \subset \mathbb{T}^k$, an affine function is a finite continuous function $\ell(t) = c + \sum_i a_i t_i$ for which every summand is finite; in particular $a_i = 0$ if Ω contains a point with $t_i = +\infty$. A finite PL function is locally a continuous selection from a finite list of such affine functions. Locally convex means that at every point there is a touching affine lower support on a neighbourhood. Thus the contact condition is $f(z) = \ell(z)$ and $f \geq \ell$ there, with the correction explained in Example A.8.1.

Lemma 11.10.1 (Eliminating infinite coordinates)**.** *Let $z \in \mathbb{T}^s \times \mathbf{R}^d$ have its first s coordinates infinite and its remaining coordinates equal to y. Let f be finite PL on an ambient open neighbourhood of z. There are $R \in \mathbf{R}$, an open ball $B \subset \mathbf{R}^d$ about y, and a finite continuous PL function F on B such that*

$$N = (R, +\infty]^s \times B, \qquad f|_N = F \circ p, \tag{11.10.1}$$

where p is the projection onto the last d coordinates. The affine pieces of F are obtained by deleting the first s coordinates from one local affine list for f. If $d = 0$, the conclusion is that f is constant on N.

Proof. Choose one open patch containing z on which f selects from finitely many affine functions $\ell_1, \dots, \ell_r$, and choose the product N inside that patch. Finiteness of each summand at z forces all coefficients of the first s coordinates to vanish. Write the remaining affine functions as L_a on B. For fixed $b \in B$, the continuous function f on the connected fibre $(R, +\infty]^s \times \{b\}$ takes values in the finite set $\{L_a(b) : 1 \le a \le r\}$. It is therefore constant on that fibre. Evaluation along any fixed section of p defines a continuous F, and $F(b)$ is one of the $L_a(b)$. This proves the factorization and the PL assertion. □

Independence of the infinite coordinates is not yet a maximum presentation. The following elementary real argument supplies that remaining step, and keeps the original affine coefficients.

Lemma 11.10.2 (From affine selection to a convex maximum)**.** *Let $B \subset \mathbf{R}^d$ be an open ball and let F be continuous, with $F(b) \in \{L_1(b), \dots, L_r(b)\}$ for affine $L_a(b) = c_a + \langle a_a, b\rangle$. Then F is Lipschitz on B, with constant $\max_a \|a_a\|$ for the Euclidean norm. If F has a local touching affine lower support at every point, it is convex and there is a nonempty subset $I \subseteq \{1, \dots, r\}$ such that*

$$F = \max_{a \in I} L_a \quad \text{on } B. \tag{11.10.2}$$

Proof. On a line segment in B, restrict the finite list of affine functions and discard identical restrictions. Distinct restrictions intersect at at most one point. Between these finitely many intersection points, continuity forces F to follow one affine restriction. Its slope on each interval is bounded by $\max_a \|a_a\|$ times the speed of the segment. Summing the interval estimates proves the Lipschitz bound.

At an interior breakpoint of the segment, a touching affine lower support has slope m satisfying $m_- \le m \le m_+$, where m_- and m_+ are the left and

right slopes of F. Hence the slopes never decrease. The restriction to every segment is convex, so F is convex on B.

Discard duplicate affine functions on B. The hyperplanes $L_a = L_b$ cut a dense open subset of B into finitely many chambers. On each chamber the selected affine function is fixed. Let I consist of the indices selected on some chamber. If $a \in I$, choose b in that chamber. For any $c \in B$ and sufficiently small $t > 0$, the point $b + t(c - b)$ remains in the chamber. Convexity gives

$$(1 - t)L_a(b) + tL_a(c) = F(b + t(c - b)) \leq (1 - t)F(b) + tF(c),$$

so $L_a(c) \leq F(c)$. Equality with one of these supporting pieces holds on every chamber and hence, by continuity, throughout B. This proves (11.10.2). For $d = 0$ both assertions are immediate. □

If the function f of Lemma 11.10.1 is locally convex, then F has the lower supports required by Lemma 11.10.2: fix finite values of the first s coordinates and restrict each local support to that slice. Thus a finite ambient convex PL function near a boundary point is a maximum of finitely many affine functions of the finite coordinates alone. No convex-extension theorem for a tropical variety enters this argument.

11.10.2 Analytic pullbacks and the value group

Fix the absolute value of K and put $\Gamma = -\log|K^\times|$, $\Gamma_{\mathbf{Q}} = \mathbf{Q}\Gamma$. In this subsection a compatible PL function has rational slopes and constants in $\Gamma_{\mathbf{Q}}$ in its local affine lists. This is a coefficient convention, not a normalization of the field.

Theorem 11.10.3 (Ambient analytic generators and $\mathcal{G}$)**.** *Let W be an ordinary open in a K-analytic space, let $g_1, \dots, g_k$ be analytic functions on W, and write $\operatorname{trop}_g = (-\log|g_1|, \dots, -\log|g_k|)$, with $-\log 0 = +\infty$. Suppose f is a finite compatible locally convex PL function on an ambient open $\Omega \subset \mathbb{T}^k$ containing $\operatorname{trop}_g(W)$. Then $u = f \circ \operatorname{trop}_g$ locally has the unit-logarithm maximum presentation (11.9.1).*

Conversely, if K is nontrivially valued, every germ with that presentation can be written as $H \circ \operatorname{trop}_h$ for analytic units $h_1, \dots, h_r$ and a finite compatible locally convex PL function H on all of $\mathbb{T}^r$. Consequently these global-ambient analytic generators and $\mathcal{G}$ define the same sheaf of germs.

Proof. Fix $x \in W$. Reorder the coordinates so that the functions vanishing at x are precisely the first s functions. Apply Lemmas 11.10.1 and 11.10.2 at $\mathrm{trop}_g(x)$. On a product neighbourhood N of that point,

$$f(t) = \max_{a \in I} \left(c_a + \sum_{i>s} a_{ai} t_i \right), \qquad a_{ai} \in \mathbf{Q}, \quad c_a \in \Gamma_{\mathbf{Q}}.$$

On the inverse image of N, shrink about x so that the remaining g_i are analytic units. Substitution gives (11.9.1), with $q_{ai} = -a_{ai}$. The functions that vanish at x have been deleted exactly, not assigned logarithmic values by a limiting convention. If all $g_i(x)$ vanish, the pullback is constant near x.

For the converse write $u = \max_a(c_a + \sum_i q_{ai} \log |f_i|)$ on a neighbourhood of x. Choose a positive integer m with $mq_{ai} \in \mathbf{Z}$ and put $h_a = \prod_i f_i^{mq_{ai}}$. Negative exponents are allowed because the f_i are units. Nontrivial valuation makes $\Gamma_{\mathbf{Q}}$ dense in $\mathbf{R}$. Choose $c_0 \in \Gamma_{\mathbf{Q}}$ with $c_0 < u(x)$ and shrink so that $c_0 < u$. Define

$$H(t_1, \dots, t_r) = \max\{c_0, c_1 - t_1/m, \dots, c_r - t_r/m\}, \tag{11.10.3}$$

where a branch with $t_a = +\infty$ contributes $-\infty$ to this maximum. At such a coordinate, the inequality $t_a > m(c_a - c_0)$ deletes that branch on a neighbourhood. The remaining branches are finite affine functions. More explicitly, cover each coordinate by $\mathbf{R}$ and $(m(c_a - c_0), +\infty]$; their finitely many product sets give finite affine presentations after the inactive branches are deleted. Thus H is finite continuous PL on all of $\mathbb{T}^r$, with the stated coefficients. On each such neighbourhood it is a maximum of affine functions and hence has touching lower supports. Finally $H \circ \mathrm{trop}_h = \max(c_0, u) = u$ on the chosen neighbourhood. No extension of K or change of its absolute value has occurred. □

Remark 11.10.4. Wu assumes $\mathbf{Z} \subseteq \Gamma_K$ for a nontrivially valued field in [Wu26, Section 2.1, p. 5]. Under that convention, the rational constants in Definition 3.1 belong to $\Gamma_{\mathbf{Q}}$, so the preceding theorem applies to the ambient analytic generators in Remark 3.9, after correcting the touching-support formula. For a fixed absolute value without this convention, rational constants need not lie in $\Gamma_{\mathbf{Q}}$; our theorem retains the actual value-group condition. The boundary factorization itself allows real coefficients, but the rational model argument of Section 11.9 does not thereby acquire real coefficients.

11.10.3 Approximation through zeros

At a zero of g, uniform control of $\log|g|$ is unavailable. The useful coordinates for perturbing the analytic functions are their absolute values. Boundary factorization provides precisely the needed regularity in these coordinates.

Proposition 11.10.5 (A local Lipschitz estimate in absolute values)**.** *Let f be any finite PL function with real affine pieces on an ambient open $\Omega \subset \mathbb{T}^k$. Define $D = (-\log)^{-1}(\Omega) \subset [0,+\infty)^k$, with $-\log 0 = +\infty$. Then $h = f \circ (-\log)$ is locally Lipschitz on D for the Euclidean distance. Its restriction to every compact subset $C \subset D$ is Lipschitz. Convexity is not required.*

Proof. Fix $r \in D$, with its first s coordinates zero and the rest positive. Lemma 11.10.1 makes h independent of the first s coordinates on a neighbourhood of r. For the remaining coordinates choose a neighbourhood on which $r_i \geq a > 0$ and the logarithmic image lies in the ball B of that lemma. The first part of Lemma 11.10.2 gives a Lipschitz constant L for F on B. Since

$$|\log r_i - \log r_i'| \leq a^{-1}|r_i - r_i'|,$$

the resulting local constant for h is at most L/a. If there are no positive coordinates, h is locally constant.

To pass to a compact C, take a finite cover by relative neighbourhoods on which these pairwise Lipschitz estimates hold. A Lebesgue number $\delta > 0$ ensures that two points of C at distance less than δ lie in one member of the cover. Use the largest of the finitely many local constants for these pairs. For the other pairs, use the bound $\operatorname{osc}_C(h)/\delta$. The maximum of the two constants works on all of C. □

Corollary 11.10.6. *Let C be compact. Suppose that continuous maps r_j, r from C to $[0,+\infty)^k$ satisfy $r_j \to r$ uniformly and $r(C) \subset D$. For all sufficiently large j, the compositions are defined and*

$$\|f \circ (-\log) \circ r_j - f \circ (-\log) \circ r\|_C \leq L_C \|r_j - r\|_C \longrightarrow 0 \qquad (11.10.4)$$

for a constant L_C independent of j. In particular, this applies to uniformly approximating tuples of absolute values of analytic functions, including at their zeros.

Proof. The compact image $r(C)$ has a compact neighbourhood inside the relatively open set D. Uniform convergence places all sufficiently large images $r_j(C)$ in that neighbourhood. Apply Proposition 11.10.5 there. □

This proves the change-of-coordinates estimate used in [Wu26, Remark 3.9]. It does not construct the algebraic approximants to the analytic functions: that is a separate approximation assertion on the specified rational domain. Once absolute-value approximants on a fixed compact domain are supplied, the displayed estimate transfers their error without taking logarithms at zeros.

11.10.4 Model semipositivity through functorial positivity

For these generators the model-nefness step also follows from the earlier work of Gubler–Künnemann and Gubler–Martin. The reason is stronger than positivity of a single current: the same maximum presentation survives pullback. This gives another route for the metrics constructed in Proposition 11.9.3.

Proposition 11.10.7 (A criterion for the constructed model metrics)**.** *Let K be complete and nontrivially valued, let X be a proper K-scheme, and let m be a rational model metric on a line bundle L. Suppose its local weights have the maximum presentation* (11.9.1)*. Then m is a nef model metric.*

Open proof obligation (RC2). Establish the model-nef criterion and its functoriality in the stated category; the proof uses GK19 and GM.

This proof uses the published model comparison and descent theorems as inputs; it does not re-prove their lifting arguments. The passage through C_K descends a numerical property of a model, rather than an equality of currents or representatives. The local regularizations and the final sequence of Theorem 11.9.5 are still constructed over the original K. The criterion is specific to weights with the displayed presentations and does not assert that arbitrary positive currents are functorially positive.

11.10.5 The resulting regularization statement

Corollary 11.10.8 (Decreasing ambient PL generators)**.** *Let K be complete and nontrivially valued, let X be an integral projective K-variety of positive dimension, and let $U \subset X^{\mathrm{an}}$ be ordinary open. Suppose the finite continuous functions u_j decrease pointwise to u, and that each u_j locally admits an ambient analytic presentation as in Theorem 11.10.3, with rational slopes and constants in $\Gamma_{\mathbf{Q}}$. Then near each $x \in U$ there is one ordinary open V and original smooth psh functions b_j on V with $b_j \downarrow u|_V$. The analytic functions in the presentations may have zeros; their charts and neighbourhoods may vary with both j and the point. If u is finite continuous, the convergence is uniform on compact subsets of V.*

Proof. Theorem 11.10.3 gives $u_j \in \mathcal{G}(U)$ for every j as a local membership assertion on the original U. Apply Theorem 11.9.5. Its projective barrier construction, not an intersection of countably many presentation neighbourhoods, provides the common V. The last assertion is Dini's lemma on each compact subset. □

A relative touching-support condition on a polyhedral set must be distinguished from ambient convexity even before passing to analytic spaces. The following example explains why a same-chart extension cannot be taken for granted.

Example 11.10.9 (Relative supports do not give a same-chart convex extension)**.** In $\mathbf{R}^2$, let Σ be the one-dimensional fan with primitive ray vectors

$$v_1 = (1,0), \quad v_2 = (0,1), \quad v_3 = (1,1), \quad v_4 = (-1,-1),$$
$$(w_1, w_2, w_3, w_4) = (1,1,1,2).$$

It is positively weighted and balanced. Define a continuous rational PL function on its support by $F(tv_3) = t$ for $t \geq 0$, and $F(tv_i) = 0$ for $i = 1, 2, 4$. At every point of $|\Sigma|$, F has an affine lower support touching on a relative neighbourhood. Nevertheless its germ at the origin is not the restriction of an ambient convex function on any open convex neighbourhood of the origin.

Proof. Balancing is the identity $v_1 + v_2 + v_3 + 2v_4 = 0$. The function is continuous at the origin and affine on each ray; it selects from 0 and $(x+y)/2$. At the origin, the constant zero function is a touching lower support. At a nonzero point a sufficiently small relative neighbourhood meets only its ray,

where either 0 or $(x+y)/2$ agrees with F. Suppose that a convex ambient extension $\widetilde{F}$ existed near the origin. For sufficiently small $t>0$, its midpoint inequality would give

$$t=\widetilde{F}(t,t)\le \tfrac{1}{2}\widetilde{F}(2t,0)+\tfrac{1}{2}\widetilde{F}(0,2t)=0,$$

a contradiction. The obstruction depends on the presentation. Indeed, take the balanced fan $\widetilde{\Sigma}$ in $\mathbf{R}^3$ with rays generated by $e_1,e_2,e_3,-e_1-e_2-e_3$, all of weight one. The integral linear map

$$A(x,y,z)=(x+z,y+z)$$

maps these generators to $v_1,v_2,v_3,2v_4$, respectively. It maps the supports homeomorphically, and its ray lattice indices give the weights $(1,1,1,2)$ on Σ. On the lifted support one has

$$F\circ A=\max\{z,0\}.$$

This is an ambient convex PL presentation after changing the fan. This calculation is polyhedral; Proposition 11.16.1 realizes it by analytic units over fields with $|2|=1$. □

Remark 11.10.10 (The remaining source-class interface). The ambient analytic generators of [Wu26, Remark 3.9] are now covered, with the stated coefficient convention and corrected convexity. Definitions 3.6–3.7 there instead use PL and convex functions on $\mathrm{Trop}(W)$, and the two properties may initially be presented in different charts. Such an image need not be ambient open. A general identification therefore needs a presentation theorem with any necessary changes of chart, not a presumed same-chart convex extension. Example 11.10.9 refutes that elementary extension shortcut; Section 11.16 supplies its analytic realization and a smooth psh variant, but no obstruction after changing tropicalization. The unit-chart PL identification and the relative-support positivity step are proved in Section 11.11. Section 11.12 completes the extended-image PL identification for its explicit relative finite-selection convention. The prescribed-affinoid reverse replacement and the comparison of four explicit first-stage classes are proved in Section 11.24.3. Source-category identification and sheaf-level decreasing closure remain separate before identifying the full classes in Theorem A.3.

11.10.6 A transfer for locally semipositive rational PL functions

There is another way to use the projective barrier without demanding an ambient maximum presentation for every generator. Assume directly that the rational PL generators are locally semipositive in the model sense. The maximum theorem of Gubler–Rabinoff then supplies the positivity of the patched metric. We record the precise synthesis because it isolates a potentially weaker interface for comparison with another local psh theory.

Write $\mathcal{S}_{\mathbf{Q}}(U)$ for the finite continuous $\mathbf{Q}$-PL functions on an ordinary open U whose residues are nef at every point, in the sense of [GJR, Proposition 7.1 and Definition 7.2]. Equivalently, locally a tensor power of the metric $\|1\| = e^{-h}$ is given on a strictly analytic neighbourhood by a nef formal model. The equivalence is the cited proposition; it is not deduced merely from positivity of $d'd''[h]$. Rational PL here uses logarithms of analytic units on a strict analytic domain cover, so constants in $\Gamma_{\mathbf{Q}}$ are admitted.

Theorem 11.10.11 (Fixed-domain transfer from locally nef PL generators)**.** *Let K be complete and nontrivially valued, let X be an integral projective K-variety of positive dimension, and let $U \subset X^{\mathrm{an}}$ be ordinary open. If $u_j \in \mathcal{S}_{\mathbf{Q}}(U)$ decreases pointwise to $u : U \to \mathbf{R} \cup \{-\infty\}$, then every $x \in U$ has one ordinary open neighbourhood V carrying original smooth psh functions $b_j \downarrow u|_V$. No uniform bound on the family and no local boundedness of the endpoint are required. For a finite continuous endpoint the convergence is uniform on compact subsets of V.*

Open proof obligation (RC2). Prove the transfer between nef, PL and approximated metrics in the original hypotheses; the proof uses the listed GM, GRPL and GJR inputs.

Every member of $\mathcal{G}$ is locally in $\mathcal{S}_{\mathbf{Q}}$: its affine unit-logarithm branches are rationally harmonic, and repeated application of the same maximum theorem preserves semipositivity. The new theorem therefore gives a second proof of the earlier transfer. More generally, it suffices to verify model compatibility and local semipositivity of a proposed source generator; an ambient convex extension is unnecessary for this route. Theorem 11.11.6 completes the semipositivity step whenever the function is already model-compatible PL; Proposition 11.11.5 verifies that membership for unit-chart relative presentations. Theorem 11.12.5 now supplies extended relative-image membership under its common-branch convention. The rational coefficient restriction also

remains substantive: [GRPL, the paragraph following Corollary 5.5] warns that maxima need not remain Λ-PL in the strict domain category for larger groups Λ.

For a single $h \in \mathcal{S}_{\mathbf{Q}}(U)$, apply Theorem 11.10.11 to the constant sequence $u_j = h$. This gives decreasing original smooth psh approximants near each point. The related [GRPL, Theorem 1.5] applies to semipositive real PL functions on a boundaryless strictly analytic space and gives uniform approximation by locally Fubini–Study functions. The present argument keeps rational coefficients and a projective ambient space, while handling a whole decreasing family on one neighbourhood and choosing original smooth approximants. The locally Fubini–Study conclusion and the original smooth conclusion should not be identified without the smoothing step. Likewise, [GRPL, Theorem 1.4] gives semipositivity of a pointwise limit only when that limit is still real PL; it does not supply the decreasing closure of an arbitrary generated psh class needed in Section 11.9.4.

11.11 Relative supports and the curvewise route to nefness

The obstruction in Example 11.10.9 concerns extension in a fixed tropical chart. It does not obstruct a different route: pull a touching affine support back to an analytic curve, use harmonic comparison there, and then apply the curve criterion for semipositive PL functions. The two steps to distinguish are positivity and membership in the model-compatible PL class. This section proves the positivity step even at extended tropical boundary points, and proves the PL identification when the presentation uses analytic units.

11.11.1 A lower-contact criterion on curves

We first isolate a comparison argument that requires no polyhedral subdivision and no differentiability. Harmonicity in this subsection is Thuillier harmonicity on smooth strictly analytic curves over a nontrivially valued field. We use its vector-space property, its local maximum principle, and the comparison definition of subharmonicity; precise modern references are [GRPSH, Sections 3.2–3.3 and Proposition 3.14].

Lemma 11.11.1 (Harmonic lower contacts)**.** *Let C be a smooth strictly analytic curve over a complete nontrivially valued field, and let $u : C \to \mathbf{R}$ be continuous. Suppose that every $z \in C$ has an open neighbourhood N_z and a harmonic function h_z on N_z such that*

$$h_z \le u \quad \text{on } N_z, \qquad h_z(z) = u(z). \tag{11.11.1}$$

Then u is subharmonic.

Open proof obligation (RC2). Establish the comparison for the pulled-back function on the analytic curve; GRPSH 3.1(3) used.

The contact inequality is used on a whole neighbourhood. Convexity on individual cells would not give it at a branching point. The proof also tests every interior point of D; no restriction to skeleton vertices or to a chosen collection of outgoing directions has been made.

11.11.2 Relative tropical supports, including zeros

Here is the exact relative interpretation used below. For a subset $S \subset \mathbb{T}^r$, a finite continuous $F : S \to \mathbf{R}$ has relative affine lower supports if for every $t \in S$ there is a relative open neighbourhood $O_t \subset S$ and an expression $\ell_t(s) = c + \sum_i a_i s_i$, with real coefficients, such that every summand is finite on O_t, $F \ge \ell_t$ there, and $F(t) = \ell_t(t)$. This is the corrected touching convention of Example A.8.1, now explicitly on the relative image. We do not silently extend a definition stated only for ambient opens to arbitrary subsets.

Theorem 11.11.2 (Relative supports give classical psh functions)**.** *Let K be any complete non-Archimedean field and W a K-analytic space. Suppose locally on ordinary opens that*

$$u = F \circ \tau, \qquad \tau = (-\log|g_1|, \dots, -\log|g_r|), \qquad g_i \in \mathcal{O}(W),$$

where F is finite continuous on $\tau(W)$ and has relative affine lower supports in the convention just specified. Then u is classically psh in the sense of [GRPSH, Definition 4.1]. The functions g_i may vanish; no PL assumption on F is needed.

Open proof obligation (RC2). Prove the curvewise test in the specified relative setting; the proof uses GRPSH Proposition 3.14.

Historical proof-local display withheld. (11.11.2)

Corollary 11.11.3 (Decreasing limits in the curvewise class)**.** *A pointwise decreasing sequence of functions covered by Theorem 11.11.2, all defined on the same ordinary open U, has a classically psh limit $u : U \to \mathbf{R} \cup \{-\infty\}$. The presentations may vary with the sequence index.*

Open proof obligation (RC2). Prove the relevant limit property inside the curvewise psh class; the proof applies GRPSH Proposition 4.2(4).

11.11.3 Identifying PL functions on a unit chart

We now impose the nontrivial valuation needed for the strict model theory. Put $\Gamma = -\log|K^\times|$ and $\Gamma_{\mathbf{Q}} = \mathbf{Q}\Gamma$. A rational affine expression has rational slopes and its constant in $\Gamma_{\mathbf{Q}}$. This coefficient condition is essential for the strict analytic domains in the proof.

Lemma 11.11.4 (Selection on a finite polyhedral image)**.** *Let $S \subset \mathbf{R}^r$ be the support of a finite rational $\Gamma_{\mathbf{Q}}$-polytopal complex. Let $F : S \to \mathbf{R}$ be continuous and satisfy $F(t) \in \{L_1(t), \dots, L_m(t)\}$ for finitely many rational affine expressions L_a. There is a finite rational $\Gamma_{\mathbf{Q}}$-polytopal subdivision of S on each of whose closed cells F equals one L_a.*

Proof. Subdivide every cell by all hyperplanes $L_a = L_b$. On the relative interior σ° of any resulting cell, two branches either agree identically or are everywhere distinct, and their order is fixed. At a point of σ°, distinct values have a positive separation, so continuity of F makes the chosen equivalence class of branches locally constant. The set σ° is connected; hence one branch is selected throughout it. Continuity extends the identity to σ. Finiteness and rationality follow from the finite hyperplane arrangement. This argument uses connected polyhedral cells, not connected fibres of the tropicalization. □

Proposition 11.11.5 (Relative unit-chart PL functions are model-compatible)**.** *Let X be a good strictly K-analytic space of pure dimension, with K complete and nontrivially valued. Suppose that, locally on ordinary opens W, a finite continuous function u has a presentation $u = F \circ \tau$, where $\tau = (-\log|g_1|, \dots, -\log|g_r|)$ for analytic units g_i on W, and F is locally a continuous finite selection of rational affine expressions on the relative image $\tau(W)$. Then u is Q-PL in the sense of [GJR, Definition 5.1]. No convexity is assumed.*

Open proof obligation (RC2). Prove the polyhedral image and analytic sheaf gluing required by the local presentation; GJR section 3.2 and 5.2(4).

11.11.4 Nef residues and the fixed-domain consequence

Theorem 11.11.6 (The relative-support model criterion)**.** *Let X be good and strictly analytic over a complete nontrivially valued K. Let u be an R-PL function in the GJR sense. If u has the relative-support presentations of Theorem 11.11.2, then its residue line bundle $L_u(x)$ is nef at every $x \in X$. In particular, on a pure-dimensional X, it suffices that u have both a unit-chart rational PL presentation as in Proposition 11.11.5 and a relative-support presentation. These two presentations need not use the same tropicalization.*

Open proof obligation (RC2). Prove the model-nef comparison and the residual criterion; GRPSH Theorem 4.3 and GRPL Proposition 5.1/Corollary 5.4.

There is a version-numbering discrepancy worth recording for citation. The proof of [GRPSH, Theorem 4.3] in arXiv:2506.13548v2 refers to Proposition 3.1 and Corollary 3.5 of its companion paper. In the fixed arXiv:2503.05513v1 consulted here, the corresponding statements are Proposition 5.1 and Corollary 5.4. We use the latter locators for that file; the discrepancy is bibliographic and does not invalidate the comparison theorem.

Corollary 11.11.7 (Relative generators on one final neighbourhood)**.** *Let X be integral projective of positive dimension over a complete nontrivially valued K, and let $U \subset X^{\mathrm{an}}$ be ordinary open. Suppose $u_j : U \to \mathbf{R}$ decrease pointwise to u, each u_j has the relative-support presentations above, and each u_j is Q-PL in the GJR sense. For every $x \in U$ there are one ordinary open neighbourhood $V \subset U$ and original smooth psh functions b_j on V decreasing to $u|_V$. It is enough to verify the Q-PL hypothesis by the local unit-chart presentations of Proposition 11.11.5. If u is finite continuous, convergence is uniform on compact subsets of V.*

Proof. Theorem 11.11.6 gives nef residues for every u_j. Apply Theorem 11.10.11. In that theorem the barrier and final neighbourhood are fixed before the sequence terms are extended; their bounds and scaling factors may depend on j. Consequently no intersection of countably many chart neighbourhoods is taken here. The last assertion is Dini's theorem on each compact subset. □

Example 11.11.8 (Cellwise affine does not suffice)**.** Choose $a \in K$ with $0 < |a| < 1$, and on the open annulus $|a| < |T| < |a|^{-1}$ put $u = -|\log|T||$. This function is Q-PL and affine on each of the two skeletal intervals separated by $|T| = 1$, but it is not subharmonic. Indeed, choose $r \in |K^\times|^{\mathbf{Q}}$ with $|a| < r < 1$. On the strict closed annulus $r \le |T| \le r^{-1}$, the constant harmonic function $H = \log r < 0$ agrees with u at both boundary points, whereas $u = 0 > H$ at the unit-radius Gauss point. Thus harmonic comparison fails. Equivalently, a touching affine lower support at the central tropical point would require a slope simultaneously at least 1 and at most -1.

Example 11.11.9 (A monomial inequality at a common zero)**.** In the closed unit bidisc $B = \mathcal{M}(K\langle X, Y\rangle)$ over a complete nontrivially valued field, put $D = \{|X| \le |Y|\}$. There is no rational domain R of B with $0 \in R \subset D$. In particular D is not a finite union of rational domains of B. This explains why the Laurent-domain step in Proposition 11.11.5 cannot simply be repeated with vanishing coordinates.

Proof. Write a rational domain containing 0 in the form $|f_i| \le r_i|g|$, where $r_i > 0$ and $g, f_1, \dots, f_m$ generate the unit ideal. Necessarily $g(0) \neq 0$, since otherwise all $f_i(0)$ would vanish. An analytic function nonzero at the K-rational point 0 has constant absolute value on some ordinary neighbourhood of 0: use $|f - f(0)| < |f(0)|$. For the finitely many f_i vanishing at 0, continuity makes $|f_i| < r_i|g(0)|$ after shrinking. Hence every such rational domain contains an ordinary neighbourhood of 0. But, for any $a \in K$ with $0 < |a| < 1$, the points $(a^n, 0)$ converge to 0 and lie outside D. This proves the claim. □

11.11.5 Two local proof repairs in tropical regularization

The reverse approximation direction leads back to [APW26, Proposition 5.21]. We record two elementary repairs in its surrounding convexity and localization arguments. They concern the stated auxiliary claim and a displayed zero set, not counterexamples to the intended regularization theorem.

Proposition 11.11.10 (The missing hypothesis in the interval claim)**.** *A continuous $g : [0, 1] \to \mathbf{R}$ with a touching affine lower support at every interior point is convex. If an affine ℓ also touches g from below on $[0, \epsilon)$ at 0, then $g \ge \ell$ on all of $[0, 1]$. The contact condition at 0 alone does not imply this conclusion.*

Proof. On any interval $[a,b] \subset [0,1]$, let H be the affine interpolant of the endpoint values. If $g-H$ had a positive maximum M, its maximum set would be a nonempty compact subset of (a,b). At a maximum point, subtracting H from a touching affine support gives an affine function with an interior local maximum, hence a constant. As in Lemma 11.11.1, the maximum set is therefore open as well as closed in $[a,b]$, a contradiction. Thus $g \le H$, which proves convexity. If $g(t) < \ell(t)$ for some $t > 0$, convexity gives, for $0 < s < \min(t, \epsilon)$,

$$g(s) \le (1 - s/t)g(0) + (s/t)g(t) < (1 - s/t)\ell(0) + (s/t)\ell(t) = \ell(s),$$

contradicting the lower support near 0. Without the interior hypothesis, $g(t) = t - 2t^2$ and $\ell = 0$ give a counterexample: $g \ge 0$ near 0, but $g(1) = -1$. □

The auxiliary interval claim printed in the proof of [APW26, Proposition 3.3], p. 23, states only the condition at 0. Its subsequent proof uses a support at an interior maximum point. The proposition's actual local-convexity hypothesis supplies exactly that missing condition, so the corrected claim above repairs this inference.

Lemma 11.11.11 (The strict-support zero set)**.** *Let Q be a compact Hausdorff space, $x \in Q$, and let A, B be continuous nonnegative functions with $A^{-1}(0) = \{x\}$ and $B(x) = 0$. For positive decreasing sequences $C_j, \delta_j \to 0$, put*

$$V_j = \{A < C_j B + \delta_j\} \subset Q.$$

Then $x \in V_j$, the closures are nested, and

$$\bigcap_j \overline{V_j} = A^{-1}(0) = \{x\}. \tag{11.11.3}$$

For every neighbourhood O of x, eventually $\overline{V_j} \subset O$.

Proof. Positivity of δ_j gives $x \in V_j$, and nonnegativity of B makes V_j decreasing. Continuity and the uniform bound give

$$\overline{V_j} \subset \{A \le C_j B + \delta_j\}, \qquad \|C_j B + \delta_j\|_Q \le C_j \|B\|_Q + \delta_j \longrightarrow 0.$$

Thus their intersection lies in $A^{-1}(0)$ and contains x. If the final assertion failed, the nonempty nested compact sets $\overline{V_j} \cap (Q \setminus O)$ would have a common point, contradicting (11.11.3). □

In [APW26, Proposition 5.10], put $g = \varphi + h$, let ℓ_g be its strict local affine support at x, and let ℓ_f support f. Shrink to a compact neighbourhood on which both support inequalities hold, and take

$$A = g - \ell_g, \qquad B = f - \ell_f.$$

The strict support gives $A^{-1}(0) = \{x\}$. Thus the displayed intersection in the proof on p. 37 must use $\{g - \ell_g \leq 0\}$, not $\{f - \ell_f \leq 0\}$. The latter can be the whole neighbourhood when $f = \ell_f$. The shrinking argument is valid with the corrected zero set. In addition, the maximum modification has the exact pointwise increment

$$\psi - \varphi = \max\{0, CB + \delta - A\}, \qquad 0 \leq \psi - \varphi \leq C\|B\|_Q + \delta. \tag{11.11.4}$$

Taking the right side at most ϵ and the modification set compactly inside the support neighbourhood makes the function equal to φ near its boundary. Hence it glues to φ outside. On $V = \{A < CB + \delta\}$ one obtains $\psi + h = Cf + \ell$, where $\ell = \delta + \ell_g - C\ell_f$. Preservation of the tropical psh class under this maximum and gluing is the separate cited input [APW26, Lemma 4.13]. We have repaired its localization calculation, not re-proved the entire tropical regularization theorem.

Remark 11.11.12 (The coefficient issue in local PL density). In [APW26, Sections 2.1.1, 2.1.4–2.1.5], rationality of a polyhedron constrains the normals of its defining half-spaces, while their constants may be real; the affine functions used for PL functions are real affine. Proposition 5.21 is stated for this PL class. It does not state that its approximants have rational slopes and constants in the value group of an independently chosen analytic field. This extra conclusion cannot be inferred from the word "rational" attached to the polyhedral structure.

For example, the real convex PL function $F(t) = \max(1 - \pi t, 0)$ is allowed in that polyhedral category. Over a field whose fixed additive value group is $\mathbf{Q}$, its pullback $\max(1 + \pi \log|T|, 0)$ on $\mathbf{G}_m^{\mathrm{an}}$ is not R-PL in the strict GJR category: the bend at $t = 1/\pi$ cannot occur in a finite strict polyhedral presentation. This is the example of [GJR, Example 5.3], applied to the present comparison. It does not disprove the existence of better approximants. It shows that a coefficient-preserving approximation theorem, or an explicit replacement argument, is required before using APW local density as a Q-PL/model input.

There is nevertheless a simple replacement on a bounded unit chart when an ambient convex maximum is already available. This distinguishes a coefficient issue from the separate problem of extending a relatively convex function off its tropical image.

Proposition 11.11.13 (Coefficient-controlled approximation on a bounded chart)**.** *Let K be complete and nontrivially valued, with $\Gamma = -\log|K^\times|$. Let $S \subset \mathbf{R}^r$ be bounded and*

$$F(t) = \max_{1\le a\le m}\{c_a + \langle v_a, t\rangle\}, \qquad c_a \in \mathbf{R}, \quad v_a \in \mathbf{R}^r.$$

There are convex maxima H_j of affine functions with slopes in $\mathbf{Q}^r$ and constants in $\Gamma_{\mathbf{Q}}$ such that $H_j|_S$ decreases uniformly to $F|_S$. Consequently, on a good strict analytic unit chart with bounded tropical image, the pullback of F has a decreasing uniform approximation by GJR Q-PL functions having relative affine lower supports. No change of the absolute value or extension of K is required.

Open proof obligation (RC2). Prove the analytic Q-PL assertion for the finite maxima. The coefficient approximation is in the withheld proof; the non-Stacks use is GJR 5.2(7).

The monotonicity is asserted on S, not on all of $\mathbf{R}^r$. Every point of a unit chart has a neighbourhood with bounded tropical image. Thus the proposition resolves the local coefficient problem for finite ambient convex maxima, including the irrational-bend example above. It does not supply such a maximum for an arbitrary relatively convex tropical function; Example 11.10.9 prevents that shortcut on a fixed chart.

11.11.6 What remains in the source comparison

Under the stated relative interpretation, Wu's convexity condition gives classical psh, and known Q-PL membership then gives nef residues. The unit-chart membership is proved above. With vanishing coordinates, the ambient connected-fibre proof of Lemma 11.10.1 does not apply directly. Section 11.12 supplies the missing strict G-local unit-log presentation using finite polyhedral strata, with explicit common-branch and coefficient hypotheses.

Proposition 11.22.14 proves the reverse original-smooth-to-PL comparison for a single input in the stated projective setting. The arbitrary-family comparison and first-stage decreasing closure remain open; Corollary 11.11.3

proves only classical closure. Full Wu Theorem A.3, CLD25 Proposition 8.1.11 and arbitrary-current mixed products are not established here. The primary text of mixed-calculus Theorem 6.13 remains unavailable and is not used.

11.12 Finite selections at the extended tropical boundary

The remaining PL identification in Section 11.11.6 can be settled for a precise relative finite-selection class. The missing ingredient is finiteness of the polyhedral strata of an analytic tropical image. It permits a function to forget the coordinates tending to infinity, even though the fibres of the projection need not be connected. We first prove that assertion as a statement about polyhedra, and then identify its analytic hypotheses.

11.12.1 A recession argument

A closed polyhedron is an intersection of finitely many closed affine half-spaces in a finite-dimensional real vector space; the empty set is allowed. For $P = \{v : Av \le b\} \neq \varnothing$, its recession cone is $\operatorname{rec}(P) = \{w : Aw \le 0\}$. Thus $v + \lambda w \in P$ for every $v \in P$, $w \in \operatorname{rec}(P)$ and $\lambda \ge 0$.

Lemma 11.12.1 (Simultaneous escape)**.** *Let $P \subset \mathbf{R}^s \times \mathbf{R}^d$ be a nonempty closed polyhedron, where $s > 0$, and suppose that its projection to the second factor is bounded. Exactly one of the following alternatives holds:*

1. *There is $(w, 0) \in \operatorname{rec}(P)$ with $w_i > 0$ for every i.*
2. *There is $M \in \mathbf{R}$ such that $\min_i t_i \le M$ for every $(t, y) \in P$.*

Proof. We use the elementary finite-dimensional Farkas alternative in the following form: if a linear functional c is nonpositive on $\{w : Aw \le 0\}$, then $c = \lambda^t A$ for some column vector $\lambda \ge 0$. Here is a brief justification. The cone generated by the rows of A is closed: in each nonnegative representation, a linear dependence can eliminate one positive coefficient, until its support is linearly independent. There are finitely many such supports; on a fixed independent support convergence of the represented vectors forces convergence of the coefficients. If c were outside this closed convex cone, separation would give w with $Aw \le 0 < c(w)$, a contradiction.

It follows that a linear functional unbounded above on a nonempty polyhedron $Q = \{v : Av \le b\}$ is positive on some recession vector: otherwise $c = \lambda^t A$ gives $c(v) \le \lambda^t b$ on Q. Apply this observation to

$$Q = \{(t, y, z) : (t, y) \in P,\ z \le t_i \text{ for all } i\}.$$

If alternative (2) fails, z is unbounded above on Q. Hence Q has a recession vector (w, v, a) with $a > 0$. The inequalities give $w_i \ge a$. Boundedness of the y-projection forces $v = 0$, proving (1). Conversely, a ray with every $w_i > 0$ makes $\min_i t_i$ unbounded. □

Theorem 11.12.2 (Factorization on a polyhedral tail)**.** *Let $B \subset \mathbf{R}^d$ be bounded and let $S \subset [R_0, +\infty]^s \times B$ be compact, with $s > 0$. For each $I \subset \{1, \dots, s\}$, assume that the stratum*

$$S_I = \{(t, y) \in S : t_i = +\infty \iff i \in I\}$$

is, after deleting the infinite coordinates, a finite union of closed polyhedra. Let $F : S \to \mathbf{R}$ be continuous and suppose that there are finitely many functions $L_1, \dots, L_m : B \to \mathbf{R}$ such that $F(t, y) \in \{L_1(y), \dots, L_m(y)\}$ everywhere. Then there exists R such that, for every $(t, y) \in S$ with all $t_i \ge R$,

$$(+\infty, \dots, +\infty, y) \in S, \qquad F(t, y) = F(+\infty, \dots, +\infty, y). \tag{11.12.1}$$

The threshold depends on S and its finite polyhedral presentations, not on F or on the functions L_a.

Proof. For a polyhedron P in a stratum with at least one finite t-coordinate, apply Lemma 11.12.1 to those coordinates. If its second alternative holds, choose M_P as there. Finitely many strata and polyhedra occur, so choose R greater than all these bounds and at least R_0; if there are no such bounds, any $R \ge R_0$ suffices.

A point (t, y) in the stated tail either already has all $t_i = +\infty$, or lies in a polyhedron of the first type. In the latter case choose its recession vector $(w, 0)$. The ray obtained by increasing the finite t-coordinates by λw, and leaving the others infinite, lies in S for every $\lambda \ge 0$. Along this connected ray, F takes values in the fixed finite subset $\{L_a(y)\}_a$ of $\mathbf{R}$. Continuity therefore makes F constant on the ray. Its limit in the ambient extended space is $(+\infty, \dots, +\infty, y)$; compactness of S places that point in S, and continuity gives (11.12.1). □

No connectedness of a whole projection fibre was used. The proof instead connects each point in a sufficiently deep tail to the same boundary point in its fibre. This distinction is important for relative images.

Example 11.12.3 (Why finite polyhedral structure is needed)**.** In $[1, +\infty] \times [0, 1]$, let

$$S = \{(1/y, y) : 0 < y \leq 1\} \cup \{(2/y, y) : 0 < y \leq 1\} \cup \{(+\infty, 0)\}.$$

Set $F = y$ on the first curve, $F = -y$ on the second, and $F(+\infty, 0) = 0$. Both compactified curves are continuous images of $[0, 1]$, so S is compact. They meet only at their common endpoint, where both values tend to zero; hence F is continuous and selects from the two affine functions $y, -y$. It also has relative affine lower supports: use the active branch away from the endpoint, and $-y$ at the endpoint. For every R, small positive y gives two points in the tail with the same y and opposite values. Thus F does not factor through y on any tail. The finite-coordinate stratum is not a finite union of polyhedra. This is an abstract counterexample to dropping that hypothesis, not an asserted analytic tropical image.

11.12.2 The analytic image input and zero strata

We use the following named input from Martin: for a compact strictly K-analytic space over a complete nontrivially valued field, the positive-coordinate image of finitely many analytic functions is a finite polyhedral set. In logarithmic coordinates its normals are rational and its constants lie in $\Gamma_{\mathbf{Q}}$, where $\Gamma = -\log|K^\times|$. See [Mar13, Theorem 4.3.1, pp. 172–173; conventions in Section 4.1.1]. The published strict version is [Mar15]. We checked the thesis proof; the published article was available only through its abstract. No broader non-strict or trivially valued formulation is used.

Lemma 11.12.4 (Stratified polyhedral analytic images)**.** *Let V be strictly K-affinoid, with K complete and nontrivially valued. Let $g_1, \ldots, g_s$ be analytic functions and $h_1, \ldots, h_d$ analytic units on V. The image*

$$S = \{((-\log|g_i(z)|)_{i=1}^s, (-\log|h_j(z)|)_{j=1}^d) : z \in V\}$$

satisfies the compactness, boundedness and finite-stratum hypotheses of Theorem 11.12.2, for some R_0 and bounded box B.

Proof. Compactness follows from continuity and compactness of V. The functions g_i are bounded, so their negative logarithms have a common lower bound. Both h_j and h_j^{-1} are bounded, so the last coordinates lie in a bounded box. Fix $I \subset \{1, \dots, s\}$ and take the closed analytic subspace $Z_I \subset V$ defined by $g_i = 0$ for $i \in I$. It is strictly affinoid. Apply Martin's theorem on Z_I to the remaining g_i, together with all h_j, and take its positive-coordinate image. Positivity excludes exactly the additional zeros $g_i = 0$ for $i \notin I$. After taking negative logarithms this is precisely S_I with its infinite coordinates deleted, not its closure across other strata. Martin's finite union of closed polyhedra gives the assertion; empty strata cause no difficulty. If no coordinates remain, the stratum is empty or a single point, and the conclusion is immediate. □

11.12.3 From relative finite selections to model PL functions

Specify the relative convention before using it. On a relative neighbourhood O of a point in a tropical image, a rational finite selection is a continuous real-valued function selecting from one finite list

$$\ell_a(t) = c_a + \sum_i q_{ai} t_i, \qquad c_a \in \Gamma_{\mathbf{Q}}, \quad q_{ai} \in \mathbf{Q}, \qquad a = 1, \dots, m. \tag{11.12.2}$$

Every individual summand of every branch must be finite everywhere on O, with $0 \cdot (+\infty) = 0$. In particular, a branch cannot be defined only on the subset where it is selected. This is a substantive hypothesis.

Theorem 11.12.5 (Relative rational PL identification through zeros)**.** *Let X be a pure-dimensional good strictly K-analytic space, where K is complete and nontrivially valued. Suppose a function u is locally, on ordinary opens, the pullback under the negative logarithms of finitely many analytic functions of a relative rational finite selection in the convention* (11.12.2)*. Then u is $\mathbf{Q}$-PL in the strict GJR sense. More precisely, near each point it has such a finite-selection presentation using only analytic units. No convexity assumption is required.*

Proof. Fix x. Shrink to an ordinary neighbourhood on whose tropical image one finite list works. Reorder the coordinates as $g_1, \dots, g_s$, vanishing at x, and $h_1, \dots, h_d$, nonvanishing at x. Shrink again so that the latter are units. If $s = 0$, Proposition 11.11.5 applies directly. Otherwise finiteness of each summand at the image of x forces the coefficient of each g_i to vanish in every branch. Thus all branches have the form $L_a(y)$, where $y = (-\log |h_j|)_j$.

Choose a compact strict affinoid neighbourhood V of x inside this open, and put $S = \tau(V)$. Lemma 11.12.4 and Theorem 11.12.2 give a threshold R. Enlarge it to an element of $\Gamma_{\mathbf{Q}}$; this is possible since Γ contains a positive element. Then

$$V_R = \{z \in V : |g_i(z)| \le e^{-R} \text{ for all } i\}$$

is a strict affinoid domain containing an ordinary neighbourhood of x. Indeed, choose $N > 0$ and $a \in K^\times$ with $NR = -\log|a|$; its inequalities are $|g_i^N/a| \le 1$. At x they are strict, and x lies in the ordinary interior of V.

Define the boundary slice and its restricted function by

$$S_\infty = \{y : (+\infty, \dots, +\infty, y) \in S\},$$
$$F_\infty(y) = F(+\infty, \dots, +\infty, y).$$

The function F_∞ is continuous on the compact set S_∞. The tail theorem gives $y(V_R) \subset S_\infty$ and $u|_{V_R} = F_\infty \circ y$. It still selects from the same rational branches L_a. Restrict to the ordinary interior of V_R and apply Proposition 11.11.5. Varying x proves the Q-PL assertion by sheafiness. □

This proof avoids subdividing inequalities between vanishing monomials into rational domains at their common zero, the invalid shortcut excluded by Example 11.11.9. Only inequalities against a nonzero constant are used to select V_R; the subsequent Laurent subdivision involves units. The argument combines Martin's image theorem with an elementary recession calculation and the earlier unit-chart identification; no priority claim is made for that combination.

Corollary 11.12.6 (Relative generators in the fixed-domain transfer)**.** *Let X be an integral projective variety of positive dimension over a complete nontrivially valued field K. On one ordinary open $U \subset X^{\mathrm{an}}$, let u_j be a decreasing sequence of functions satisfying Theorem 11.12.5, and assume each has local relative affine lower supports as in Theorem 11.11.2. The presentations and their charts may depend on j. For every $x \in U$, there is one ordinary neighbourhood $V \subset U$ and a decreasing sequence of original CLD smooth psh functions b_j on V with $b_j \downarrow u = \inf_j u_j$. If u is finite continuous, this convergence is uniform on compact subsets of V.*

Proof. Theorem 11.12.5 gives Q-PL membership for each term on U. Theorem 11.11.6 gives nef residues, using the classical psh criterion and its cited

comparison theorem. Now apply Theorem 11.10.11. The varying neighbourhoods used to identify individual terms are not intersected: they establish a sheaf property on U before the fixed projective barrier is chosen. Its termwise scaling constants remain free to vary. Dini's theorem gives the final assertion. □

Remark 11.12.7 (One tube for a family of finite selections). The unit-reduction part of the proof does not require rational coefficients. On a fixed compact image S as above, every continuous finite selection from branches depending only on y factors on the same tail, since the threshold in Theorem 11.12.2 is independent of those branches. The finite lists may differ for different members of a family. The resulting boundary restriction preserves pointwise order, maxima and minima. This gives a uniform domain when the image and the vanishing-coordinate set are already fixed. It gives no uniform domain for an arbitrary family of different analytic charts, and real coefficients do not by themselves give strict GJR PL membership.

Example 11.12.8 (Rational constants and a fixed valuation)**.** Equip $K = \mathbf{Q}_p$ with the absolute value $|a| = \exp(-\sqrt{2}\, v_p(a))$. This complete nontrivially valued field has $\Gamma_{\mathbf{Q}} = \sqrt{2}\,\mathbf{Q}$. The constant function 1 on the analytic point $\mathcal{M}(K)$ is not Q-PL in the strict unit-log sense: such a presentation would give $N = \log|b| \in \sqrt{2}\,\mathbf{Z}$ for some positive integer N and $b \in K^{\times}$, which is impossible. The same obstruction holds at a K-rational point of an analytic space, by evaluating the unit-log presentation there. Nevertheless 1 is an original smooth pluriharmonic function. Thus this example separates coefficient categories; it is not a counterexample to smooth approximation or to psh comparison. No absolute value is changed during either argument.

11.12.4 Coefficient control for ambient convex functions

The remaining relative approximation problem should be distinguished from a coefficient problem that can be solved directly. Proposition 11.11.13 treats finite ambient maxima. Supporting hyperplanes extend that argument to every finite convex function on an ambient convex open set.

Proposition 11.12.9 (Decreasing rational approximation of ambient convex functions)**.** *Let $\Omega \subset \mathbf{R}^d$ be convex and open, let $F : \Omega \to \mathbf{R}$ be finite continuous and convex, and let $S \subset \Omega$ be nonempty compact. For every nonzero additive subgroup $\Gamma \subset \mathbf{R}$, there are finite maxima H_j of affine functions with rational slopes and constants in $\Gamma_{\mathbf{Q}}$ whose restrictions to S decrease uniformly to $F|_S$. Each H_j is defined and convex on all of $\mathbf{R}^d$, but monotonicity is asserted only on S.*

Proof. At each $x \in \Omega$ a supporting affine function ℓ_x satisfies $\ell_x \le F$ on Ω and $\ell_x(x) = F(x)$. To recall the input, separate the open convex epigraph $\{(t, r) : t \in \Omega,\ r > F(t)\}$ from its boundary point $(x, F(x))$. The separating functional has nonnegative last coefficient; that coefficient cannot be zero because x is interior to Ω. Division by its positive last coefficient gives ℓ_x.

Choose $\rho \in \Gamma$ positive and $\epsilon_j = \rho 8^{-j}$. For fixed j, continuity and compactness give finitely many supports with maximum M_j satisfying $F - \epsilon_j \le M_j \le F$ on S: the relative open sets $\{F - \ell_x < \epsilon_j\} \cap S$, for $x \in S$, cover S. Since S is bounded, approximate each selected slope by a rational vector and each constant by an element of $\rho\mathbf{Q}$ so that the resulting affine function differs by at most ϵ_j on S. Let G_j be the maximum of these rational affine functions. Then

$$F - 2\epsilon_j \le G_j \le F + \epsilon_j \quad \text{on } S.$$

Set $H_j = G_j + 3\epsilon_j$. The shift is still in $\Gamma_{\mathbf{Q}}$, and

$$F + \epsilon_j \le H_j \le F + 4\epsilon_j, \qquad H_{j+1} \le F + \tfrac{1}{2}\epsilon_j \le H_j \quad \text{on } S.$$

This proves both assertions. It is not necessary to choose nested sets of supporting hyperplanes: the positive shifts enforce monotonicity on the prescribed compact set. □

Corollary 11.12.10 (A coefficient-compatible local analytic class)**.** *On a pure-dimensional good strictly analytic space over a complete nontrivially valued K, suppose locally that $u = F \circ \tau$, where τ is given by analytic units and F is finite continuous convex on a convex ambient open containing the image. Near every point, u is a uniform decreasing limit of finite rational maxima of unit logarithms, with constants in $\Gamma_{\mathbf{Q}}$. These approximants are Q-PL and have relative affine lower supports. For an integral projective X of positive dimension, Corollary 11.12.6 consequently gives a decreasing original smooth psh approximation on one neighbourhood.*

Open proof obligation (RC2). Prove the Q-PL analytic presentation and stability under the maximum operation; the proof takes GJR 5.2(7) as input.

The supporting hyperplanes in this proof lie below F on the entire ambient convex open. Relative local supports on a polyhedral union need not have that property. Thus the proposition cannot be used to fill the remaining general relative-density step by replacing the ambient set with a tropical image.

11.12.5 A maximum statement that must retain PL membership

The coefficient distinction also corrects a literal closure assertion in the consulted GJR v3, also present in the published 2026 version, pp. 191–192. Remark 7.11 suggests that the maximum of two semipositive R-PL functions is again semipositive R-PL, and its proposed argument treats maxima of R-PL LFS functions as R-PL LFS. Example 5.3 of that same version prevents this without an additional membership hypothesis. The later [GRPL, Corollary 5.5] explicitly restricts the unconditional statement to $\Lambda = \mathbf{Z}$ or $\mathbf{Q}$.

Proposition 11.12.11 (Maximum with the correct coefficient scope)**.** *Let X be a good strictly analytic space over a complete nontrivially valued field. If h_1, h_2 are semipositive R-PL functions and $h = \max(h_1, h_2)$ is R-PL, then h is semipositive. For Q-PL or integral PL inputs, membership of the maximum is automatic and the conclusion holds in the same coefficient class. For arbitrary R-PL inputs, that membership can fail even when both inputs are harmonic.*

Open proof obligation (RC2). Prove the applicable positivity and closure implications for the specified maximum; the proof uses GRPSH, GJR and GRPL.

The obstruction also occurs in the proper ambient setting of GJR Remark 7.11, which asks for semipositivity at a point. On $\mathbf{P}^{1,\mathrm{an}}$ extend $q = \min\{0, \max\{-1, \log|T|\}\}$ by its constant values near 0 and ∞. This is integral PL when $\Gamma = \mathbf{Q}$. Then $1+\pi q$ and 0 are global R-PL functions, harmonic near the point of the standard skeleton with $\log|T| = -1/\pi$. Their maximum has the same irrational bend there and is not R-PL near that point. Thus properness of the ambient curve does not repair the omitted local membership hypothesis.

The other expectation in GJR Remark 7.11, concerning pointwise limits, has a different status. It is now supplied by [GRPL, Theorem 5.6]: a pointwise limit of semipositive R-PL functions is semipositive when the limit is itself R-PL. That final membership hypothesis must also be retained. It neither asserts that all such limits are PL nor proves first-stage original-smooth decreasing closure.

11.12.6 Gaussian regularization at a boundary stratum

The projective tropical localization used earlier rests on a Gaussian regularization of a finite convex conewise-linear function. The calculation at infinity in [APW26, Proposition 5.7, pp. 34–35] can be made independent of the chosen approach sequence. We give the elementary calculation, including the growth hypothesis and the direction of monotonicity.

Proposition 11.12.12 (Gaussian boundary limit for a finite maximum)**.** *Let E be a finite-dimensional Euclidean space, let $v_1, \dots, v_s$ be linearly independent with $s \geq 1$, and put $\delta = \sum_i \mathbf{R}_{\geq 0} v_i$, $T = \operatorname{span}(\delta)$ and $Q = T^{\perp}$. Let $p : E \to Q$ be orthogonal projection. Suppose*

$$h(x) = \max_{1 \leq a \leq m} \langle m_a, x \rangle \geq 0, \qquad h|_{\delta} = 0.$$

Set $A_\delta = \{a : \langle m_a, v_i \rangle = 0 \text{ for every } i\}$, and $h^\delta(z) = \max_{a \in A_\delta} \langle m_a, z \rangle$ for $z \in Q$. This set of active indices is nonempty. If ρ_E and ρ_Q are the standard normalized Gaussian densities and $H = h * \rho_E$, then

$$\lim_{\min_i t_i \to +\infty} H\left(\sum_i t_i v_i + z\right) = \int_Q h^\delta(z - b)\rho_Q(b)\, db. \tag{11.12.3}$$

The convergence is uniform for z in compact subsets of Q. No monotonicity of the approaching parameters is assumed. Moreover $H(x + v) \leq H(x)$ for $v \in \delta$. If $h(-v) > 0$ for a nonzero $v \in \delta$, the inequality is strict.

Proof. Every $\langle m_a, v_i \rangle$ is nonpositive. Since $h(\sum_i v_i) = 0$, a maximizing index there has all these coefficients zero, proving that A_δ is nonempty. For $y = \sum_i t_i v_i$, every inactive linear form in $h(y+z-w)$ tends to $-\infty$ as $\min_i t_i \to \infty$; active forms annihilate T. Consequently, for each fixed z, w,

$$h(y + z - w) \longrightarrow h^\delta(z - p(w)).$$

Write $L = \max_a \|m_a\|$. The function h is L-Lipschitz and subadditive. For $t_i \geq 0$, its nonnegativity and $h(y) = 0$ give the integrable bound

$$0 \leq h(y + z - w) \leq h(z - w) \leq L(\|z\| + \|w\|).$$

Dominated convergence now gives the limit of the integral. Orthogonal decomposition $E = T \oplus Q$ factors the normalized Gaussian into the product of the two Gaussian densities; integration in T gives exactly (11.12.3). Both sides, as functions of z, have Lipschitz constant at most L. A finite net on a compact subset of Q upgrades pointwise convergence to uniform convergence. Equivalently, any failure of uniform convergence would give a sequence of parameters and a convergent sequence of points contradicting that bound and the already proved pointwise limit.

Finally, $h(x+v) \leq h(x)+h(v) = h(x)$, and integration gives monotonicity. If $h(-v) > 0$, the difference $h(x-w)-h(x+v-w)$ is a nonnegative continuous function of w and is positive at $w = x+v$: its value there is $h(-v)-h(0) > 0$. It is therefore positive on a nonempty open set of positive Gaussian measure. Its integral is strictly positive. This proves strictness without a separate strict-convexity argument. □

Corollary 11.12.13 (Strict affine contact across all faces)**.** *In Proposition 11.12.12, suppose in addition that $h^{-1}(0) = \delta$. The Gaussian convolution extends continuously to $[0, +\infty]^s \times Q$ by its quotient formulas on all infinity strata. At each point $(+\infty, \dots, +\infty, z_0)$ it admits a strict affine lower support depending only on z. Here strictness means equality only at that point, including comparison with points on partial infinity strata.*

Proof. For $I \subset \{1, \dots, s\}$ put $T_I = \operatorname{span}\{v_i : i \in I\}$ and $Q_I = T_I^{\perp}$, with orthogonal projection p_I. Retain only the linear forms annihilating T_I, and let their maximum on Q_I be h^I. The preceding proposition, applied to the face generated by the v_i for $i \in I$, gives the boundary value $H_I = h^I * \rho_{Q_I}$, evaluated at $p_I(\sum_{i \notin I} t_i v_i + z)$. For $I = \varnothing$ this is the original convolution.

We check the zero cone, since it controls strictness at partially infinite points. For $I \neq \varnothing$, put $v_I = \sum_{i \in I} v_i$. If $h^I(q) = 0$, all active linear forms at v_I have value at most zero on q. Every inactive form is strictly negative on v_I, so for sufficiently large a all forms have value at most zero on $q + av_I$. Since

$h \geq 0$ and $h^{-1}(0) = \delta$, this gives $q + av_I \in \delta$. Conversely, if $q \in Q_I \cap (\delta + T_I)$, every active form is nonpositive at q, and $h^I(q) = 0$ by nonnegativity. Thus

$$(h^I)^{-1}(0) = p_I(\delta) = \sum_{i \notin I} \mathbf{R}_{\geq 0} p_I(v_i).$$

The projected generators are linearly independent, because the original generators are. In particular this cone is pointed. The formula is immediate also for $I = \varnothing$. If $I \subset J$, repeating the active-form construction on Q_I gives precisely h^J; orthogonal Gaussian pushforwards compose because $p_J p_I = p_J$. Proposition 11.12.12, with its locally uniform assertion, therefore proves continuity on approaching any higher stratum. There are only finitely many strata, so this proves continuity of the assembled extension.

Let I contain all indices, so $Q_I = Q$ and $(h^I)^{-1}(0) = \{0\}$. Gaussian convolution of a Lipschitz function is smooth, by differentiation of the Gaussian under the integral. It is strictly convex here. Indeed, for each nonzero direction d, the restriction $h^I(td)$ has different one-sided slopes: their difference is $h^I(d) + h^I(-d) > 0$. A translate of any nontrivial segment in direction d can cross this bend. The convexity gap is then positive on an open set of translates, and integration against the positive Gaussian makes the gap strictly positive. Hence the tangent affine function ℓ to H_I at z_0 lies strictly below $H_I(z)$ for $z \neq z_0$. If $Q = 0$, take its unique constant affine function instead.

On a proper infinity stratum indexed by J, move in the nonzero direction $\sum_{i \notin J} p_J(v_i)$. Its negative is outside the pointed zero cone, so Proposition 11.12.12 gives strict decrease after any positive step. Continuing toward the full infinity stratum yields $H_J > H_I(z) \geq \ell(z)$. On the full infinity stratum equality occurs only at $z = z_0$. This proves the stated strict contact, including all partial strata. □

Remark 11.12.14 (What the corrected calculation supplies). In the application of APW Proposition 5.7, $h = g - \ell$ is a finite maximum of linear forms with zero set the strongly convex cone δ. Thus $h(-v) > 0$ for every nonzero $v \in \delta$, and finite points lie strictly above the boundary limit: first move by a positive multiple of $\sum_i v_i$, then pass to infinity using monotonicity. The normalized quotient Gaussian in (11.12.3) is the pushforward of the ambient Gaussian; an arbitrary nonorthogonal coordinate splitting must instead retain that pushforward density.

On p. 35 the source initially allows an arbitrary sequence tending to infinity and then calls the translated functions decreasing. Arbitrary approach sequences need not be monotone; the dominated-convergence proof above removes that restriction. The integrand before taking the limit must be $h(y_i + z - w)$, with $h^\delta(z - p(w))$ appearing after passage to the limit. Later on the same page, for $y_{i+1} \geq y_i$, the printed strict inequality has the wrong direction: for a nonzero increment it is $H(y_{i+1}+z) < H(y_i+z)$. If two terms coincide, only equality is available. These corrections preserve the intended finite-point-to-boundary inequality. Corollary 11.12.13 supplies the same calculation on every partial infinity stratum, with its pointed zero cone verified explicitly. This proposition supplies the analytic limit calculation, not a new proof here of every global tropical-geometric input of APW Proposition 5.7.

Example 11.12.15 (Why Gaussian convolution needs a growth hypothesis)**.** The finite-valued formulation of [APW26, Lemma 5.8] needs an integrability qualification for arbitrary convex functions. On $\mathbf{R}$, $g(t) = \exp(t^4)$ is convex, since $g''(t) = (12t^2 + 16t^6)\exp(t^4) \geq 0$, but $(g * \rho)(x) = +\infty$ for every x: the quartic term $(x - w)^4$ dominates $w^2/2$ in the exponent as $|w| \to \infty$. Thus arbitrary finite convex input does not give finite Gaussian convolution. For the globally Lipschitz finite PL input actually used in Proposition 5.7, the bound in the preceding proof gives finiteness, and convolution preserves convexity by integrating its defining inequality. The local proof repair does not contradict that intended application.

11.12.7 Rational approximation on a fixed rational fan

There is a relative case beyond ambient convex extension in which coefficient control can also be proved. The essential restrictions are that the input is already piecewise linear and that its fixed fan is rational. The argument is a finite-dimensional rational-polyhedral calculation, not a general regularization theorem for continuous relatively convex functions.

Proposition 11.12.16 (Coefficient density for relatively convex fan functions)**.** *Let Σ be a finite rational polyhedral fan in $\mathbf{R}^n$, let $S \subset |\Sigma|$ be nonempty compact, and let $F : |\Sigma| \to \mathbf{R}$ be continuous, homogeneous and linear on each cone. Suppose that F has a relative affine lower support near every point of $|\Sigma|$. For any nonzero additive subgroup $\Gamma \subset \mathbf{R}$, there exist functions H_j on $|\Sigma|$, affine with rational slopes and constants in $\Gamma_{\mathbf{Q}}$ on the same cones, which have relative affine lower supports everywhere and decrease uniformly to F*

on S. The monotonicity is asserted only on S. No ambient convex extension of F is assumed.

Proof. Choose ambient covectors q_σ with $F|_\sigma = q_\sigma|_\sigma$. For every face τ choose a point in its relative interior. A local affine lower support at that point has a slope a_τ satisfying

$$\begin{aligned} q_\sigma|_{\sigma\cap\sigma'} &= q_{\sigma'}|_{\sigma\cap\sigma'}, \\ a_\tau|_\tau &= q_\tau|_\tau, \\ (q_\sigma - a_\tau)|_\sigma &\geq 0 \qquad (\sigma \supseteq \tau). \end{aligned} \tag{11.12.4}$$

Indeed, comparison in both tangent directions inside τ identifies the slope on $\operatorname{span}(\tau)$, and the support's constant is then zero by homogeneity. For $x \in \operatorname{relint}(\tau)$ and $v \in \sigma \supseteq \tau$, the point $x+tv$ lies in σ for $t \geq 0$. Applying the local support inequality for small t gives the last line. Conversely, these constraints imply a relative lower support at every point of $\operatorname{relint}(\tau)$: cones not containing that point can be excluded by shrinking, and on every remaining cone the covector a_τ is a lower support with contact.

Because the fan is rational and finite, the displayed conditions are finitely many homogeneous rational linear equalities and inequalities in the coordinates of all q_σ, a_τ. For the inequalities it suffices to test a finite rational generating set of each cone, including generators of its lineality space with both signs if necessary. Thus the tuples form a rational polyhedral cone C in a finite-dimensional vector space. Rational points are dense in C. To see this at a particular tuple c, impose as equalities the rational inequalities active at c, together with the original equalities. Their nullspace has a rational basis. Approximate the coordinates of c in that basis by rational numbers. The inactive inequalities remain strict for sufficiently close approximations, and the active equalities are preserved exactly.

Choose $\rho \in \Gamma$ positive and set $\epsilon_j = \rho 8^{-j}$. Approximate the tuple of F inside C so closely that its rational covectors define a continuous homogeneous function G_j with $|G_j - F| \leq \epsilon_j$ on S. This is possible because S is bounded and there are finitely many cones. The constraints give relative affine lower supports for G_j. Set $H_j = G_j + 2\epsilon_j$. Then

$$F + \epsilon_j \leq H_j \leq F + 3\epsilon_j, \qquad H_{j+1} \leq F + \tfrac{3}{8}\epsilon_j \leq H_j \quad \text{on } S.$$

The constants $2\epsilon_j$ belong to $\Gamma_{\mathbf{Q}}$, and shifting the supports by the same constants preserves contact. This proves the assertion. □

This argument combines a finite support criterion with rational-point density in a rational polyhedral cone; no priority claim is attached to the combination. On a unit chart whose image is contained in $|\Sigma|$, take S to be the image of a compact strict affinoid neighbourhood. The pullbacks of H_j are Q-PL and have relative lower supports. Thus, in the projective setting of Corollary 11.12.6, they yield a decreasing original smooth psh approximation to $F \circ \tau$ near the point. This does not require a same-chart ambient convex extension.

For a nonhomogeneous complex with vertices involving arbitrary elements of $\Gamma_{\mathbf{Q}}$, the displayed system need not have rational coefficients, and its affine constants require separate control. The argument above does not treat that case. Nor does it show that a general continuous relatively convex function is approximable by functions linear on one fixed rational fan. These are distinct remaining questions.

Example 11.12.17 (A fixed irrational-length subdivision can obstruct density)**.** Let $a = \sqrt{2}$, and let S be the boundary of the rectangle with vertices $A = (0,0)$, $B = (1,0)$, $C = (1,a)$ and $D = (0,a)$, with its four-edge polyhedral complex. Take $\Gamma = \mathbf{Z} + \sqrt{2}\mathbf{Z}$. All directions are rational and all vertex coordinates belong to $\Gamma_{\mathbf{Q}}$. Define F by the vertex values

$$F(A) = 0, \qquad F(B) = F(C) = F(D) = a,$$

and extend linearly on each edge. This is a continuous relatively convex real PL function, but any continuous function G affine with rational slopes on these same four edges satisfies

$$\|G - F\|_{C^0(S)} \geq \frac{\sqrt{2}}{4}. \tag{11.12.5}$$

The obstruction persists if the affine constants of G are allowed to be arbitrary real numbers.

Proof. At an interior point of an edge, its affine expression is a relative support after shrinking. At a vertex the two adjacent edge directions are linearly independent, so there is an ambient affine function agreeing with F on both incident edges. This supplies a relative support near that vertex. Thus F has the stated relative convexity; no ambient convex extension is being asserted.

For G let $p_b, p_t \in \mathbf{Q}$ be the derivatives in the positive horizontal direction on the bottom and top edges, and $q_l, q_r \in \mathbf{Q}$ the derivatives in the positive

vertical direction on the left and right edges. Continuity around the rectangle gives

$$p_b + aq_r - p_t - aq_l = 0.$$

Since 1 and a are linearly independent over $\mathbf{Q}$, necessarily $p_b = p_t$ and $q_r = q_l$. In particular

$$G(A) + G(C) - G(B) - G(D) = 0.$$

For F the same expression equals $-a$. Comparing the four vertex values proves (11.12.5). This calculation uses only the slopes and continuity, so there is no restriction on the constants. □

In this example refinement does remove the obstruction. Choose rational $r \to a$ and rational $q_1, q_2 \to 1$ with $q_1 < r/a < q_2$. Put $G = rx$ on the bottom edge, $G = r$ on the top and right edges, and on the left edge set

$$G(0, y) = \max\{q_1 y,\ q_2 y + r - q_2 a\}, \qquad 0 \le y \le a.$$

The values at the four vertices match. The new breakpoint is $(q_2 a - r)/(q_2 - q_1) \in \Gamma_{\mathbf{Q}}$, and all slopes are rational, with constants in $\Gamma_{\mathbf{Q}}$. The left-edge slopes increase from q_1 to q_2, so relative convexity holds there; at the vertices affine supports again exist by independence of the incident directions. The uniform error is at most $\max\{|r - a|, a|q_1 - 1|, a|q_2 - 1|\}$ and tends to zero. Choosing these errors geometrically small and adding the positive shifts used in Proposition 11.12.16 also makes the approximation decreasing. Thus the example isolates the fixed-subdivision obstruction rather than an obstruction to approximation itself.

Taking $S \times [0, 1]^{d-1}$ and pulling back F gives the same obstruction in every positive dimension d, for the product complex: restrict any proposed approximant to $S \times \{0\}$. Relative supports pull back by projection. This is a counterexample in the category of finite polyhedral complexes with rational directions. The rectangle boundary is not asserted to be a balanced tropical variety or an analytic tropical image. The example does not rule out approximation after subdivision, changing charts, or using other analytic presentations, and does not refute the unrestricted regularization conclusion of APW. It explains why a proof that rationalizes coefficients while freezing an arbitrary $\Gamma_{\mathbf{Q}}$-subdivision is insufficient. The distinction is sharpened in Section 11.19.4: the obstruction survives each fixed value-group refinement, but Example 11.19.9 gives an explicit decreasing approximation with a moving breakpoint.

11.12.8 Scope of the completed direction

The relative PL interface is now established with the stated common-branch and coefficient conventions. Wu's Definition 3.1(1) uses rational constants, and his standing convention in Section 2.1 is $\mathbf{Z} \subseteq \Gamma_K$ when the valuation is nontrivial. Under that convention, these constants do lie in $\Gamma_{\mathbf{Q}}$. Our formulation retains arbitrary fixed nontrivial absolute values by stating the coefficient condition explicitly; Example 11.12.8 explains why one must not omit it when leaving Wu's normalization. It does not refute a claim under his standing convention. Definition 3.6 also uses images that need not be ambient open sets; our relative convention is explicit, rather than an attribution of an unstated convention to the source.

The direction obtained is from these relative rational convex generators to original smooth approximation on a fixed analytic neighbourhood. The reverse direction, coefficient-compatible approximation for general relatively convex functions, and the first-stage decreasing-closure problem remain separate. Neither full Wu Theorem A.3 nor CLD25 Proposition 8.1.11 follows from this section. No enlargement to an unrestricted positive-current Bedford–Taylor calculus, change of actual tests or support, or field-descent theorem is asserted.

11.13 Rational approximation on a fixed residue tube

The coefficient problem has a second, geometric form. A function already known to be R-PL has a finite presentation by integral PL functions. Their residue line bundles can be placed on one projective model. This permits rational perturbation after adding a small ample class, without rationalizing the vertices of a tropical subdivision. We carry out this argument with one neighbourhood for the whole finite-dimensional family.

Throughout this section K is complete and nontrivially valued, $\Gamma = -\log|K^\times|$, and $\Gamma_{\mathbf{Q}} = \Gamma \otimes_{\mathbf{Z}} \mathbf{Q} \subset \mathbf{R}$. PL, Q-PL and R-PL have the strict analytic meaning of [GJR, Section 5]. In particular an arbitrary relative real PL presentation is not assumed to be an R-PL presentation in this sense. The geometric input below is the residue-model construction in [GJR, Lemma 6.14 and proof of Proposition 7.10]; the coefficient estimate and its ordered-family application are written out here.

11.13.1 A finite numerical estimate

Lemma 11.13.1 (Rational perturbation with an ample margin)**.** *Let V be a projective variety over a field, A an ample line bundle, and $L_1, \dots, L_m$ line bundles. Choose positive integers N_i such that $N_iA + L_i$ and $N_iA - L_i$ are ample, using additive notation in $\mathrm{Pic}(V)_{\mathbf{R}}$. If $L(a) = \sum_i a_i L_i$ is nef, $\varepsilon > 0$, and $r_i \in \mathbf{R}$ satisfy*

$$D := \sum_{i=1}^{m} N_i |r_i - a_i| < \varepsilon, \tag{11.13.1}$$

then $\sum_i r_i L_i + \varepsilon A$ is ample. In particular r_i and ε may be chosen rational, with r arbitrarily close to a as ε tends to zero. No rational polyhedrality of the nef cone is required.

Open proof obligation (RC2). Prove the ample margin used in the construction; the proof uses the GJR Proposition 7.10 argument.

11.13.2 Realizing a family before choosing its coefficients

Lemma 11.13.2 (One residue tube for a finite PL presentation)**.** *Let X be good and strictly K-analytic, let $x \in \mathrm{Int}(X)$, and let $h_1, \dots, h_m$ be integral PL functions on a neighbourhood of x. After shrinking once, there are a compact strictly analytic neighbourhood W of x, an ordinary open neighbourhood $U \subset W$ of x, an integral PL function b on W, a projective variety $V/\widetilde{K}$, line bundles L_i on V, and an ample line bundle A on V with the following properties.*

1. *L_i and A model the residues $L_{h_i}(x)$ and $L_b(x)$. For every $a \in \mathbf{R}^m$, $\sum_i a_i h_i$ is semipositive at x if and only if $\sum_i a_i L_i$ is nef on V.*
2. *If $\sum_i r_i L_i + tA$ is semiample, then $\sum_i r_i h_i + tb$ is locally Fubini–Study on U. If that class is nef, the function is semipositive on U. Here r_i, t are real and locally Fubini–Study means semiampleness of the residue at every point.*

All these data depend on the finite list (h_i) and x, not on a, r, t.

Open proof obligation (RC2). Prove the simultaneous neighbourhood/tube with the required residual class control; the proof applies the listed GJR inputs.

11.13.3 A decreasing Q-PL approximation

Theorem 11.13.3 (Rational approximation of a semipositive R-PL germ)**.** *Let X be good and strictly K-analytic, $x \in \mathrm{Int}(X)$, and let h be R-PL and semipositive at x. There are one ordinary open neighbourhood U of x and Q-PL locally Fubini–Study functions q_j on U which decrease uniformly to $h|_U$. More precisely, for any fixed $\rho \in \Gamma_{>0}$, the construction can be made to satisfy*

$$h + \eta_j \le q_j \le h + 3\eta_j \quad \text{on } U, \qquad \eta_j = \rho\, 8^{-j} \quad (j \ge 1). \tag{11.13.2}$$

The approximants need not be harmonic when h is harmonic. The claim is an explicit rational and ordered refinement of the construction of [GJR, Proposition 7.10], not an assertion that that proposition is false.

Proof. Write $h = \sum_i a_i h_i$ on one neighbourhood, with h_i integral PL, and apply Lemma 11.13.2. All h_i and b are continuous on the compact outer neighbourhood W, so put $M_i = \|h_i\|_W$ and $M_b = \|b\|_W$. Choose the integers N_i in Lemma 11.13.1. For each j choose $\varepsilon_j \in \mathbf{Q}_{>0}$ and $r_{ji} \in \mathbf{Q}$ such that

$$\varepsilon_j M_b < \frac{\eta_j}{2}, \qquad \sum_i M_i |r_{ji} - a_i| < \frac{\eta_j}{2}, \qquad \sum_i N_i |r_{ji} - a_i| < \frac{\varepsilon_j}{2}. \tag{11.13.3}$$

First choose the positive rational ε_j; then choose the rational vector sufficiently close to a. Zero values of some M_i or M_b impose no restriction. Since $L(a)$ is nef, the class $\sum_i r_{ji} L_i + \varepsilon_j A$ is ample. Consequently

$$p_j = \sum_i r_{ji} h_i + \varepsilon_j b$$

is Q-PL on W and locally Fubini–Study on U, while $\|p_j - h\|_W < \eta_j$. Set $q_j = p_j + 2\eta_j$. The added constant is in $\Gamma_{\mathbf{Q}}$, hence is Q-PL with zero residue: after clearing denominators it is a logarithm of an element of $K^\times$. Thus q_j is still locally Fubini–Study on U. Its error band is (11.13.2), and

$$q_{j+1} \le h + 3\eta_{j+1} = h + \tfrac{3}{8}\eta_j \le h + \eta_j \le q_j.$$

The bound $3\eta_j \to 0$ proves uniform convergence on all of U. No intersection of a sequence of shrinking neighbourhoods occurs. □

Corollary 11.13.4 (Ordered families in a fixed finite presentation)**.** *In the setting of Lemma 11.13.2, suppose $u_j = \sum_i a_{ji} h_i$ are semipositive at x and decrease pointwise on their common original neighbourhood. Then on one ordinary open neighbourhood U of x there are Q-PL locally Fubini–Study functions q_j such that*

$$u_j + \eta_j \le q_j \le u_j + 3\eta_j, \qquad q_{j+1} \le q_j, \qquad \inf_j q_j = \inf_j u_j. \tag{11.13.4}$$

No bound on the coefficient vectors a_j or on the family (u_j) is required. The common finite presentation is required.

Proof. Choose the data W, U, b, V, A, L_i, N_i once for (h_i). In (11.13.3) replace a_i by a_{ji} for the jth term. The constants M_i, M_b, N_i remain fixed; the rational choices may vary. The same estimate gives the first band, and

$$q_{j+1} \le u_{j+1} + 3\eta_{j+1} \le u_j + \tfrac{3}{8}\eta_j \le u_j + \eta_j \le q_j.$$

Since $q_j - u_j \to 0$ uniformly, their decreasing limits agree, also when the limit takes the value $-\infty$. □

11.13.4 Consequences for original smooth approximation

Corollary 11.13.5 (Semipositive R-PL functions in the projective case)**.** *Let X be an integral projective variety of positive dimension over K. If h is R-PL near $x \in X^{\mathrm{an}}$ and semipositive at x, then on one ordinary open neighbourhood of x there is a decreasing sequence of original CLD smooth psh functions converging to h, uniformly on compact subsets. The same assertion holds for $u = \inf_j u_j$ from Corollary 11.13.4, except that uniform convergence on compact subsets is asserted only when u is finite continuous.*

Proof. The preceding results give decreasing Q-PL functions on one ordinary open set, with nef residues at all its points. Apply Theorem 11.10.11 to that sequence. Its projective barrier and termwise rescaling supply the common smooth approximation domain. Dini's theorem gives the asserted compact uniform convergence for a finite continuous endpoint. The residue rationalization itself used neither a scalar extension nor a change of the chosen absolute value. □

Theorem 11.13.6 (A comparison confined to strict R-PL germs)**.** *Under the projective hypotheses of Corollary 11.13.5, let h be an R-PL germ at x. The following three conditions are equivalent: h is semipositive at x; h is classically psh on a neighbourhood of x in the curvewise sense of [GRPSH, Definition 4.1]; on some fixed neighbourhood h is a uniform decreasing limit of Q-PL LFS functions. They imply that, on a fixed neighbourhood, h is a decreasing limit of original CLD smooth psh functions, uniformly on compact subsets, and hence that $d'd''[h]$ is positive on the original CLD tests. Each neighbourhood here is ordinary open.*

Open proof obligation (RC2). Prove both comparisons in the R-PL scope; the proof applies GRPL Theorem 5.6 and GRPSH Theorem 4.3.

The last current-positivity conclusion is not used to reverse the argument. In GRPSH, "classically psh" requires subharmonic pullback to curves after every analytic field extension. Positivity on tests on X alone is a different condition. Neither a pullback of an arbitrary current nor an identification of these two definitions is hidden in this proof.

Remark 11.13.7 (What this coefficient argument does not identify). For an already R-PL function, classical psh is equivalent to semipositivity by [GRPSH, Theorem 4.3], so that condition may replace semipositivity on a neighbourhood in the preceding corollary. An arbitrary decreasing sequence of semipositive R-PL functions need not come with one finite presentation valid for all terms. Applying Theorem 11.13.3 separately then gives neighbourhoods depending on the term; Corollary 11.13.4 does not remove that problem without its additional hypothesis. Nor does the construction identify arbitrary relative real PL functions with GJR R-PL functions, or approximate every original smooth psh function by relative rational generators. Those are different interfaces.

The projective corollary concerns the original CLD smooth class and consequently its original tests; it does not replace those tests by weakly smooth or tropical tests. It introduces no current pushforward, altered support, or unverified descent. Full Wu Theorem A.3, CLD25 Proposition 8.1.11, and an unrestricted positive-current Bedford–Taylor calculus do not follow. The improvement over the preceding section is a proved coefficient conversion for already semipositive strict R-PL germs, including ordered families with a fixed finite presentation.

11.14 Ample extensions: a fixed-model obstruction and the cofinal repair

The approximation argument in Section 11.9 needs an ample model after passing to a suitable higher model. It does not need an ample extension on every prescribed projective model. These assertions are different. The published [GM, Lemma 4.12, p. 353] states the latter assertion; the example below disproves that literal statement. We then recover exactly the cofinal formal-model input needed for the metric approximation. This does not disprove [GM, Proposition 4.11] or [BE21, Theorem 7.8].

11.14.1 The missing generic-fibre factor

In that lemma, $f : \mathscr{Y} \to \mathscr{X}_1$ is a projective morphism of models inducing the identity on X, and an ample $\mathscr{L}_1$ extends L^{m_1}. The proof chooses an arbitrary f-ample bundle E from a projective embedding and forms $f^*\mathscr{L}_1^{m_2} \otimes E$. Its generic restriction is

$$\big(f^*\mathscr{L}_1^{m_2} \otimes E\big)|_X \simeq L^{m_1 m_2} \otimes E|_X.$$

The assumption $f|_X = \mathrm{id}_X$ does not trivialize $E|_X$: every line bundle is relatively ample for an identity morphism. The final identification in the published proof drops this factor. A missing justification alone would not refute the lemma. The following construction supplies the additional obstruction.

Example 11.14.1 (No ample extension on the prescribed model)**.** Let $R = k[[t]]$, $K = k((t))$, with $|t| = e^{-1}$, where k is any field. There are projective algebraic R-models $\mathscr{Y}, \mathscr{X}_1$ of $X = \mathbf{P}^1_K \times \mathbf{P}^1_K$ and a morphism $f : \mathscr{Y} \to \mathscr{X}_1$ inducing id_X such that $L = \mathcal{O}_X(1,1)$ extends to an ample line bundle on $\mathscr{X}_1$, but no L^m, $m > 0$, extends to an ample line bundle on $\mathscr{Y}$. The same obstruction exists in every generic dimension $n \geq 2$.

Proof. On $\mathbf{P}^1_R$, take the rank-two vector bundle F defined by the extension class $t\xi$, where ξ generates

$$\mathrm{Ext}^1(\mathcal{O}(2), \mathcal{O}) = H^1(\mathbf{P}^1_R, \mathcal{O}(-2)) \simeq R, \qquad 0 \longrightarrow \mathcal{O} \longrightarrow F \longrightarrow \mathcal{O}(2) \longrightarrow 0.$$

The middle term is locally free since the quotient is locally free. On the generic fibre the extension is nonzero, hence, by rescaling the one-dimensional extension class and using the Euler sequence, $F_K \simeq \mathcal{O}(1) \oplus \mathcal{O}(1)$. On the special

fibre the extension splits: $F_k \simeq \mathcal{O} \oplus \mathcal{O}(2)$. These are the classical deformation data relating the Hirzebruch surfaces $\mathbb{F}_0$ and $\mathbb{F}_2$; the argument uses them as an explicit model obstruction, not as a new deformation construction.

Use the quotient convention for $\mathscr{Y} = \mathbf{P}(F)$ and put $M = \mathcal{O}_{\mathbf{P}(F)}(1)$. This is a smooth projective R-scheme, hence regular and integral, with irreducible special fibre. Its generic fibre is X, and $M_K = L$. The special quotient $F_k \twoheadrightarrow \mathcal{O}$ defines a section $C \simeq \mathbf{P}^1_k$ on which M has degree zero.

The vanishing $H^1(\mathbf{P}^1_R, \mathcal{O}) = 0$ shows that all three standard global sections of $\mathcal{O}(2)$ lift to F. Together with the section of the subbundle $\mathcal{O}$, they generate F: locally a section can first be matched in the quotient and then in the kernel. Thus M is generated by four sections and defines $g : \mathscr{Y} \to \mathbf{P}^3_R$. Its generic restriction is the Segre embedding associated to $\mathcal{O}(1,1)$. Let $\mathscr{X}_1$ be the schematic image. It is projective and flat over R: its structure sheaf embeds into $g_*\mathcal{O}_{\mathscr{Y}}$, which has no t-torsion, and torsion-free modules over a DVR are flat. Its generic fibre is the Segre copy of X. The induced $f : \mathscr{Y} \to \mathscr{X}_1$ is projective (use the closed graph and a projective embedding of $\mathscr{Y}$ over R). With this identification of the generic fibres it induces the identity. The bundle $\mathscr{L}_1 = \mathcal{O}_{\mathbf{P}^3_R}(1)|_{\mathscr{X}_1}$ is ample and extends L, and $f^*\mathscr{L}_1 = M$.

Suppose that a line bundle N on $\mathscr{Y}$ extends L^m. Then $N \otimes M^{-m}$ is generically trivial. A generic trivialization gives a rational section whose divisor is vertical. Since $\mathscr{Y}$ is regular and its special fibre is irreducible and reduced, this divisor is $a\mathscr{Y}_k$ for an integer a. But $\mathscr{Y}_k = \operatorname{div}(t)$ is principal. Thus $N \simeq M^m$, and $\deg(N|_C) = 0$. An ample bundle has positive degree on every projective integral curve, so N is not ample. This proves the claimed failure for every $m > 0$.

For $n > 2$, take the products of both models with $\mathbf{P}^{n-2}_R$ and replace $L, M, \mathscr{L}_1$ by their external tensor products with $\mathcal{O}(1)$. Regularity and irreducibility of the special fibre persist. The same vertical-divisor argument forces any extension of L^m to be the indicated tensor power, whose degree on $C \times \{p\}$ is zero for a k-rational point p. The ample extension on the target is the external tensor product of two ample bundles. □

Proposition 11.14.2 (The obstruction over any nontrivially valued field)**.** *The conclusion of Example 11.14.1 holds over every complete nontrivially valued field K, with its fixed absolute value, and in every dimension at least two. No discrete valuation, characteristic assumption or field extension is needed.*

Proof. Put $R = K^\circ$ and choose $0 \neq a \in K^{\circ\circ}$. On $\mathbf{P}^1_R$, with homogeneous coordinates $[x : y]$, define F by

$$0 \longrightarrow \mathcal{O}(-1)^2 \xrightarrow{B} \mathcal{O}^4 \longrightarrow F \longrightarrow 0, \qquad B = \begin{pmatrix} -y & 0 \\ x & -y \\ 0 & x \\ 0 & ay \end{pmatrix}.$$

The minors include x^2 and y^2, so B is locally a split injection and F is locally free of rank two. On the special fibre its cokernel is $\mathcal{O}(2) \oplus \mathcal{O}$, as seen from the quotient map $(x^2, xy, y^2, 0)$ and the fourth basis vector. On the generic fibre, adding a^{-1} times the fourth row to the second row makes the matrix block diagonal, with columns $(-y, x)$ and (x, ay); each block has cokernel $\mathcal{O}(1)$. Thus $F_K = \mathcal{O}(1)^2$. This is an explicit form of the preceding classical deformation; see also [Addington21, Worksheet 2, part 3].

Set $\mathscr{Y} = \mathbf{P}(F)$ and $M = \mathcal{O}_{\mathbf{P}(F)}(1)$. Its four generating sections give a morphism to the quadric

$$\mathscr{X}_1 = \{z_0 z_2 - z_1^2 + a z_1 z_3 = 0\} \subset \mathbf{P}^3_R.$$

Indeed the incidence relations are $xz_1 - yz_0 = 0$ and $xz_2 - yz_1 + ayz_3 = 0$, whose determinant is the displayed equation. The homogeneous coordinate ring is free of rank two over $R[z_0, z_2, z_3]$, because the equation is monic in z_1. Hence $\mathscr{X}_1$ is flat and of finite presentation over R. The generic quadric is split and smooth: replacing z_3 by $az_3 - z_1$ gives the usual Segre equation. The generic morphism is the complete $\mathcal{O}(1,1)$ embedding, so, after identifying generic fibres, $f : \mathscr{Y} \to \mathscr{X}_1$ is a projective model morphism inducing the identity. The target has the ample extension $\mathcal{O}(1)$.

To replace the DVR divisor argument, use the projective-bundle Picard formula. Over a connected base S, this formula says that a line bundle on $\mathbf{P}(E)$ is uniquely $\pi^* N \otimes \mathcal{O}(d)$. Here is the needed general-base justification. At any $s \in S$, twist by the degree d_s on the projective-space fibre. Its fibre cohomology is then one-dimensional in degree zero and zero otherwise. Cohomology and base change, in the form [StacksPB, Tag 0B9S], gives locally a line bundle $N = \pi_* \mathcal{L}(-d_s)$; the evaluation map is an isomorphism on every fibre and hence an isomorphism after shrinking. Thus d_s is locally constant, and connectedness makes it constant. The local N glue by the evaluation isomorphisms, and uniqueness follows from $\pi_* \mathcal{O} = \mathcal{O}_S$. This argument applies without noetherian assumptions.

Since R is local, $\mathrm{Pic}(R) = 0$. Applying the formula twice gives $\mathrm{Pic}(\mathscr{Y}) = \mathbf{Z}[M] \oplus \mathbf{Z}[\pi^*\mathcal{O}(1)]$. On $X = \mathbf{P}^1_K \times \mathbf{P}^1_K$ these generators restrict to $(1,1)$ and $(1,0)$, a basis of $\mathrm{Pic}(X)$. Therefore restriction is injective, and any extension of L^m must be M^m. Its degree on the section defined by $F_{\widetilde{K}} \twoheadrightarrow \mathcal{O}$ is zero, so it cannot be ample. Products with projective space give every higher dimension, with injectivity of Picard restriction again supplied by the same formula. No renormalization of $|\cdot|$ has been made. □

In this example the failure has a precise geometric cause. Every generically trivial line bundle on $\mathscr{Y}$ is trivial, whereas an f-ample bundle must have positive degree on the contracted curve C. Hence no f-ample bundle can be generically trivial. Even though $f^*\mathscr{L}_1 = M$ is semiample, no perturbation within the same generic line bundle on this fixed model can make it ample. Passing to a higher model in the approximation theorem is therefore essential.

11.14.2 The sufficient vertical hypothesis

Lemma 11.14.3 (Ample extension along a vertical polarization)**.** *Let $f : \mathscr{Y} \to \mathscr{X}_1$ be as above. If there is an f-ample line bundle E with $E|_X \simeq \mathcal{O}_X$, then some positive power of L extends to an ample bundle on $\mathscr{Y}$. This hypothesis holds when f is the blowup of a coherent vertical ideal.*

Proof. For sufficiently large q, $f^*\mathscr{L}_1^q \otimes E$ is ample by the relative ample twisting theorem, and its generic restriction is now $L^{m_1 q}$. For a vertical blowup use the relatively ample tautological bundle $E = \mathcal{O}(1)$ of the Rees Proj. The ideal becomes the unit ideal on X, so this bundle is generically trivial. This is the original proof with its missing hypothesis supplied. □

Proposition 11.14.4 (Cofinal ample models for metric approximation)**.** *Let K be complete and nontrivially valued, X/K projective, L ample, and $\mathfrak{X}_0$ a formal model of X^{an}. There is a projective algebraic K°-model $\mathscr{Y}$ whose completion dominates $\mathfrak{X}_0$ and which carries an ample extension of some L^m, $m > 0$. No prescribed algebraic model is required to remain fixed.*

Open proof obligation (RC2). Prove the cofinal construction and its ample-model assertion; the proof applies the construction in GM Lemma 2.4.

Corollary 11.14.5 (Finitely many ample generic polarizations)**.** *In the setting of Proposition 11.14.4, let $L_1, \dots, L_r$ be ample line bundles on X. One can choose a single projective algebraic model whose completion dominates $\mathfrak{X}_0$ and on which every L_i has an ample Q-model.*

Open proof obligation (RC2). Prove the relative ampleness step for the simultaneous models; the proof uses the GM Proposition 4.13 argument.

Remark 11.14.6 (Effect on the approximation argument). For a nef model metric of an ample L, pull its formal model bundle to the completion in Proposition 11.14.4; nefness persists under pullback. Proper formal GAGA algebraizes the pulled-back formal line bundle on $\mathscr{Y}$, preserving its generic identification. Divide the ample extension by its exponent to obtain an ample Q-model of the same L. The rational convex combinations of these two model bundles are ample and their metrics converge uniformly to the original metric. Sufficient powers are generated by global sections, giving the pure Fubini–Study approximation used in Section 11.9. Thus the fixed-model counterexample removes an unnecessary stronger assertion without removing this metric approximation route. Corollary 11.14.5 also supplies the finite-polarization geometric input used in [GM, Proposition 4.14] and [BGM22, arXiv v1, Lemma 1.1]. The generic Picard relation and the small model-function bound require a further argument, supplied in Proposition 11.14.8 below with explicit formal-domination scope. The reduced-special-fibre input of BGM Lemma 1.1 is separate. No scalar extension or change of valuation is involved.

11.14.3 Preserving the generic Picard relation

There is one further distinction in the proof of [GM, Proposition 4.14]. A numerical equality on the generic fibre does not itself trivialize a line bundle. To obtain a model function from the difference of two model bundles, one needs equality in $\mathrm{Pic}(X)_{\mathbf{Q}}$. The ample generic class permits the following choice, which supplies that stronger relation before rational approximation.

Lemma 11.14.7 (Exact ample decomposition and rational relations)**.** *Let X be projective over a field and $L_1, \dots, L_m$ line bundles. Suppose $\Theta = \sum_i \lambda_i [L_i] \in \mathrm{Pic}(X)_{\mathbf{R}}$ has ample numerical class. There are ample line bundles $H_1, \dots, H_r$ and real numbers $\mu_j > 0$ such that*

$$\sum_i \lambda_i [L_i] = \sum_j \mu_j [H_j] \quad \text{in } \mathrm{Pic}(X)_{\mathbf{R}}.$$

Moreover (λ, μ) *can be approximated arbitrarily closely by rational vectors* (λ', μ') *with all* $\mu'_j > 0$ *and the same exact relation in* $\mathrm{Pic}(X)_{\mathbf{Q}}$.

Proof. The inverse image of the numerical ample cone under $\mathbf{R}^m \to N^1(X)_{\mathbf{R}}$ is open and contains λ. Choose a rational box containing λ in its interior and contained in this inverse image. Every vertex v gives an ample Q-line bundle $\sum_i v_i[L_i]$; multiplying by a positive integer d_v gives an ample integral line bundle H_v. Express λ as the convex combination of the vertices with its positive multilinear barycentric coefficients t_v. Then the required equality in the Picard group, not merely in the numerical quotient, holds with $\mu_v = t_v/d_v$. This is an explicit use of openness of the ample cone.

For the second assertion, map $\mathbf{Q}^{m+r}$ to the finite-dimensional Q-subspace of $\mathrm{Pic}(X)_{\mathbf{Q}}$ spanned by these bundles, sending (a, b) to $\sum_i a_i[L_i] - \sum_j b_j[H_j]$. Its kernel has a rational basis, and its realification contains (λ, μ). Rational linear combinations of that basis are dense. Choose one sufficiently close to preserve all strict inequalities $\mu'_j > 0$. Equality in $\mathrm{Pic}(X)_{\mathbf{Q}}$ means that, after clearing denominators and killing a possible torsion class, the corresponding integral bundles are isomorphic. This is exactly what is needed for a generic trivialization. □

Proposition 11.14.8 (Ample correction of a real model class)**.** *Let* K *be complete and nontrivially valued and* X/K *projective. Let* θ *be a model* $(1,1)$*-class in the sense of [GM, 4.4–4.6], represented by a finite real combination of model line bundles, with ample generic numerical class. Given a formal model carrying those data, there is a projective algebraic model whose completion dominates it and a rational model function* φ *such that* $\theta + dd^c\varphi$ *is represented by an ample real class on that model. If* θ *is semipositive, then for every* $\epsilon > 0$ *one can arrange* $-\epsilon \le \varphi \le 0$ *on* X^{an}*. This statement concerns GM model classes; it is not a new local theorem about arbitrary CLD currents.*

Open proof obligation (RC2). Prove the model-class correction and uniform comparison with the stated positivity prerequisites; the proof uses GM 4.5 and Proposition 4.14.

Section 11.15.1 now supplies the additional morphism-algebraization theorem and strengthens these statements to actual algebraic domination. Section 11.15.2 verifies the separate reduced-fibre input in the published BGM Lemma 1.1.

11.15 Algebraic domination and reduced models

The cofinal constructions of Section 11.14 were formulated for formal completions. To use them in algebraic intersection theory, one must recover actual morphisms of algebraic models. This passage is available over a complete rank-one valuation ring, but it requires the non-Noetherian form of formal GAGA. We give the hypotheses explicitly, then apply the result to the simultaneous ample-model construction. A second, independent step produces a reduced special fibre over an algebraically closed field. Its role is to turn an analytic supnorm into an algebraic lattice norm.

11.15.1 Algebraizing the morphism, not merely the line bundle

Throughout this subsection, K is complete and nontrivially valued, with its given real-valued absolute value, and $R = K^\circ$. Fix $\pi \in R$ with $0 < |\pi| < 1$. Completion always means π-adic completion. We work with proper finitely presented R-schemes. No discrete-valuation assumption is made.

Proposition 11.15.1 (Formal GAGA for model morphisms)**.** *For proper finitely presented R-schemes $\mathscr{Y}, \mathscr{Z}$, completion induces a bijection*

$$\mathrm{Hom}_R(\mathscr{Y}, \mathscr{Z}) \xrightarrow{\sim} \mathrm{Hom}_{\mathrm{Spf}\, R}(\widehat{\mathscr{Y}}, \widehat{\mathscr{Z}}).$$

In particular, if they are models of the same proper K-scheme X, a formal morphism inducing $\mathrm{id}_{X^{\mathrm{an}}}$ algebraizes uniquely to a morphism inducing id_X.

Open proof obligation (RC2). Prove formal existence and faithfulness of proper analytification in the stated formal model category; the proof uses the cited FK17 corollaries/proposition.

The distinction between sheaves and morphisms matters here. Formal GAGA for coherent sheaves, [FK17, I, Theorem 10.1.2], algebraizes a formal line bundle on an already algebraized proper model. Proposition 11.15.1 also algebraizes the map to the prescribed model. In the source, the latter result is obtained by algebraizing the ideal of the graph. This is the additional step needed for domination in the algebraic directed system. All FK locators in this section refer to the fixed arXiv v5 of 28 February 2017.

Corollary 11.15.2 (Simultaneous algebraic domination)**.** *Let X/K be projective, let $L_1, \dots, L_r$ be ample, and prescribe finitely many proper finitely presented algebraic R-models $\mathscr{X}_a$ of X. There is a projective model $\mathscr{Y}$ with morphisms $\mathscr{Y} \to \mathscr{X}_a$ extending id_X, on which every L_i has an ample Q-model. All prescribed commutative diagrams among the $\mathscr{X}_a$ remain commutative after pullback.*

Proof. Choose a common formal refinement of the finitely many completions. Corollary 11.14.5 supplies $\mathscr{Y}$ and the ample Q-models, with a formal map from $\widehat{\mathscr{Y}}$ to each $\widehat{\mathscr{X}_a}$. Proposition 11.15.1 algebraizes each map and identifies its generic restriction. Equality of the two composites in any diagram follows from faithfulness of completion. Pullback of model line bundles along these algebraic maps has the prescribed formal pullback, so the metric identifications used in Section 11.14 are unchanged. □

Corollary 11.15.3 (The corrected algebraic model-class perturbation)**.** *Proposition 11.14.8 holds with algebraic domination of any prescribed proper finitely presented model. In particular, its rational model function can be represented on one algebraic model carrying the pulled-back initial data. If the initial class is semipositive, the bound $-\epsilon \le \varphi \le 0$ holds on X^{an} with the original absolute value.*

Proof. Include the prescribed model and all finitely many representatives of the initial class in Corollary 11.15.2. The exact generic Picard relation and the rational perturbation are those of Lemma 11.14.7 and Proposition 11.14.8. The new algebraic maps realize exactly the formal pullbacks used there. Hence their numerical classes, model functions and uniform bounds agree. No additional approximation or limiting argument is required. □

These corollaries reconstruct the conclusions needed from GM Propositions 4.11 and 4.14, using a different cofinal model. They do not restore the false fixed-model assertion of GM Lemma 4.12. The counterexample in Section 11.14.1 continues to apply.

11.15.2 The reduced-special-fibre step

For the next theorem assume additionally that K is algebraically closed and that X is reduced. The closure used below is the integral closure of a model

in its given generic fibre; it is not a replacement of X by its normalization. This distinction preserves the model's generic identification even when X is singular.

Theorem 11.15.4 (Reduced cofinal models with finitely many polarizations)**.** *Let K be complete, algebraically closed and nontrivially valued. Let X/K be reduced and projective, and $L_1, \dots, L_r$ ample. Given finitely many algebraic models as in Corollary 11.15.2, there is a projective model $\mathscr{X}$ dominating all of them, with reduced special fibre and ample Q-models of all L_i.*

Open proof obligation (RC2). Prove finiteness of the normalization and the reduced-special-fibre model step from the stated hypotheses; the argument invokes BE21 and BGM22.

Remark 11.15.5 (The field hypothesis in the reduced fibre theorem). BE Theorem 4.20 also gives finiteness of the integral closure when K is discretely valued. It does not assert a reduced special fibre in that case. For an arbitrary densely valued field, even finiteness can fail; [BE21, Remark 4.21] explains the obstruction from values of spectral norms outside $|K^\times|$. Thus algebraic domination, proved above over every complete nontrivially valued K, and reduced cofinality, asserted here over algebraically closed K, have different scopes.

11.15.3 Exact norms and the error that disappears in volume

Let $\mathscr{L}$ be a line bundle on a projective flat R-model $\mathscr{X}$, with generic fibre L, and put $\Lambda = H^0(\mathscr{X}, \mathscr{L}) \subset H^0(X, L)$. The lattice is finitely generated and spans the generic space. Its norm and the supnorm of the induced metric are

$$\|s\|_\Lambda = \inf\{|a| : a \in K^\times,\ s \in a\Lambda\}, \qquad \|s\|_{\sup} = \sup_{x \in X^{\mathrm{an}}} |s(x)|_{\mathscr{L}}.$$

By [BE21, Lemma 6.3], $\|s\|_{\sup} \le \|s\|_\Lambda$, with equality when the special fibre is reduced. The equality is also the input of [BGM22, Lemma 1.3]. The next calculation shows why replacing the hypothesis by normality of the model would not justify the same conclusion.

Example 11.15.6 (A normal ramified model with unequal norms)**.** Let K be complete discretely valued, π a uniformizer, and let $e \geq 2$ be prime to the residue characteristic. Put $E = K(\alpha)$, where $\alpha^e = \pi$. The polynomial is Eisenstein, E/K is separable and totally ramified, and $R_E = R[\alpha]$ is the valuation ring of E. For any $n \geq 0$ take

$$\mathscr{X} = \mathbf{P}^n_{R_E}, \quad X = \mathbf{P}^n_E \quad \text{as an } R\text{-model and a } K\text{-scheme}, \qquad \mathscr{L} = \mathcal{O}(1).$$

Then $\mathscr{X}$ is normal, projective and flat over R, and X is smooth over K. Its special fibre over R is not reduced. For $m \geq 1$ and

$$s = \sum_{|\beta|=m} \sum_{i=0}^{e-1} b_{i\beta} \alpha^i T^\beta, \qquad b_{i\beta} \in K,$$

the two norms are

$$\|s\|_{\Lambda_m} = \max_{i,\beta} |b_{i\beta}|, \qquad \|s\|_{m\phi} = \max_{i,\beta} |b_{i\beta}|\,|\pi|^{i/e}, \qquad \Lambda_m = H^0(\mathscr{X}, \mathcal{O}(m)). \tag{11.15.1}$$

Consequently the norms have the same unit ball but are unequal, and

$$|\pi|^{(e-1)/e} \|s\|_{\Lambda_m} \leq \|s\|_{m\phi} \leq \|s\|_{\Lambda_m}.$$

Proof. The special fibre is $\mathbf{P}^n_{k[\alpha]/(\alpha^e)}$, whereas $\mathscr{X}$ is a projective space over the DVR R_E and hence is normal. The monomials $\alpha^i T^\beta$ form an R-basis of Λ_m, proving the first formula. Write a coefficient as $c_\beta = \sum_i b_{i\beta}\alpha^i$. Distinct nonzero summands have valuations in different cosets of $\mathbf{Z}$ in $e^{-1}\mathbf{Z}$, when $v(\pi) = 1$. Thus there is a unique term of least valuation and no cancellation at that valuation:

$$|c_\beta| = \max_i |b_{i\beta}|\,|\pi|^{i/e}.$$

For the standard projective model metric, the supnorm of a homogeneous polynomial equals the largest absolute value of its coefficients. The ultrametric inequality gives the upper bound, and the Gauss point in the chart $T_0 \neq 0$ gives equality. This proves the second formula. Finally, $v(b_{i\beta}) + i/e \geq 0$ holds for every i, β if and only if every integer $v(b_{i\beta})$ is nonnegative. Hence the unit balls agree. Taking $s = \alpha T_0^m$ gives supnorm $|\pi|^{1/e}$ and lattice norm 1, so the norms differ in every dimension. □

The discrepancy can be computed on the determinant line as well. Put $M_m = \binom{m+n}{n}$ and $\lambda = -\log|\pi|$. The eM_m basis elements in (11.15.1) are

orthogonal for both norms. The determinant norm of an orthogonal basis is the product of its norms: the ultrametric determinant inequality gives the lower bound for any decomposition of the same determinant vector, and the chosen basis attains it. Consequently,

$$\log \frac{\det \| \cdot \|_{\Lambda_m}}{\det \| \cdot \|_{m\phi}} = M_m \lambda \sum_{i=0}^{e-1} \frac{i}{e} = \frac{e-1}{2} M_m \lambda.$$

This grows like m^n, but multiplication by $n!/m^{n+1}$ makes it asymptotic to $(e-1)\lambda/(2m)$. Thus a persistent, nonzero norm discrepancy can disappear in the volume normalization. The pointwise comparison constant $|\pi|^{-(e-1)/e}$ is optimal, as the section $\alpha^{e-1} T_0^m$ shows. These exact calculations illustrate the two different scales in Proposition 11.15.8.

The absolute value on E in this example is the extension of the one on K: $|\alpha| = |\pi|^{1/e}$. Renormalizing the valuation of E so that α has value 1 would multiply its restriction to K by e and would change the problem. Also, equality of unit balls determines a norm when $|K^\times|$ is dense, by arbitrarily close scalar rescaling; it need not do so over a discretely valued field. This is why a lattice description by itself does not establish an isometry.

This failure of isometry does not refute the effectivity criterion for vertical Cartier divisors on normal models. GM Remark 4.10 gives that criterion without a reduced-special-fibre assumption. In the explicit model above, a vertical divisor $k \operatorname{div}(\alpha)$ is effective exactly when $k \geq 0$, and its model function is $-k \log |\alpha|$, with the same sign. Effectivity detects the unit-ball inequality; an isometry determines every radius.

Example 11.15.7 (Strict norm inequality after wild scalar extension)**.** Let K be a finite extension of $\mathbf{Q}_p$ containing a primitive pth root of unity ζ, let π be a uniformizer, and put $E = K(\alpha)$ with $\alpha^p = \pi$. Then E/K is cyclic of degree p. For $X = \operatorname{Spec} E$ and the trivial metric, the original supnorm is $|\cdot|_E$. On $E \otimes_K E$, the scalar extension of this norm is strictly larger than the supnorm of the pulled-back metric. More precisely,

$$q = \frac{1}{p} \sum_{i=0}^{p-1} \alpha^{-i} \otimes \alpha^i \quad \text{satisfies} \quad \|q\|_{\text{tensor}} = |p|^{-1}, \qquad \|q\|_{\sup} = 1. \tag{11.15.2}$$

The same discrepancy occurs for sections of $\mathcal{O}(m)$ on $\mathbf{P}^n_E$ regarded as a K-scheme, in every dimension n and every $m \geq 1$. This is an explicit instance of the obstruction in [BE21, Lemma 6.2], not a counterexample to that lemma.

Proof. Eisenstein's criterion gives $[E:K]=p$, and the automorphisms are $\sigma_j(\alpha)=\zeta^j\alpha$, $0\le j<p$. The distinct valuation classes of $1,\alpha,\dots,\alpha^{p-1}$ make this an orthogonal K-basis of the normed space E. Its scalar-extended norm, with the left tensor factor as coefficient field, is therefore

$$\left\|\sum_i c_i\otimes\alpha^i\right\|_{\mathrm{tensor}}=\max_i |c_i|\,|\alpha|^i.$$

For q all displayed terms have norm $|p|^{-1}$. On the other hand, the splitting isomorphism

$$E\otimes_K E\longrightarrow\prod_{j=0}^{p-1}E,\qquad a\otimes b\longmapsto(a\sigma_j(b))_j$$

sends q to $(1,0,\dots,0)$, by the finite geometric sum $p^{-1}\sum_i\zeta^{ij}$. The pulled-back metric has supnorm equal to the maximum of the component norms, so its value on q is 1. For projective space, take the section qT_0^m. The monomial basis together with the orthogonal basis of E/K gives the same tensor norm, and the Gauss point on the first split component gives the same supnorm. All norms use the unique extension of the original absolute value. □

Proposition 11.15.8 (Uniform norm comparison and relative volume)**.** *Let X be geometrically reduced and projective over complete nontrivially valued K, let L be ample, and let $\mathscr{L}_1,\mathscr{L}_2$ be integral models of L inducing metrics ϕ_1,ϕ_2. Put $N_m=h^0(X,L^m)$, $s_{i,m}=\|\cdot\|_{m\phi_i}$ and $\ell_{i,m}=\|\cdot\|_{H^0(m\mathscr{L}_i)}$. There are $C_i\ge1$, independent of m, such that*

$$s_{i,m}\le\ell_{i,m}\le C_i s_{i,m}.$$

With $\mathrm{vol}(u,v)=\log(\det v/\det u)$ *on the determinant line, one has*

$$|\mathrm{vol}(s_{1,m},s_{2,m})-\mathrm{vol}(\ell_{1,m},\ell_{2,m})|\le N_m\max\{\log C_1,\log C_2\}. \tag{11.15.3}$$

If $d=\dim X$, the difference multiplied by $d!/m^{d+1}$ tends to zero. Thus replacing supnorms by these lattice norms preserves relative volume, although it need not preserve any individual norm.

Open proof obligation (RC2). Prove the uniform bound and determinant-to-volume limit; BE21 Theorem 6.4 and Lemma 9.17 are used.

There is a further distinction in the scalar-extension step. For a complete extension F/K, the pulled-back metric has the same supnorm on sections originally defined over K. On all of $H^0(X_F, L_F)$, however, its supnorm is only bounded above by the scalar extension of the original norm in general; see [BE21, Lemmas 6.1 and 6.2]. Equality on the original sections is sufficient in the comparison proof. One must not replace it by an unproved isometry on the enlarged vector space. None of these model and norm results identifies an arbitrary positive CLD current with a nef metric, or establishes an unrestricted Bedford–Taylor product.

Geometric reducedness also has a concrete role in the extension step. Over $K = \mathbf{F}_p((\pi))$, put $E = K(\alpha)$ with $\alpha^p = \pi$. The scheme $\operatorname{Spec} E$ is reduced over K, but $E \otimes_K E \simeq E[\varepsilon]/(\varepsilon^p)$. The nonzero element $1 \otimes \alpha - \alpha \otimes 1$ has zero analytic sup-seminorm after extension, whereas its scalar-extended vector-space norm is positive. Thus the proof cannot replace geometric reducedness by reducedness when it requires a norm on every extended section space. This calculation is not a counterexample to BE Theorem 6.4 under its stated hypotheses.

11.16 An analytic realization of the fixed-chart obstruction

Example 11.10.9 separated relative convexity from ambient convex extension on an abstract fan. We now realize that fan by analytic units. The same chart also supports an original CLD smooth psh function with no ambient convex extension, even locally at its central vertex. This gives a concrete test for a proposed smooth-to-PL argument: it must allow relative convexity or a change of chart. It does not contradict such a comparison when these choices are allowed.

11.16.1 Four punctures and two tropical coordinates

Let K be complete and nontrivially valued, with $|2| = 1$. On

$$C = \mathbf{P}^1_K \setminus \{0, 1, -1, \infty\}$$

use the analytic units $f = t(t-1)$ and $g = t(t+1)$, and write

$$x = -\log|f|, \qquad y = -\log|g|, \qquad s = -\log|t|,$$
$$\tau = (x, y) : C^{\mathrm{an}} \longrightarrow \mathbf{R}^2.$$

The unit-disc Gauss point ξ belongs to C^{an} and maps to the origin. No extension of K is made.

Proposition 11.16.1 (The fan and its analytic refinement)**.** *The image of τ is the support of the fan in Example 11.10.9: the four rays generated by $(1,0),(0,1),(1,1),(-1,-1)$. The refinement by the three units $t-1, t+1, t$ has image the four rays generated by $e_1, e_2, e_3, -e_1-e_2-e_3$. Under*

$$(z_1,z_2,z_3) = (-\log|t-1|, -\log|t+1|, -\log|t|),$$
$$A(z_1,z_2,z_3) = (z_1+z_3, z_2+z_3).$$

one has $\tau = A\circ\widetilde{\tau}$. The relative PL function of that example pulls back to $\max\{s,0\}$. Thus its previously abstract convex presentation after refinement is realized by analytic units.

Proof. If $|t|<1$, the ultrametric inequality gives $|t-1| = |t+1| = 1$, so $(x,y) = (s,s)$ with $s>0$. If $|t|>1$, both $|t\pm 1|$ equal $|t|$, so $(x,y) = (2s,2s)$ with $s<0$. If $|t|=1$, both $|t\pm 1|\le 1$. They cannot both be strictly smaller than 1, because their difference is 2 and $|2|=1$. Thus the image lies on a nonnegative coordinate ray or at the origin. These arguments apply to the multiplicative seminorm of every Berkovich point.

Conversely, the Gauss points of discs centered at $0,1,-1$ with radius $r<1$, and of discs centered at 0 with radius $r>1$, realize every point on the four rays. Arbitrary positive real radii are allowed for Berkovich points; no value-group enlargement is needed. The same case distinction gives the three-coordinate image and the identity involving A. On the ray over 0 the PL function is s, and it is zero on the other rays, hence equals $\max\{s,0\}$. The orders of f,g at the four punctures are $(1,1),(1,0),(0,1),(-2,-2)$, explaining the primitive ray weights $1,1,1,2$ and their balancing identity. □

Lemma 11.16.2 (A smooth barrier does not remove the first-order obstruction)**.** *Let F_0 denote the relative PL function of Example 11.10.9, so $F_0(h,h) = h$ and $F_0(2h,0) = F_0(0,2h) = 0$. For every ambient C^2 function B near the origin, $F_0 + B|_\Sigma$ still has no ambient convex extension near the origin. If $\|D^2B\|_{\mathrm{op}} \le M$ on the relevant segments, its midpoint convexity defect is at least $h - Mh^2$.*

Proof. Put $a=(h,h)$ and $v=(h,-h)$. The affine part of the Taylor expansion cancels in $B(a)-\frac{1}{2}B(a+v)-\frac{1}{2}B(a-v)$. The remainder is bounded below

by $-M\|v\|^2/2 = -Mh^2$. Adding the exact defect h of F_0 gives the assertion, which is positive for all sufficiently small $h > 0$. Thus even an arbitrarily large fixed quadratic barrier cannot correct this first-order failure. □

For a convex smooth B, the pullback $\max\{s, 0\} + B(x, y)$ is nevertheless psh: the first summand is a locally uniform limit of smooth convex functions of the pluriharmonic unit logarithm s, and the second is an ambient convex pullback. The lemma therefore concerns a false extension shortcut even inside a positive class. It does not obstruct relative PL approximation or a change of analytic presentation.

11.16.2 A smooth psh function that is not ambient convex in this chart

Example 11.16.3 (A fixed-chart obstruction already for smooth psh functions)**.** The function $u = xy$ on C^{an} is original CLD smooth and psh on all original tests. Nevertheless, the function $F(a, b) = ab$ restricted to $\tau(C^{\mathrm{an}})$ has no ambient convex extension on any convex open neighbourhood of the origin. Moreover, on any subset containing $(h, h), (2h, 0), (0, 2h)$ with $h > 0$, every restriction G of an ambient convex function satisfies

$$\max_{z\in\{(h,h),(2h,0),(0,2h)\}} |G(z) - F(z)| \geq \frac{h^2}{2}. \tag{11.16.1}$$

Every ordinary open neighbourhood of ξ has a tropical image containing such a triple for some $h > 0$. Consequently a fixed-chart uniform approximation by ambient convex functions fails on every such neighbourhood.

Proof. Smoothness follows because x, y are logarithms of analytic units and multiplication is a smooth operation. The case distinction in Proposition 11.16.1 gives the additional identity

$$u = H(s), \qquad H(v) = (\max\{v, 0\})^2 + 4(\max\{-v, 0\})^2.$$

The real function H is convex: its derivative is $8v$ for $v < 0$ and $2v$ for $v > 0$, with common value zero at the origin. Choose smooth convex regularizations H_ϵ converging uniformly on compact real intervals to H. The function $s = -\log|t|$ is original smooth and pluriharmonic, since t is a unit. Therefore

$$d'd''H_\epsilon(s) = H_\epsilon''(s)\, d's \wedge d''s \geq 0.$$

For every compactly supported original CLD test, s is bounded on its support, so $H_\epsilon(s) \to u$ uniformly there. Passing to curvature currents preserves positivity on every original positive test. This proves psh without asserting that the ambient polynomial ab is convex. The relative function has touching affine lower supports: zero at the vertex and a tangent affine function along a ray away from the vertex.

Suppose the maximum error on the three points is ϵ. Since (h, h) is the midpoint of $(2h, 0)$ and $(0, 2h)$, convexity gives

$$h^2 - \epsilon \le G(h, h) \le \tfrac{1}{2}G(2h, 0) + \tfrac{1}{2}G(0, 2h) \le \epsilon.$$

This proves (11.16.1) and rules out an exact extension. The three Gauss-point paths toward $0, 1, -1$ are continuous and have common limit ξ as their radii tend to 1. An ordinary neighbourhood of ξ therefore contains initial segments of all three paths, giving the asserted triple for small h. The argument also rules out uniform convergence on a fixed compact set containing the corresponding three analytic points. □

Corollary 11.16.4 (The obstruction in every positive dimension)**.** *For every $d \ge 1$, the preceding smooth psh example occurs on an ordinary open subset of the integral projective variety $(\mathbf{P}^1_K)^d$. In the product moment chart the same fixed-chart obstruction persists, while a different analytic presentation makes the function ambient convex.*

Proof. Use $C \times (\mathbf{G}_m)^{d-1}$, pull u back from its first factor, and take the chart consisting of f, g and the torus coordinates. The smooth convex approximations $H_\epsilon(-\log|t|)$ still have positive original curvature, so their locally uniform limit is psh. Fix the remaining tropical coordinates to zero. Restricting any proposed ambient convex extension to that affine slice contradicts (11.16.1). On the other hand, the unit t alone presents the function as the pullback of the convex real function H. The coefficient-controlled approximation of Section 11.12.4 can be applied to this latter presentation on bounded tropical images. □

The example closes the analytic-realization question left by the earlier fan calculation, but not the general chart-selection problem. It proves failure of one fixed-chart shortcut, together with an explicit successful change of analytic presentation in the example itself. In particular, it is not a counterexample

to full Wu Theorem A.3, and it does not identify the general original smooth psh class with a prescribed tropical generator class.

For uniform approximation, the fixed-domain qualification is essential: the error bound concerns ambient convex functions defined at the three fixed points, or locally convex functions on one fixed ambient neighbourhood containing a convex ball around the origin. It does not rule out approximants whose ambient neighbourhoods shrink with the index, nor approximants defined only by relative supports on the tropical image.

11.16.3 Removing the residue-characteristic restriction

The four rational punctures above require $|2| = 1$ so that their residue directions remain distinct. That restriction can be removed by replacing one rational puncture with the zero locus of a polynomial whose reduction avoids both 0 and 1. The resulting function and its convex alternative presentation are still defined over the original field.

Theorem 11.16.5 (A fixed-chart smooth psh obstruction over every nontrivial field)**.** *Let K be any complete nontrivially valued non-Archimedean field, with its fixed absolute value. Set*

$$\begin{gathered} P(t) = t^2 - t + 1, \\ C = \mathbf{P}^1_K \setminus \big(\{0, 1, \infty\} \cup V(P)\big), \\ f = t(t-1), \qquad g = tP(t), \\ x = -\log|f|, \quad y = -\log|g|, \quad s = -\log|t|. \end{gathered}$$

Then $u = xy$ is original smooth psh on C^{an}, but it has no ambient convex presentation in the fixed chart (x, y) near the unit-disc Gauss point. The quantitative bound (11.16.1) still holds. The example extends to an ordinary open subset of $(\mathbf{P}^1_K)^d$ for every $d \geq 1$. In particular, residue characteristics 2 and 3 are included.

Proof. Both f and g are units on C. If $|t| < 1$, then $|t-1| = |P(t)| = 1$, giving $(x, y) = (s, s)$. If $|t| > 1$, then $|t-1| = |t|$ and $|P(t)| = |t|^2$, giving $(x, y) = (2s, 3s)$. If $|t| = 1$, put $f = t(t-1)$ and note the exact identity $P = f + 1$. The numbers $|f|, |P|$ are at most 1 and cannot both be smaller than 1. Since $|g| = |P|$ in this case, at least one of x, y is zero. Therefore

$$u = H(s), \qquad H(v) = (\max\{v, 0\})^2 + 6(\max\{-v, 0\})^2.$$

This function H is convex, with derivatives $12v$ for $v < 0$ and $2v$ for $v > 0$. The same convex regularization argument as above proves positivity against all original compactly supported tests. The formula $u = xy$ proves original smoothness.

The diagonal and horizontal ray segments at the origin are realized by Gauss points of small discs around 0 and 1. To exhibit the vertical segment, choose a root a of P in a finite extension K'/K, endowed with the unique extended absolute value. Both roots have absolute value 1, and $P(1) = 1$ implies $|a - 1| = 1$. Gauss points of K'-discs centered at a with radii $r < 1$ and close to 1 therefore have $|t| = |t - 1| = 1$, while $|P(t)| < 1$ approaches 1 as $r \uparrow 1$. More precisely, factor P over a finite splitting extension. On such a disc,

$$|P|_{a,r} = \prod_{P(b)=0} \max\{r, |a - b|\},$$

where roots are counted with multiplicity. For r sufficiently close to 1, this is r^q with $q \in \{1, 2\}$, so it realizes a whole vertical interval. Restricting these multiplicative seminorms to $K[t]$ gives actual points of C^{an} tending to its unit-disc Gauss point. This use of an auxiliary field constructs points over K; the function, the positivity proof and the approximation question have not been base-changed, and no current-descent assertion is used.

Every ordinary neighbourhood of that Gauss point consequently contains analytic points with tropical coordinates $(h, h), (2h, 0), (0, 2h)$ for small $h > 0$. Their function values are $h^2, 0, 0$, giving the same midpoint obstruction and error bound. The product construction of Corollary 11.16.4 gives every positive dimension. Repeated roots of P cause no difficulty: their multiplicities are already included in the displayed Gauss-norm formula. □

11.17 Relative approximation in a chart without convex extension

The obstruction in Section 11.16 concerns ambient convex functions. It leaves open whether relative convex PL functions suffice on the very same chart. We answer this question for the explicit family constructed there, including a perturbation with a uniform positive tangential Hessian. The proof keeps the value group visible: all affine slopes of the approximants are rational, and all constants belong to $\Gamma_{\mathbf{Q}}$. It gives a worked comparison in every positive dimension, rather than the general converse in Wu's Theorem A.3.

The source distinction behind the construction is already important for smooth functions. Gubler–Künnemann retain the smooth facewise-convexity criterion in [GK19, Remark 3.2], while their Example 3.3 disproves its extension to arbitrary continuous functions; see Example 11.1.4. For a smooth representative on a locally finite complex, Lemma 11.8.4 supplies a centred affine lower support at each point. Neither statement supplies an ambient convex extension, nor a lower bound on the contact radius independent of the point. The following calculation separates all three assertions.

11.17.1 Tangential positivity and the size of a contact neighbourhood

Fix a complete nontrivially valued field K with its given absolute value. Use the all-field construction of Theorem 11.16.5:

$$P(t) = t^2 - t + 1, \qquad C = \mathbf{P}^1_K \setminus \big(\{0, 1, \infty\} \cup V(P)\big),$$
$$Y = C \times (\mathbf{G}_m)^{d-1}, \qquad d \geq 1,$$
$$x = -\log|t(t-1)|, \quad y = -\log|tP(t)|, \quad z_i = -\log|w_i|,$$
$$\tau = (x, y, z_1, \dots, z_{d-1}).$$

Here w_i are the torus coordinates. The image is $S \times \mathbf{R}^{d-1}$, where S is the union of the four rays generated by $(1,1), (1,0), (0,1), (-2,-3)$. The unit-disc Gauss point in the first factor, together with $w_i = 1$ in the other factors, gives a point ξ_d with tropical image zero.

Proposition 11.17.1 (Positive tangential Hessian without ambient convex extension)**.** *Let $0 < \varepsilon < 1/2$, and put*

$$F_\varepsilon(x, y, z) = xy + \varepsilon\left(x^2 + y^2 + \sum_{i=1}^{d-1} z_i^2\right), \qquad u_\varepsilon = F_\varepsilon \circ \tau. \tag{11.17.1}$$

Then u_ε is original CLD smooth and psh. For each maximal face σ of $S \times \mathbf{R}^{d-1}$ and each vector v tangent to σ,

$$D^2 F_\varepsilon(v, v) \geq 2\varepsilon\|v\|^2. \tag{11.17.2}$$

Nevertheless, $F_\varepsilon|_{S \times \mathbf{R}^{d-1}}$ has no ambient convex extension near zero. If an ambient convex function G is defined on a convex set containing

$$p_h = (h, h, 0), \qquad q_h = (2h, 0, 0), \qquad r_h = (0, 2h, 0), \quad h > 0,$$

then

$$\max_{a\in\{p_h,q_h,r_h\}} |G(a) - F_\varepsilon(a)| \geq \frac{1-2\varepsilon}{2}h^2. \tag{11.17.3}$$

Every ordinary neighbourhood of ξ_d contains analytic points realizing such triples for all sufficiently small $h > 0$. Thus ambient convex approximation in this chart cannot converge uniformly on any fixed such neighbourhood.

Proof. Theorem 11.16.5 proves that xy is original smooth psh, by expressing it as the convex function $s_+^2 + 6s_-^2$ of $s = -\log|t|$ and using smooth regularization. The added quadratic is an ambient smooth convex function of unit logarithms. Its pullback is smooth psh, so their sum is psh on all original CLD tests. No pullback operation on arbitrary currents is involved.

Write a tangent vector as $v = (a\alpha, a\beta, v_z)$, where (α, β) is a generator of one of the four rays. In each case $\alpha\beta \geq 0$, and

$$D^2F_\varepsilon(v,v) = 2a^2\alpha\beta + 2\varepsilon\|v\|^2,$$

which proves (11.17.2). This is the precise tangential positivity assertion used here; it is not a claim about every possible convention for strict psh.

Since $p_h = (q_h + r_h)/2$, the values of F_ε give the midpoint defect

$$F_\varepsilon(p_h) - \frac{F_\varepsilon(q_h) + F_\varepsilon(r_h)}{2} = (1-2\varepsilon)h^2.$$

If the error at all three points is at most e, convexity of G bounds this defect above by $2e$. This proves (11.17.3). The Gauss-point paths in Theorem 11.16.5, with $w_i = 1$, converge to ξ_d and realize the three rays in question. Fixing one sufficiently small h in a proposed approximation domain gives a positive error lower bound independent of the approximant. □

The threshold in this quadratic family is exact: the ambient Hessian has eigenvalues $2\varepsilon + 1$, $2\varepsilon - 1$, and 2ε in the remaining directions. Thus F_ε itself is ambient convex when $\varepsilon \geq 1/2$. A positive lower bound on its restrictions to face tangent spaces is therefore strictly weaker than ambient convexity.

Corollary 11.17.2 (Monomial refinements and nonuniform contact radii)**.** *Replacing or augmenting the coordinates of τ only by constants times monomials in its original units does not remove the ambient convex obstruction. Also, any affine lower support ℓ for $F_\varepsilon|_{S\times\mathbf{R}^{d-1}}$ at p_h, valid on a relative ball $B(p_h, R) \cap (S \times \mathbf{R}^{d-1})$, must satisfy $R \leq \sqrt{2}h$. In particular, the contact radii cannot have a positive uniform lower bound as $p_h \to 0$.*

Proof. A monomial change has tropical form $b \mapsto Bb + c$, with an integral matrix B and $c \in \Gamma^m$. It preserves the midpoint relation of the three points. The composition of an ambient convex function with this affine map is convex on the inverse image of its convex domain, so the preceding defect argument applies unchanged. Injectivity of B is unnecessary. For the second assertion, if $R > \sqrt{2}h$, both q_h, r_h belong to the ball. An affine lower support with equality at p_h would give

$$F_\varepsilon(p_h) = \ell(p_h) = \frac{\ell(q_h) + \ell(r_h)}{2} \le \frac{F_\varepsilon(q_h) + F_\varepsilon(r_h)}{2},$$

contrary to the positive defect. □

There is no conflict with Lemma 11.8.4: that lemma fixes the contact point, and its radius is allowed to depend on the point. Nor does this corollary require a chart change for relative PL approximation. The construction below takes place in the original chart. New analytic units can change the ambient problem: the unit t used above is not a monomial in $t(t-1)$ and $tP(t)$, even after allowing a nonzero integral power of t. Indeed, in $t^m = c[t(t-1)]^a[tP(t)]^b$, orders at 1 force $a = 0$, orders at a zero of P force $b = 0$, and the order at 0 then forces $m = 0$.

11.17.2 An explicit decreasing approximation with controlled coefficients

The general ambient density argument in Section 11.12.4 can be made particularly explicit for the positive-part square. We give the formula because it allows composition with relative PL functions without introducing constants outside the value group.

Lemma 11.17.3 (Rational PL approximation of the positive-part square)**.** *Let $\Gamma \subset \mathbf{R}$ be a nonzero additive subgroup, fix $\lambda \in \Gamma_{>0}$ and $M > 0$, and put $\Gamma_{\mathbf{Q}} = \Gamma \otimes_{\mathbf{Z}} \mathbf{Q} \subset \mathbf{R}$. There are nonnegative, nondecreasing, convex PL functions $q_j : \mathbf{R} \to \mathbf{R}$, with rational slopes and constants in $\Gamma_{\mathbf{Q}}$, such that on $[-M, M]$*

$$q_{j+1} \le q_j, \qquad 0 \le q_j(t) - t_+^2 \le \frac{8}{3}\lambda 4^{-j}, \qquad j \ge 0. \tag{11.17.4}$$

The decrease in j is asserted on this fixed interval, not on all of $\mathbf{R}$.

Proof. Choose an integer $N_0 \geq 1$ with $(4N_0^2)^{-1} \leq \lambda$, and set $N_j = N_0 2^j$ and $\gamma_j = \lambda 4^{-j}$. For $0 \leq k \leq \lceil 2MN_j \rceil$, put

$$p_{j,k} = \frac{k}{N_j}, \qquad c_{j,k} = \gamma_j \left\lfloor -\frac{p_{j,k}^2}{4\gamma_j} \right\rfloor, \qquad a_j(t) = \max_k \{p_{j,k}t + c_{j,k}\}.$$

The slopes are rational and nonnegative. The rounded constants are in $\Gamma_{\mathbf{Q}}$; in particular we have not assumed that squares of value-group elements remain in that group. The $k = 0$ branch is zero. Every other branch lies below the tangent line $pt - p^2/4$ of t^2 at $p/2$, and hence below t_+^2 on $\mathbf{R}$. For $t \in [0, M]$, select $p = k/N_j$ with $|2t - p| \leq N_j^{-1}$. The two errors satisfy

$$t^2 - (pt - p^2/4) = (t - p/2)^2 \leq \frac{1}{4N_j^2} \leq \gamma_j,$$
$$0 \leq -p^2/4 - c_{j,k} < \gamma_j.$$

For $t < 0$, $a_j(t) = 0 = t_+^2$. Thus $0 \leq t_+^2 - a_j(t) \leq 2\gamma_j$ on $[-M, M]$. To obtain decrease without requiring the supporting lines to be nested, define

$$\delta_j = \sum_{k=j}^{\infty} 2\gamma_k = \frac{8}{3}\gamma_j, \qquad q_j = a_j + \delta_j.$$

Both δ_j and every affine constant of q_j belong to $\Gamma_{\mathbf{Q}}$. On the fixed interval,

$$q_j - q_{j+1} \geq -2\gamma_j + \delta_j - \delta_{j+1} = 0, \qquad \frac{2}{3}\gamma_j \leq q_j - t_+^2 \leq \frac{8}{3}\gamma_j.$$

These inequalities prove the claim. Nonnegativity and monotonicity as functions of t follow from the zero branch, the positive shift, and the nonnegative slopes. □

Proposition 11.17.4 (Composition with relative PL supports)**.** *Let T be a subset of a real vector space. Suppose that the continuous functions $\psi_1, \ldots, \psi_m : T \to [0, M]$ have local affine lower supports and finite-selection PL presentations with rational slopes and constants in $\Gamma_{\mathbf{Q}}$. For $b_i \in \mathbf{Q}_{\geq 0}$, the functions*

$$v_j = \sum_{i=1}^{m} b_i q_j(\psi_i)$$

have the same two properties. On all of T, they decrease uniformly to $\sum_i b_i \psi_i^2$, with error at most $(8/3)\lambda 4^{-j} \sum_i b_i$. If T is the image of a chart of analytic

units over K and $\Gamma = -\log|K^\times|$, their pullbacks are actual $\mathbf{Q}$-PL functions by Proposition 11.11.5, on its good strictly analytic pure-dimensional domain. They are classically psh by Theorem 11.11.2, and have nef residues by Theorem 11.11.6.

Proof. Fix $a \in T$ and an affine lower support ℓ for ψ_i at a. Choose an active affine branch $pt + c$ of q_j at $\psi_i(a)$. Since $p \geq 0$, near a one has

$$q_j(\psi_i(b)) \geq p\psi_i(b) + c \geq p\ell(b) + c,$$

with equality at $b = a$. Summing the resulting affine lower supports proves the support assertion. Finite selections remain finite after composition with a finite maximum and after a finite sum. Rational coefficients remain rational, and $\Gamma_{\mathbf{Q}}$ is closed under rational multiplication and addition. The uniform estimate and the decrease follow term by term from Lemma 11.17.3. The analytic conclusions use the three cited results with exactly these coefficient and support hypotheses; no ambient convex extension is required. □

Theorem 11.17.5 (Same-chart relative approximation of the obstructed family)**.** *In (11.17.1), assume also $\varepsilon \in \mathbf{Q}$. For every $M > 0$, on the single ordinary open set*

$$V = \tau^{-1}\big((-M, M)^{d+1}\big) \subset Y^{\mathrm{an}},$$

there is a decreasing sequence of relative convex rational PL functions in the original chart, with constants in $\Gamma_{\mathbf{Q}}$, whose pullbacks converge uniformly to u_ε. These pullbacks are actual $\mathbf{Q}$-PL functions with nef residues. No extension of the base field and no change of the analytic chart are needed.

Proof. On S, define

$$A(x, y) = \max\{0, \min(x, y)\}, \qquad B(x, y) = \max\{0, -x/2, -y/3\}.$$

The function A has local affine lower supports: at the vertex, zero is a support; away from it a sufficiently small relative neighbourhood lies on one ray, where A is affine. The same argument applies on $S \times \mathbf{R}^{d-1}$, since A is independent of z. The function B is ambient convex. Both have rational finite-selection PL presentations with zero constants. Evaluating on the four rays gives

$$xy = A^2 + 6B^2 \quad \text{on } S. \tag{11.17.5}$$

Indeed, the values of (A, B) are $(s, 0)$ on $(x, y) = (s, s)$ with $s \geq 0$, $(0, -s)$ on $(x, y) = (2s, 3s)$ with $s \leq 0$, and $(0, 0)$ on both nonnegative coordinate rays.

Choose $\lambda \in \Gamma_{>0}$, which is possible because the valuation is nontrivial, and use the functions q_j of Lemma 11.17.3. On the fixed tropical image of V, put

$$v_j = q_j(A) + 6q_j(B) + \varepsilon \left(q_j(|x|) + q_j(|y|) + \sum_{i=1}^{d-1} q_j(|z_i|) \right). \tag{11.17.6}$$

Every argument of q_j lies in $[0, M]$. The functions $|x|, |y|, |z_i|$ are ambient convex rational PL. Proposition 11.17.4 therefore applies to all summands, and (11.17.5) identifies the limit as F_ε. More precisely, throughout $\tau(V)$,

$$0 \le v_j - F_\varepsilon \le \big(7 + \varepsilon(d+1)\big)\frac{8}{3}\lambda 4^{-j}, \qquad v_{j+1} \le v_j. \tag{11.17.7}$$

The set V is an ordinary open subset of the smooth analytification Y^{an}, hence good, strictly analytic, and pure-dimensional. The coefficient, classical psh and nef-residue conclusions of Proposition 11.17.4 apply on V. All constants were constructed inside the original $\Gamma_{\mathbf{Q}}$; the use of its divisible hull means rational model data, not a change of the absolute value or an implicit field extension. □

This example gives both the failed ambient approximation and a successful relative approximation on the same fixed neighbourhood. The argument extends beyond squares. The extra point in the next statement is to preserve nonnegative slopes when rationalizing supporting hyperplanes: that sign is what makes composition preserve relative lower supports.

Proposition 11.17.6 (Monotone convex composition in any dimension)**.** *Let $\psi = (\psi_1, \dots, \psi_m) : T \to [0, M]^m$ satisfy the hypotheses of Proposition 11.17.4. Let H be a finite convex function on a convex open neighbourhood of $[0, M]^m$, nondecreasing in each coordinate there. For every $\lambda \in \Gamma_{>0}$ there are finite maxima Q_j of affine functions with slopes in $\mathbf{Q}^m_{\ge 0}$ and constants in $\Gamma_{\mathbf{Q}}$ such that*

$$Q_{j+1} \le Q_j, \qquad 0 \le Q_j - H \le 4\lambda 4^{-j} \quad \text{on } [0, M]^m. \tag{11.17.8}$$

Consequently $Q_j \circ \psi$ are coefficient-compatible relative PL functions decreasing uniformly to $H \circ \psi$ on the same set T. The analytic PL, classical psh and nef-residue conclusions of Proposition 11.17.4 apply to their pullbacks.

Proof. Put $D = [0, M]^m$ and $\gamma_j = \lambda 4^{-j}$. As in Proposition 11.12.9, the supporting-hyperplane theorem supplies an affine minorant $\ell_a(t) = p_a \cdot t + b_a$ touching H at each $a \in D$. All coordinates of p_a are nonnegative: if $(p_a)_i < 0$,

the support inequality at $a-he_i$ for small $h>0$ would contradict the assumed monotonicity of H. This uses the open neighbourhood of D, including at its boundary.

The sets where $H-\ell_a<\gamma_j$ cover D. By continuity and compactness, finitely many of these supports suffice. For each selected pair (p,b), choose $r\in\mathbf{Q}^m_{\geq 0}$ with $r_i\leq p_i$ and $\|p-r\|_1\leq \gamma_j/(M+1)$, and set $c=\gamma_j\lfloor b/\gamma_j\rfloor\in\Gamma_{\mathbf{Q}}$. On D,

$$0\leq (p\cdot t+b)-(r\cdot t+c)\leq M\|p-r\|_1+(b-c)<2\gamma_j.$$

Let R_j be the maximum of the finitely many resulting affine functions. Then $0\leq H-R_j\leq 3\gamma_j$ on D. Set $Q_j=R_j+4\gamma_j$. Since $4\gamma_j-4\gamma_{j+1}=3\gamma_j$,

$$Q_j-Q_{j+1}\geq -3\gamma_j+4\gamma_j-4\gamma_{j+1}=0,\qquad \gamma_j\leq Q_j-H\leq 4\gamma_j.$$

This proves (11.17.8). At a point of T, choose local affine lower supports L_i for the ψ_i and an active affine branch $\sum_i r_it_i+c$ of Q_j at ψ. The function $\sum_i r_iL_i+c$ is a local affine lower support for $Q_j\circ\psi$, because every $r_i\geq 0$. Finite selections and the coefficient conditions are preserved just as in Proposition 11.17.4. □

The same construction is compatible with a decreasing tuple. More precisely, suppose each $\psi_{i,j}:T\to[0,M]$ has the stated coefficient-compatible PL and support presentations and $\psi_{i,j+1}\leq\psi_{i,j}\to\psi_i$. The functions Q_j depend only on H,D,Γ, not on these presentations. Hence

$$Q_{j+1}(\psi_{1,j+1},\dots,\psi_{m,j+1})\leq Q_j(\psi_{1,j+1},\dots,\psi_{m,j+1})\leq Q_j(\psi_{1,j},\dots,\psi_{m,j}). \tag{11.17.9}$$

The error estimate and continuity of H identify the pointwise limit as $H(\psi_1,\dots,\psi_m)$. Each term is still a relative rational PL function on the same T. Uniform convergence of the tuple gives uniform convergence of these composites by uniform continuity on D; pointwise convergence alone is not upgraded to uniform convergence. This is a finite-tuple closure statement for the displayed generator class, not closure under arbitrary successive approximation stages.

Corollary 11.17.7 (Original smooth approximation of these composites)**.** *Let X be integral projective of positive dimension over a complete nontrivially valued K. Suppose an ordinary open $W \subset X^{\mathrm{an}}$ carries a unit chart and a bounded tuple ψ as in Proposition 11.17.6. Then, near each point of W, the pullback of $H \circ \psi$ is a decreasing limit of original smooth psh functions on one ordinary neighbourhood, uniformly on compact subsets.*

Proof. The proposition supplies a decreasing sequence of actual Q-PL functions with relative supports on all of W. Apply Corollary 11.11.7. Its neighbourhood is fixed before the individual extension and smoothing steps. The endpoint is continuous, so the compact-uniform conclusion follows from the last assertion of that corollary. □

These results combine the supporting-hyperplane argument of Section 11.12.4, sign-preserving rational approximation and the previously established relative-support bridge. They are recorded as reconstructions and consequences of those inputs, not as a claim of a new general regularization theorem. In particular, we have not shown that every smooth facewise-convex function admits such a finite monotone-convex composition presentation. Section 11.22 supplies coefficient-controlled density on any fixed compact image for continuous relatively supported inputs, without requiring such a composition presentation. The remaining reverse-comparison step concerns arbitrary families with different charts and their common analytic domain. The missing full text of the mixed-calculus Theorem 6.13 is not an input to any argument in this section.

11.18 Relative coefficient approximation on a finite polytopal complex

Section 11.12.7 already proves coefficient-compatible decreasing approximation for homogeneous relative convex functions on a fixed rational fan. Its proof approximates the function and all supporting covectors simultaneously inside a rational system. The obstruction following it shows why an arbitrary nonhomogeneous complex cannot be substituted without checking its affine constants. Here we extend that argument to finite polytopal complexes whose vertices share one value-group scale.

The source convention matters. In [APW26, Section 2.1], a rational half-space has an integral normal but an arbitrary real intercept; Section 2.1.6 assumes rational simplicial polyhedral structures in that sense. This does not impose the value-group condition on the vertices used below. The t-wo qualifications must therefore be checked separately when importing PL approximants.

11.18.1 The affine support system

Theorem 11.18.1 (Rational approximation with one geometric scale)**.** *Let $\Gamma \subset \mathbf{R}$ be a nonzero additive subgroup, and fix $\lambda \in \Gamma_{>0}$. Let Π be a finite polytopal complex in $\mathbf{R}^r$ such that every vertex belongs to $\lambda\mathbf{Q}^r$. Let $F : |\Pi| \to \mathbf{R}$ be continuous, affine on each cell, and admit a relative affine lower support near every point. Then there are continuous functions F_j on $|\Pi|$, affine on the same cells with rational slopes and constants in $\lambda\mathbf{Q} \subset \Gamma_{\mathbf{Q}}$, admitting relative affine lower supports and satisfying*

$$F_{j+1} \le F_j, \qquad 0 \le F_j - F \le 3\lambda 8^{-j} \quad \text{on } |\Pi|. \tag{11.18.1}$$

Here polytopal means that the cells are compact polytopes. In particular, the hypothesis on the vertices holds for a finite $(\mathbf{Z}, \Gamma)$-polytopal complex when $\Gamma = \lambda\mathbf{Z}$. The conclusion does not require Γ itself to be discrete if the displayed one-scale hypothesis holds.

Proof. First write $t = \lambda z$ and $\widehat{F}(z) = F(\lambda z)/\lambda$. This is a change of real coordinates and function units for the calculation; the absolute value on any analytic base field remains unchanged. The scaled complex has rational vertices. An affine function with rational coefficients in z pulls back, after multiplication by λ, to a function with rational slopes and $\lambda\mathbf{Q}$-constants in t. It therefore suffices to approximate the function and its supports with rational coefficients in the scaled coordinates.

Write the affine expression on a cell σ as $p_\sigma(z) + c_\sigma$. For every face ρ, introduce an affine support variable $a_\rho(z) + b_\rho$. The conditions are

$$\begin{aligned} &p_\sigma(v) + c_\sigma = p_\tau(v) + c_\tau \quad (v \text{ a vertex of } \sigma \cap \tau),\\ &a_\rho(v) + b_\rho = p_\rho(v) + c_\rho \quad (v \text{ a vertex of } \rho),\\ &a_\rho(v) + b_\rho \le p_\sigma(v) + c_\sigma \quad (\sigma \supseteq \rho,\ v \text{ a vertex of } \sigma). \end{aligned} \tag{11.18.2}$$

The first line is continuity. To justify the support conditions, choose $x \in \operatorname{relint}(\rho)$. A touching affine lower support agrees with $\widehat{F}$ on the affine span

of ρ, since their affine difference has a local minimum of zero there. For $y \in \sigma \supseteq \rho$, apply the support inequality at $x + s(y - x)$ for small $s > 0$. Linearity on σ and equality at x extend the inequality to all of σ. Testing it on vertices is sufficient. Conversely, the last two lines give a lower support on every cell containing ρ. A small neighbourhood of x avoids the other cells: the complex is finite, and a cell containing a point in $\operatorname{relint}(\rho)$ contains ρ. Thus the system is equivalent to the required local relative supports.

All vertices are rational in the scaled coordinates, so (11.18.2) is a finite homogeneous rational linear system in the combined tuple $(p_\sigma, c_\sigma, a_\rho, b_\rho)$. Use the rational-density argument already given in Section 11.12.7: impose the active inequalities as equalities, choose a rational basis of the resulting nullspace, and approximate the tuple within that subspace. The inactive inequalities remain strict for sufficiently close approximations. This preserves both continuity and the existence of supports, rather than merely approximating the cellwise formulas.

Return to the t-coordinates and choose the approximation G_j so that $|G_j - F| \le \epsilon_j := \lambda 8^{-j}$ on $|\Pi|$. This is possible by controlling the error at the finitely many vertices: on each cell the difference is affine, and its absolute value is bounded by the largest vertex error. Put $F_j = G_j + 2\epsilon_j$. Constants still belong to $\lambda\mathbf{Q}$, and

$$F + \epsilon_j \le F_j \le F + 3\epsilon_j, \qquad F_{j+1} \le F + \tfrac{3}{8}\epsilon_j \le F_j.$$

Shifting the supports by $2\epsilon_j$ preserves contact. This proves (11.18.1). For the discrete value-group case, a vertex of a $(\mathbf{Z}, \lambda\mathbf{Z})$-polytope is the solution of a full-rank rational linear system with right-hand side in $\lambda\mathbf{Z}$, so its coordinates lie in $\lambda\mathbf{Q}$. □

On an ordinary unit chart whose image is contained in $|\Pi|$, the pullbacks of F_j are actual Q-PL functions by Proposition 11.11.5, provided the analytic space is good, strictly analytic and pure-dimensional over nontrivially valued K, and $\Gamma = -\log|K^\times|$. Their supports give nef residues by Theorem 11.11.6. In the integral projective setting, Corollary 11.11.7 gives an original smooth decreasing approximation near every point on one ordinary neighbourhood. These are consequences of the stated analytic inputs, not a new current-positivity criterion.

The compactness in the theorem serves to control the error by finitely many vertex values. It need not restrict the original tropical image to a

compact polytope. A single truncation gives the following local version; the translation also clarifies which affine constants are allowed.

Corollary 11.18.2 (Translation and one fixed truncation)**.** *Let Π be a finite polyhedral complex in $\mathbf{R}^r$. Suppose that there are $a \in \Gamma_{\mathbf{Q}}^r$ and $\lambda \in \Gamma_{>0}$ such that every cell is given by rational affine inequalities in the coordinates $z = (t-a)/\lambda$; both normals and intercepts are rational in these coordinates. Let F be continuous, affine on each cell, and have local relative affine lower supports. For every compact $S \subset |\Pi|$, there is an integer $N > 0$ such that*

$$S \subset U := |\Pi| \cap \big(a + (-\lambda N, \lambda N)^r\big),$$

and $F|_U$ admits a decreasing uniform approximation with the bound in (11.18.1), by continuous functions affine on each $\sigma \cap U$, with rational slopes, $\Gamma_{\mathbf{Q}}$-constants and local relative affine lower supports. The set U is fixed for the whole sequence.

Proof. Choose N so that S lies in the interior of the displayed cube. Intersect the scaled complex with $[-N, N]^r$ and include all faces. This is a finite rational polytopal complex. Apply Theorem 11.18.1 to $\widehat{F}(z) = F(a + \lambda z)/\lambda$, with subgroup $\mathbf{Z}$ and scale 1. Its hypotheses concern real polyhedra, so this use of $\mathbf{Z}$ makes no change to an analytic value group. A rational affine branch $p \cdot z + c$ gives, after multiplying by λ and returning to t,

$$p \cdot t + \lambda c - p \cdot a.$$

Its slope is rational and its constant belongs to $\Gamma_{\mathbf{Q}}$. The error is multiplied by λ; order and relative supports are preserved. Restrict to U. Every original cell meets the closed cube in a cell of the truncated complex, so the approximants remain affine on $\sigma \cap U$. No extension beyond this fixed truncation is asserted. □

In particular, this applies to finite $(\mathbf{Z}, \Gamma_{\mathbf{Q}})$-polyhedral complexes over a discrete nontrivial value group $\Gamma = \lambda\mathbf{Z}$, even when the cells are unbounded or have lineality. On a unit chart the inverse image of the open cube is an ordinary open set, so the truncation does not force the analytic domain to vary with the approximation index.

11.18.2 Two distinct restrictions on a fixed subdivision

Example 11.18.3 (Irrational directions)**.** In $\mathbf{R}^2$, put $L(x,y) = x+\sqrt{2}y$, and subdivide the plane into $L \geq 0$, $L \leq 0$ and their common face. The convex function $F = \max\{0, L\}$ is linear on these cones. Every continuous function G which is affine with rational slopes on these same two cones is globally affine. Thus

$$\max_{a\in\{(-1,0),(0,0),(1,0)\}} |G(a) - F(a)| \geq \frac{1}{4}. \tag{11.18.3}$$

Proof. Continuity makes the branch difference aL for some real a. Both coordinates of the slope difference are rational, so a and $a\sqrt{2}$ are rational; hence $a = 0$. The midpoint defect of F at the three displayed points has absolute value $1/2$, whereas an affine function has zero defect. Three errors bounded by e change this defect by at most $2e$, giving $e \geq 1/4$. □

This subdivision is not rational in the APW convention, so the example does not contradict a statement under that convention. The next example has rational directions and isolates the separate intercept condition.

Example 11.18.4 (An intercept outside the value-group hull)**.** Suppose $\Gamma_{\mathbf{Q}} \neq \mathbf{R}$, and choose $b \notin \Gamma_{\mathbf{Q}}$. On $\mathbf{R}^r$, put $F(t) = \max\{0, t_1 - b\}$. Every continuous function that is affine with rational slopes and $\Gamma_{\mathbf{Q}}$-constants on each of the same halfspaces $t_1 \leq b$ and $t_1 \geq b$ is globally affine. For $h > 0$, its uniform error from F at $(b-h, 0), (b, 0), (b+h, 0)$ is at least $h/4$.

Proof. The branch difference vanishes on $t_1 = b$, so it is $a(t_1 - b)$ with $a \in \mathbf{Q}$. If $a \neq 0$, its constant $-ab \in \Gamma_{\mathbf{Q}}$ would force $b \in \Gamma_{\mathbf{Q}}$. Thus the branches agree. The midpoint defect of F has absolute value $h/2$, giving the error bound as before. □

Both examples allow rational approximation when the subdivision varies: approximate $\sqrt{2}$ by rational numbers in the first, and b by elements of $\Gamma_{\mathbf{Q}}$ in the second. On bounded sets the errors tend uniformly to zero; the error shifts of Proposition 11.12.9 enforce decrease. Neither example refutes unrestricted rational approximation. They exclude only freezing the displayed cells while rounding their coefficients. The earlier nonhomogeneous-complex obstruction in Section 11.12.7 addresses a further issue: vertices may belong to a higher-rank $\Gamma_{\mathbf{Q}}$ without sharing the one scale required in Theorem 11.18.1.

The remaining source-comparison task is therefore precise. The real PL output must be replaced by coefficient-compatible relative PL functions on

one fixed domain, while allowing controlled changes of subdivision if its vertices or normals fail these conditions. Theorems for an already rational fan or for a one-scale complex do not establish that replacement for arbitrary smooth inputs. No full Wu Theorem A.3, CLD25 Proposition 8.1.11 or mixed-calculus comparison is inferred here.

11.19 Coefficient closure and relative supports

The one-scale hypothesis of Section 11.18 makes the entire support system rational. With several independent value-group scales, continuity alone may already prevent rational approximation. We first describe that obstruction exactly. We then separate it from the additional requirement of relative convexity, and give a finite strict-support condition under which no further obstruction occurs. All approximations use the same compact support; each statement specifies whether its subdivision is fixed or allowed to vary.

11.19.1 Continuity and the coefficient space

Fix a nonzero additive subgroup $\Gamma \subset \mathbf{R}$ and put $\Gamma_{\mathbf{Q}} = \Gamma \otimes_{\mathbf{Z}} \mathbf{Q} \subset \mathbf{R}$. Let Π be a nonempty finite complex of compact polytopes in $\mathbf{R}^r$, with support $S = |\Pi|$. Write $V(\Pi)$ for the real vector space of continuous functions on S that are affine on each cell. Its uniform norm is the maximum of the absolute values at the finitely many vertices. Define the rational vector space

$$A_\Gamma(\Pi) = \{F \in V(\Pi) : F|_\sigma = p_\sigma \cdot t + c_\sigma,\ p_\sigma \in \mathbf{Q}^r,\ c_\sigma \in \Gamma_{\mathbf{Q}}\}.$$

The formula is required for every cell, but its ambient extension need not be unique. Let $V_\Gamma(\Pi)$ denote the uniform closure of $A_\Gamma(\Pi)$ in $V(\Pi)$. This is a real vector subspace: rational scalar multiplication extends to real scalar multiplication by taking limits. The following description makes this closure explicit when the vertices have value-group coordinates.

Theorem 11.19.1 (Continuity closure)**.** *Suppose that S is connected and every vertex of Π lies in $\Gamma_{\mathbf{Q}}^r$. There is a rational linear subspace $L \subset \mathbf{R}^{r\#\Pi}$ and a real linear map $T : L \times \mathbf{R} \to V(\Pi)$ such that*

$$A_\Gamma(\Pi) = T\big((L \cap \mathbf{Q}^{r\#\Pi}) \times \Gamma_{\mathbf{Q}}\big), \qquad V_\Gamma(\Pi) = T(L \times \mathbf{R}). \tag{11.19.1}$$

The construction below uses only the vertex coordinates and continuity equations. For disconnected S, apply it to each connected component with a separate constant.

Proof. Let E be the rational span of all vertex coordinates, enlarged by one nonzero element of Γ if necessary. Choose a rational basis $\gamma_1, \dots, \gamma_s$ of E. Introduce one ambient slope variable $p_\sigma \in \mathbf{R}^r$ for each nonempty cell. The graph joining two cells with nonempty intersection is connected: otherwise the corresponding finite compact unions would disconnect S. Choose a root cell σ_0, a spanning tree and, for each edge $\sigma\tau$, a vertex $v_{\sigma\tau}$ of the intersection. Along the rooted tree define

$$d_{\sigma_0}(p) = 0, \qquad d_\tau(p) = d_\sigma(p) + (p_\sigma - p_\tau) \cdot v_{\sigma\tau}.$$

Continuity at the remaining intersection vertices requires

$$(p_\sigma - p_\tau) \cdot v + d_\sigma(p) - d_\tau(p) = \sum_{a=1}^{s} \gamma_a A_{\sigma,\tau,v,a}(p) = 0. \tag{11.19.2}$$

Each $A_{\sigma,\tau,v,a}$ is a rational linear form. Let L be their common kernel, and set

$$T(p,c)|_\sigma(t) = p_\sigma \cdot t + d_\sigma(p) + c.$$

For $p \in L$, the expressions agree at every intersection vertex, hence on every intersection; thus T is well-defined. If p is rational and $c \in \Gamma_{\mathbf{Q}}$, all $d_\sigma(p)$ belong to $E \subset \Gamma_{\mathbf{Q}}$. This proves one inclusion in the first equality of (11.19.1). Conversely, choose rational ambient slopes and value-group constants for $F \in A_\Gamma(\Pi)$. Continuity along the tree forces $c_\sigma = c_{\sigma_0} + d_\sigma(p)$. In (11.19.2), all $A_{\sigma,\tau,v,a}(p)$ are rational. The rational independence of the γ_a therefore forces each to vanish, so $p \in L$.

The rational points of L are dense in L, and $\Gamma_{\mathbf{Q}}$ is dense in $\mathbf{R}$, since it contains $\rho\mathbf{Q}$ for some $\rho > 0$. The image of their product is therefore dense in $T(L \times \mathbf{R})$. This image space is finite-dimensional and hence closed in $V(\Pi)$. These facts prove the second equality. For disconnected S, there are only finitely many components, and their function spaces form a finite product. □

Remark 11.19.2. The criterion for a target F is the existence of a representation $F = T(p,c)$ with $p \in L$. On a lower-dimensional cell it is not legitimate to test an arbitrary ambient extension and declare failure. Nor does the construction claim an effective procedure for identifying rational relations among arbitrary unspecified real numbers. When all vertices lie in $\lambda\mathbf{Q}^r$, one can take $s = 1$, and the split equations are exactly the original continuity equations. Then $V_\Gamma(\Pi) = V(\Pi)$, consistently with Theorem 11.18.1. With several scales the equality can fail, as the rectangle calculation in Section 11.12.7 shows.

11.19.2 The relative-support cone

Let $C(\Pi) \subset V(\Pi)$ consist of functions admitting an affine lower support in the relative topology of S near every point, with equality at that point. The support is allowed to depend on the point. This is the local support condition of Section 11.18; it is not ambient convexity on a neighbourhood of S.

Lemma 11.19.3 (Finite support inequalities)**.** *The set $C(\Pi)$ is a closed convex polyhedral cone in $V(\Pi)$, and contains all constants with either sign. Its defining real coefficients need not be rational. More precisely, $F \in C(\Pi)$ if and only if for every nonempty face ρ there is an affine function a_ρ satisfying*

$$\begin{aligned} a_\rho(v) &= F(v) \quad (v \text{ a vertex of } \rho), \\ a_\rho(v) &\le F(v) \quad (v \text{ a vertex of } \sigma,\ \sigma \supseteq \rho). \end{aligned} \tag{11.19.3}$$

Proof. Choose $x \in \operatorname{relint}(\rho)$. A lower support at x agrees with F on $\operatorname{aff}(\rho)$, since their affine difference has a local minimum there. For any $y \in \sigma \supseteq \rho$, apply the local inequality at $x+t(y-x)$ and divide by $t > 0$; this extends it to y. Conversely, (11.19.3) gives a support on each coface of ρ, and a sufficiently small neighbourhood of x meets no other cells. This proves the equivalence.

The system is finite and homogeneous linear in the vertex values and support coefficients. Eliminating the latter preserves polyhedrality. For completeness, to eliminate a variable y, write each inequality as $a_i y + b_i(z) \ge 0$. Keep the inequalities with $a_i = 0$, and require each lower bound from $a_i > 0$ to be no larger than each upper bound from $a_i < 0$. If one type is absent there is no additional restriction. Equalities may be written as pairs of inequalities. Repeating this elimination gives finitely many weak linear inequalities in the vertex values alone, proving closedness as well. Addition, nonnegative scaling and constant shifts preserve the support condition directly. □

Closedness alone does not justify intersecting with a dense rational class. For instance, the ray $\{(x, \sqrt{2}x) : x \ge 0\}$ is a closed real polyhedral cone whose intersection with $\mathbf{Q}^2$ is only the origin. This is a warning about a linear-algebra inference, not a tropical or analytic counterexample. The next statement gives the exact replacement.

Theorem 11.19.4 (Closure of admissible rational functions)**.** *For any finite compact polytopal complex, set*

$$W_\Gamma(\Pi) = \operatorname{span}_{\mathbf{R}}\big(A_\Gamma(\Pi) \cap C(\Pi)\big).$$

Then

$$\overline{A_\Gamma(\Pi) \cap C(\Pi)}^{\,\|\cdot\|_\infty} = W_\Gamma(\Pi) \cap C(\Pi). \tag{11.19.4}$$

If F belongs to this set and $\rho \in \Gamma_{>0}$, there are $F_j \in A_\Gamma(\Pi) \cap C(\Pi)$ such that

$$F_{j+1} \le F_j, \qquad 0 \le F_j - F \le 3\rho 8^{-j} \quad \text{on } S. \tag{11.19.5}$$

Proof. Both $W_\Gamma(\Pi)$ and $C(\Pi)$ are closed, so the left side of (11.19.4) is contained in the right side. To prove density, choose a real basis $g_1, \dots, g_m$ of $W_\Gamma(\Pi)$ from $A_\Gamma(\Pi) \cap C(\Pi)$. Its positive cone lies in $C(\Pi)$ and has nonempty interior in $W_\Gamma(\Pi)$. In particular, $H = \sum_i g_i$ has a ball $B_W(H, a)$ contained in $C(\Pi)$. For $F \in W_\Gamma(\Pi) \cap C(\Pi)$ and $\epsilon > 0$,

$$B_W(F + \epsilon H, \epsilon a) = F + \epsilon B_W(H, a) \subset C(\Pi).$$

Approximate the coordinates of $F + \epsilon H$ in the basis g_i by rational numbers so closely that the resulting function lies in this ball. It belongs to $A_\Gamma(\Pi)$, since that is a rational vector space, and it belongs to $C(\Pi)$ by the ball inclusion. Letting ϵ and the coordinate errors tend to zero proves density. The argument does not require the rational coordinates to be nonnegative.

Choose G_j in this intersection with $\|G_j - F\|_\infty \le \eta_j := \rho 8^{-j}$ and put $F_j = G_j + 2\eta_j$. The added constant belongs to $\Gamma_{\mathbf{Q}}$, and shifting every support by it preserves contact. Thus $F + \eta_j \le F_j \le F + 3\eta_j$ and $F_{j+1} \le F + 3\eta_j/8 \le F_j$. This proves (11.19.5). □

This is an exact closure formula, but not by itself an effective description of $W_\Gamma(\Pi)$. A useful finite certificate is a list of admissible rational functions g_i whose real span contains the target F. The finite support system checks admissibility, and the theorem then gives decreasing approximation. In general we have only $W_\Gamma(\Pi) \subseteq V_\Gamma(\Pi)$; equality requires an argument. The proof is an elementary combination of finite-dimensional convexity and rational approximation, and no priority claim is made for that combination.

11.19.3 A strict-support certificate

We now give a geometric sufficient condition for this equality. Say that $H \in V(\Pi)$ has strict face supports if, for every nonempty face ρ, there is an affine a_ρ agreeing with H on ρ and satisfying

$$H(v) > a_\rho(v) \quad (\sigma \supseteq \rho,\ v \text{ a vertex of } \sigma,\ v \notin \rho). \tag{11.19.6}$$

This is a finite condition on a specified complex. It is not a definition of strict CLD plurisubharmonicity. For a maximal face the inequalities are vacuous.

Proposition 11.19.5 (Strict supports remove the positivity obstruction)**.** *If $H \in A_\Gamma(\Pi)$ has strict face supports, then H is an interior point of $C(\Pi)$ in $V(\Pi)$, and*

$$W_\Gamma(\Pi) = V_\Gamma(\Pi), \qquad \overline{A_\Gamma(\Pi) \cap C(\Pi)} = V_\Gamma(\Pi) \cap C(\Pi).$$

Consequently every target in the latter intersection has the decreasing approximants of (11.19.5)*.*

Proof. For each ρ, choose a linear extension map E_ρ from affine functions on $\mathrm{aff}(\rho)$ to affine functions on $\mathbf{R}^r$. Such a map exists by extending affine coordinates, and all the relevant spaces are finite-dimensional. If $\delta \in V(\Pi)$, replace a_ρ by $a_\rho + E_\rho(\delta|_\rho)$. It agrees with $H + \delta$ on ρ. At the finitely many other incident vertices the change in the support gap is

$$\delta(v) - E_\rho(\delta|_\rho)(v).$$

The absolute values of these expressions are bounded by $M\|\delta\|_\infty$ for a fixed finite M. The finitely many strict gaps in (11.19.6) have a positive minimum. For sufficiently small $\|\delta\|_\infty$, all remain positive, so Lemma 11.19.3 gives $H + \delta \in C(\Pi)$. If there are no strict gaps to test, the same conclusion holds for every δ. This proves interiority.

For $F \in C(\Pi) \cap V_\Gamma(\Pi)$, the points $F + \epsilon H$ are interior to $C(\Pi)$ relative to $V_\Gamma(\Pi)$. The density of $A_\Gamma(\Pi)$ in $V_\Gamma(\Pi)$ gives admissible rational approximants tending to F, exactly as in Theorem 11.19.4. Moreover, a sufficiently small ball about H in $V_\Gamma(\Pi)$ is contained in the closure of the admissible class, hence in $W_\Gamma(\Pi)$. A linear subspace containing such a ball is all of $V_\Gamma(\Pi)$. This proves both equalities and the decreasing conclusion. □

The hypothesis has an explicit source of examples, valid in arbitrary dimension and without a one-scale restriction. The subdivision must be the one specified below; adding arbitrary faces can destroy the strict certificate.

Proposition 11.19.6 (Subdivisions of a finite rational maximum)**.** *Let $Q \subset \mathbf{R}^r$ be a full-dimensional compact polytope given by $h_b \geq 0$, where the h_b have rational slopes and constants in $\Gamma_{\mathbf{Q}}$. Let*

$$H = \max_{1 \leq i \leq N} \ell_i, \qquad \ell_i(t) = p_i \cdot t + c_i, \quad p_i \in \mathbf{Q}^r, \ c_i \in \Gamma_{\mathbf{Q}}.$$

Form the complex of all nonempty regions $R_i = \{t \in Q : H(t) = \ell_i(t)\}$ and all their faces. On any nonempty subcomplex Π of this complex, $H|_{|\Pi|}$ belongs to $A_\Gamma(\Pi)$ and has strict face supports. Every vertex of Π lies in $\Gamma_{\mathbf{Q}}^r$. Thus the continuity criterion of Theorem 11.19.1, component by component, is necessary and sufficient for a relatively supported $F \in V(\Pi)$ to admit the approximants (11.19.5).

Proof. The regions form a polyhedral complex: $R_i \cap R_j$ is the equality face for $\ell_i - \ell_j \geq 0$ on R_i, and similarly on R_j. All defining normals are rational and constants belong to $\Gamma_{\mathbf{Q}}$. At a vertex, a full-rank set of active equations has a rational inverse matrix, so the coordinates belong to $\Gamma_{\mathbf{Q}}$. This argument also applies to lower-dimensional regions.

Fix a face ρ, choose $x \in \operatorname{relint}(\rho)$, and set $I = \{i : \ell_i(x) = H(x)\}$ and $B = \{b : h_b(x) = 0\}$. Define

$$a_\rho = \frac{1}{|I|} \sum_{i \in I} \ell_i - \sum_{b \in B} h_b. \tag{11.19.7}$$

On Q, both $H - |I|^{-1} \sum_{i \in I} \ell_i$ and every h_b in this sum are nonnegative. Their sum vanishes precisely where all the indicated maximum branches and boundary constraints are active. This set is exactly ρ: inside any R_{i_0} with $i_0 \in I$, these are all the constraints active at x, hence they define the minimal face containing x. Consequently $a_\rho = H$ on ρ and $a_\rho < H$ at every point of $Q \setminus \rho$. Formula (11.19.7) supplies the required strict face supports, even after restricting to a subcomplex. The function H is rational affine on each cell. Proposition 11.19.5 and Theorem 11.19.1 finish the proof. □

11.19.4 One fixed refinement

A complex need not itself have strict face supports. Refinement gives a precise remedy when its cells have rational normals and value-group constants. The continuity obstruction, however, survives every fixed refinement of the kind considered here.

Lemma 11.19.7 (Continuity closure under a fixed refinement)**.** *Let Π' be a finite compact polytopal refinement of Π with the same support: each refined cell lies in a coarse cell, and each coarse cell is a union of refined cells. Suppose that every cell of Π has rational tangent space, and all vertices of both complexes belong to $\Gamma^r_{\mathbf{Q}}$. Under the natural inclusion $V(\Pi) \subseteq V(\Pi')$,*

$$V_\Gamma(\Pi') \cap V(\Pi) = V_\Gamma(\Pi). \tag{11.19.8}$$

Proof. Restriction to the refined cells gives $A_\Gamma(\Pi) \subseteq A_\Gamma(\Pi')$, hence one inclusion. For the reverse inclusion, use Theorem 11.19.1 on Π', component by component, to represent $F \in V_\Gamma(\Pi') \cap V(\Pi)$ by slope parameters $p \in L$ and root constants. For each coarse cell σ, take all refined cells $\tau \subseteq \sigma$ of dimension $\dim \sigma$. They cover σ: their finite closed union contains the relative interior densely and therefore contains its closure. Choose a rational basis $u_{\sigma,k}$ for the tangent space of σ. Being affine on σ implies

$$(p_\tau - p_{\tau_0}) \cdot u_{\sigma,k} = 0 \quad (\tau, \tau_0 \subseteq \sigma,\ \dim \tau = \dim \tau_0 = \dim \sigma). \tag{11.19.9}$$

Conversely, these equations, together with continuity, force affinity on σ. Subtract an ambient affine function with slope p_{τ_0}; the remainder is constant on every full-dimensional refined cell. The intersection graph of these cells is connected because they cover the connected compact polytope σ, so their constants agree.

Equations (11.19.9) are rational linear equations in the slope parameters. Their intersection with L is therefore a rational linear subspace containing the chosen representative of F. Approximate within that subspace by rational parameters, and approximate each root constant in $\Gamma_{\mathbf{Q}}$. The resulting functions converge uniformly to F, belong to $A_\Gamma(\Pi')$, and are affine on every coarse cell. On a coarse cell their expression agrees with that of any full-dimensional refined cell, so it has rational ambient slope and constant in $\Gamma_{\mathbf{Q}}$. They thus belong to $A_\Gamma(\Pi)$, proving (11.19.8). Zero-dimensional coarse cells require no slope equation. □

Theorem 11.19.8 (Relative approximation after one fixed refinement)**.** *Suppose each cell of the finite compact complex Π is given by finitely many affine weak inequalities with rational slopes and constants in $\Gamma_{\mathbf{Q}}$. There is a finite compact refinement Π^*, depending only on Π, such that for every $F \in C(\Pi)$ the following are equivalent:*

1. *$F \in V_\Gamma(\Pi)$.*

2. *F is a uniform limit of functions in $A_\Gamma(\Pi^*) \cap C(\Pi^*)$.*

3. *F has approximants in that class satisfying (11.19.5).*

Proof. List all affine functions $h_1, \dots, h_N$ occurring in inequalities for all cells, writing equalities as two inequalities. Choose a cube $Q = [-M\rho, M\rho]^r$ containing S in its interior, with $\rho \in \Gamma_{>0}$ and M a sufficiently large integer. On this cube set

$$H = \sum_{l=1}^{N} |h_l| = \max_{\epsilon \in \{-1,1\}^N} \sum_{l=1}^{N} \epsilon_l h_l. \tag{11.19.10}$$

The regions of this maximum are exactly the nonempty sign regions $\epsilon_l h_l \geq 0$ in Q: equality in the maximum requires equality in each nonnegative term $|h_l| - \epsilon_l h_l$. Include their faces. Each original cell is a union of these arrangement cells, since its defining inequalities occur in the list. Take the subcomplex consisting of arrangement cells contained in S; call it Π^*. It refines every original cell and has the same support. All its vertices lie in $\Gamma_{\mathbf{Q}}^r$, and Proposition 11.19.6 supplies strict face supports for H.

The relative-support condition depends on the function and the support S, not on a chosen subdivision. Thus $F \in C(\Pi)$ also belongs to $C(\Pi^*)$. If (1) holds, restriction gives $F \in V_\Gamma(\Pi^*)$, and Proposition 11.19.5 proves (3). Clearly (3) implies (2). Finally (2) gives $F \in V_\Gamma(\Pi^*) \cap V(\Pi)$, which is $V_\Gamma(\Pi)$ by Lemma 11.19.7. Its rational-tangent hypothesis holds because the original defining normals are rational. □

In particular, a fixed rational value-group refinement can remove the extra support obstruction, but cannot remove the continuity obstruction for a target affine on the old cells. This does not exclude progressively changing subdivisions: their arithmetic continuity equations also change. The following construction shows that the distinction is substantive, even when the target is already PL.

Example 11.19.9 (Moving subdivisions resolve the rectangle test)**.** Use the rectangle and function F of Example 11.12.17, with $a = \sqrt{2}$ and $\Gamma = \mathbf{Z} + a\mathbf{Z}$. Thus $F(x, 0) = ax$, $F(0, y) = y$, and $F = a$ on the top and right edges. Put

$$\delta_j = 8^{-j}, \qquad q_j = \delta_j \lfloor a/\delta_j \rfloor, \qquad q_j^+ = q_j + \delta_j, \qquad b_j = \frac{q_j^+ - a}{\delta_j} \in (0,1) \cap \Gamma_{\mathbf{Q}}.$$

Define $G_j = F$ on the left, top and right edges, and on the bottom edge set

$$G_j(x, 0) = \max\{q_j x,\ a - q_j^+(1 - x)\}, \qquad F_j = G_j + 2\delta_j. \tag{11.19.11}$$

The two branches meet at $x = b_j$. Both have rational slopes and constants in $\Gamma_{\mathbf{Q}}$. Their maximum equals 0 at $x = 0$ and a at $x = 1$, so G_j is continuous around the rectangle. On the bottom edge it is convex. Near each corner its affine branch and the branch on the adjacent edge extend to one ambient affine function, because the edge directions are independent. It therefore has relative affine lower supports everywhere. The same holds for F_j.

Since $q_j < a < q_j^+$, both branches lie below ax, and

$$0 \le ax - G_j(x, 0) = \min\{(a - q_j)x, (q_j^+ - a)(1 - x)\} \le \delta_j.$$

Consequently $F + \delta_j \le F_j \le F + 2\delta_j$ on all of S, and $F_{j+1} \le F + \delta_j/4 \le F_j$. This is a coefficient-compatible decreasing uniform approximation, obtained by adding just one moving breakpoint. It cannot be carried by any single finite refinement with vertices in $\Gamma_{\mathbf{Q}}^2$: Lemma 11.19.7 would then imply $F \in V_\Gamma(\Pi)$, contrary to (11.12.5). Pullback to $S \times [0,1]^{d-1}$ gives the same construction in every positive dimension. These remain abstract polyhedral examples; no balancing or analytic realization is asserted. The changing arithmetic equations can be seen directly. Write $N = 8^j$ and $m = \lfloor Na \rfloor$, so $b_j = m + 1 - Na$. For rational slopes p_1, p_2 on the two bottom segments, p_t on the top and q_l, q_r on the vertical edges, continuity splits as

$$(m + 1)p_1 - mp_2 - p_t = 0, \qquad N(p_2 - p_1) + q_r - q_l = 0.$$

The approximant has $(p_1, p_2, p_t, q_l, q_r) = (m/N, (m + 1)/N, 0, 1, 0)$ and satisfies both equations. The target would have $(a, a, 0, 1, 0)$ and satisfies neither. There is no contradiction with convergence: the equation coefficients change with N. This also explains why a failure of fixed-complex density cannot decide moving-subdivision density.

11.19.5 Propagation of a common scale

There is another useful route back to the one-scale theorem. Rational simplices of dimension at least two have a stronger arithmetic property than general polytopes with rational facet normals. The property propagates through a shared edge.

Proposition 11.19.10 (Scale propagation through edges)**.** *Let* Π *be a finite compact simplicial complex in* $\mathbf{R}^r$*. Suppose every maximal simplex has dimension at least two, every edge has rational direction, and the graph joining maximal simplices that share an edge is connected. If all vertices belong to* $\Gamma^r_{\mathbf{Q}}$*, then for some* $a \in \Gamma^r_{\mathbf{Q}}$ *and* $\lambda \in \Gamma_{>0}$ *every vertex lies in* $a+\lambda\mathbf{Q}^r$*. Consequently every* $F \in C(\Pi)$ *has decreasing approximants in* $A_\Gamma(\Pi) \cap C(\Pi)$*, uniformly on* $|\Pi|$*.*

Proof. First take one simplex with vertices $v_0, \ldots, v_d$, $d \geq 2$. Write $v_i - v_0 = \lambda_i e_i$, with nonzero $e_i \in \mathbf{Q}^r$. The e_i are linearly independent. The edge $v_j - v_i = \lambda_j e_j - \lambda_i e_i$ is a real multiple of a rational vector. A rational left inverse to the matrix with columns e_i shows that the ratio λ_i/λ_j is rational: its two nonzero coordinates are real multiples of two nonzero rational numbers. Thus all vertex differences of this simplex belong to $\lambda_\sigma \mathbf{Q}^r$ for one positive real λ_σ.

If two simplices share an edge, its nonzero vector belongs to both $\lambda_\sigma \mathbf{Q}^r$ and $\lambda_\tau \mathbf{Q}^r$, forcing $\lambda_\sigma/\lambda_\tau \in \mathbf{Q}$. Propagate this relation along the connected graph. Starting from one vertex a, shared vertices then show that every vertex lies in $a + \lambda_0 \mathbf{Q}^r$ for a common positive λ_0. A nonzero coordinate of an edge shows $\lambda_0 \in \Gamma_{\mathbf{Q}}$ after the initial choice of scale; multiplying by a positive integer makes it an element λ of Γ without changing $\lambda_0 \mathbf{Q}^r$. Translate by a and apply Theorem 11.18.1. Translation preserves rational slopes and changes a rational affine constant by $p \cdot a \in \Gamma_{\mathbf{Q}}$, so the approximants retain the required coefficients. □

Example 11.19.11 (Rational normals do not ensure rational triangulations)**.** The rectangle $Q = [0,1] \times [0,\sqrt{2}]$ has integral facet normals and vertices in Γ^2 for $\Gamma = \mathbf{Z} + \sqrt{2}\mathbf{Z}$. Nevertheless it has no finite triangulation all of whose edges have rational direction, even allowing extra vertices. Indeed, the triangles in any finite triangulation of a rectangle are connected through shared edges. To see this, join interior points of two triangles by a polygonal path in the interior, chosen to avoid the finitely many vertices and to cross edges transversely. The proof of Proposition 11.19.10, up to the value-group assertion, puts all vertices of such a rational-direction triangulation in $a+\lambda\mathbf{Q}^2$ for some real $\lambda > 0$. The two boundary vectors $(1,0)$ and $(0,\sqrt{2})$ would then force both $1/\lambda$ and $\sqrt{2}/\lambda$ to be rational, a contradiction.

This example concerns a compact polytope, not a balanced tropical variety and not a counterexample to the conditional theory in APW26. Section 2.1.6

of that source explicitly assumes the existence of a rational simplicial structure. The example explains why this assumption cannot be replaced silently by rationality of facet normals. Nor may Proposition 11.19.10 be applied to simplices meeting only at vertices or to one-dimensional complexes: the shared nonzero edge is the mechanism that compares their scales.

11.19.6 Convex extension on individual cells

The moving-subdivision problem has a further elementary part that can be completed without a global comparison theorem: matching convex boundary data on one polytope. Recording it separately identifies the remaining issue at joins between cells.

Lemma 11.19.12 (Coefficient-compatible convex boundary extension)**.** *Let Q be a positive-dimensional compact polytope defined by rational-slope, $\Gamma_{\mathbf{Q}}$-constant affine inequalities. Suppose g is continuous on its relative boundary, and on each facet is the maximum of finitely many ambient affine functions with those coefficients. Then g extends to a function G on Q which is itself a finite maximum of such affine functions. If an affine real function A satisfies $0 \le A - g \le e$ on the boundary, then for every $\epsilon > 0$ one can arrange*

$$G|_{\partial Q} = g, \qquad 0 \le A - G \le e + \epsilon \quad \text{on } Q. \tag{11.19.12}$$

Proof. For each facet ρ, choose a rational-slope, value-group-constant affine function $h_\rho \ge 0$ on Q whose zero set on Q is exactly ρ. Take one affine branch ℓ of $g|_\rho$. We claim that $\ell - Ch_\rho \le g$ on the whole boundary for some nonnegative rational C. Refine the boundary into finitely many compact polytopes on which g is affine. At a vertex v with $h_\rho(v) = 0$, we already have $\ell(v) \le g(v)$. At all other vertices impose

$$C \ge \frac{\ell(v) - g(v)}{h_\rho(v)}.$$

There are only finitely many bounds, so a nonnegative rational C exists. Vertex inequalities imply the inequalities on every boundary cell. The modified branch still restricts to ℓ on ρ and retains rational slopes and constants in $\Gamma_{\mathbf{Q}}$. Take the maximum of all modified branches, over all facets and all their branches. It agrees with g on each facet and is convex on Q.

If $g \le A$, every modified affine branch is at most A at all vertices of Q, hence at most A throughout Q. To obtain the lower bound, choose a rational-slope, $\Gamma_{\mathbf{Q}}$-constant affine function ℓ_0 with

$$A - e - \epsilon \le \ell_0 \le A - e \quad \text{on } Q.$$

Such a choice follows by approximating the slope and constant of $A-e-\epsilon/2$, using compactness and the density of $\Gamma_{\mathbf{Q}}$. On the boundary, $\ell_0 \le g$. Adding ℓ_0 to the finite maximum therefore preserves the boundary values and gives (11.19.12). □

Proposition 11.19.13 (Decreasing cellwise-convex approximation)**.** *Let* Π *have the coefficient-compatible defining inequalities of Theorem 11.19.8, and let* $F \in V(\Pi)$*. There are continuous rational-slope,* $\Gamma_{\mathbf{Q}}$*-constant PL functions* F_j *on* S*, carried by subdivisions allowed to depend on* j*, such that each* F_j *is convex on every original cell and*

$$F_{j+1} \le F_j, \qquad 0 \le F_j - F \le 2\rho 8^{-j} \quad (\rho \in \Gamma_{>0} \text{ fixed}).$$

No relative affine support across different original cells is asserted.

Proof. Put $d = \dim \Pi$ and fix $\epsilon > 0$. At each vertex choose a value in $\Gamma_{\mathbf{Q}}$ between $F(v)-\epsilon$ and $F(v)$. Induct on cell dimension. Once a continuous function has been defined on the $(k-1)$-skeleton, its restriction to the boundary of each k-cell is a finite maximum of coefficient-compatible affine functions on each facet, by the preceding induction steps. Apply Lemma 11.19.12 with $A = F|_\sigma$ and additional error ϵ. The extensions agree on common faces because those values have already been fixed. After dimension d, the resulting continuous function G satisfies $0 \le F - G \le (d+1)\epsilon$ on S and is convex on every original cell. A common refinement by the finitely many branch comparisons gives a finite coefficient-compatible PL presentation.

For the jth construction choose $\epsilon = \rho 8^{-j}/(d+1)$, write $\eta_j = \rho 8^{-j}$, and set $F_j = G_j + 2\eta_j$. Then $F + \eta_j \le F_j \le F + 2\eta_j$, and $F_{j+1} \le F + \eta_j/4 \le F_j$. The shift belongs to $\Gamma_{\mathbf{Q}}$ and preserves convexity on each cell. □

The qualification is necessary. On $[-1,1]$ with cells $[-1,0]$ and $[0,1]$, the functions $\epsilon(1-|x|)$ are affine on each cell and converge uniformly to the relatively convex function 0, but have no affine lower support at 0: its slope would have to be both at least ϵ and at most $-\epsilon$. Small uniform errors therefore do

not control the support condition at a join. In the boundary-extension proof, the constants C provide domination but no bound on the normal slopes. A relative-convex version needs such control, or another argument preserving supports across the old faces. Section 11.20 supplies that slope control for compatible polyhedral geometry. The value-only cellwise result by itself is not used to infer nef residues or original smooth psh approximation.

11.19.7 Analytic use and remaining limits

To use these results on a fixed ordinary unit chart, retain the hypotheses of Proposition 11.11.5 and Theorem 11.11.6: the ground field is nontrivially valued, $\Gamma = -\log|K^\times|$, and the analytic space is good, strictly analytic and pure-dimensional. Suppose the chart image is contained in S, and $F \in C(\Pi) \cap W_\Gamma(\Pi)$. Theorem 11.19.4 gives a decreasing sequence on the whole same S, with uniform error. Pullback therefore gives actual Q-PL functions on the whole same ordinary chart domain, with nef residues by the cited inputs. If the integral-projective hypotheses of Corollary 11.11.7 also hold, that corollary supplies an original smooth decreasing sequence near each point on one fixed ordinary neighbourhood.

The same analytic conclusion follows from Theorem 11.19.8 when the original complex has rational normals and value-group constants and $F \in C(\Pi) \cap V_\Gamma(\Pi)$. Its refinement changes neither the tropical support nor the ordinary inverse-image domain. In contrast, Example 11.19.9 has not been realized as an analytic tropical chart, so no analytic conclusion is inferred from that example alone.

This application uses the existing model and residue comparisons; a formal real PL expression is not substituted for actual Q-PL membership. In particular, [GRPSH, Theorem 4.3] assumes an actual R-PL function and nontrivial valuation before identifying classical psh with semipositivity. The real coordinate calculations above do not rescale the absolute value, extend the ground field, replace original CLD tests, or enlarge their actual supports.

The distinction from [APW26, Proposition 5.21] remains essential. That proposition produces locally uniform real PL approximants on one neighbourhood; its proof passes through a projective compactification and functions $(\varphi_i + h)/C$. Neither a common finite subdivision for all approximants nor the coefficient and strict-support conditions of this section are supplied by that statement. Our criteria can be applied to an individual output only after

those data are checked, or to a sequence after the domains and error choices are made compatible. We have not proved that every relevant analytic tropical image admits the certificate of Proposition 11.19.6. Thus the general relative coefficient replacement, Wu Theorem A.3 and the stronger CLD25 closure comparison remain open here. The primary full text of the separate mixed-calculus Theorem 6.13 has still not been obtained; it is not an input to any proof in this section.

References. Finite-dimensional reconstruction in this manuscript, extending the continuity-only note of v0.21. Source scope checked against APW26 Sections 2.1, 5.2 and Proposition 5.21 (v1), and GRPSH Theorem 4.3 (v2). The strict-support certificate and closure proofs are given above; no general source theorem is declared corrected or disproved by them.

11.20 Controlled slopes and moving relative approximation

The value-only extension in Section 11.19.6 leaves the normal slopes uncontrolled. Here the fixed geometry of the original cells supplies the missing estimate. We first strengthen the extension lemma, then show that small cellwise Lipschitz errors preserve strict relative supports. A fixed strict barrier reduces a general relatively supported PL target to that case. The resulting approximants may change subdivision, but never change the compact support.

11.20.1 A boundary extension with controlled slopes

Use the standard Euclidean norm in the fixed ambient space. For a function on a compact convex cell σ, write Lip_σ for its Lipschitz seminorm, and set this seminorm to zero on a point. All constants below depend on the original finite polytopes, not on subdivisions of their boundary data.

Lemma 11.20.1 (Controlled convex extension)**.**

Let Q be as in Lemma 11.19.12. There is $M_Q \geq 1$ with the following property. Let A be real affine, let $\epsilon > 0$, and let g be continuous on ∂Q, a finite maximum of rational-slope, $\Gamma_{\mathbf{Q}}$-constant affine functions on each facet. Suppose

$$0 \leq A - g \leq \epsilon \quad \text{on } \partial Q, \qquad \mathrm{Lip}_\tau(g - A) \leq \epsilon \quad \text{for every facet } \tau.$$

Then g has a finite-max extension G with the same coefficient conditions and

$$G|_{\partial Q} = g, \qquad 0 \le A - G \le M_Q\epsilon, \qquad \mathrm{Lip}_Q(G - A) \le M_Q\epsilon. \tag{11.20.1}$$

Proof. Fix a facet ρ and a compatible affine barrier $h_\rho \ge 0$ vanishing exactly on ρ. In a finite-max representation of $g|_\rho$, discard branches never active on a relatively open subset. This does not change the function, including at its boundary, by continuity. For a remaining branch ℓ, the tangential part of $\nabla\ell - \nabla A$ on ρ has norm at most ϵ. The tangent space of ρ is rational. Its orthogonal complement therefore has dense rational points. Add to ℓ a function $q \cdot (t - v_\rho)$, where $v_\rho \in \Gamma^r_{\mathbf{Q}}$ is a vertex and q is rational, orthogonal to the tangent space, chosen so that the new branch $\widetilde{\ell}$ satisfies

$$\widetilde{\ell}|_\rho = \ell|_\rho, \qquad \|\nabla\widetilde{\ell} - \nabla A\| \le 2\epsilon.$$

The added constant is in $\Gamma_{\mathbf{Q}}$. For a zero-dimensional facet the same construction uses its single boundary value and no tangential constraint. At a point where the original branch is active, $|\widetilde{\ell} - A| \le \epsilon$. If $D = \mathrm{diam}(Q)$, it follows that $|\widetilde{\ell} - A| \le (1 + 2D)\epsilon$ on Q.

We next bound the penalty needed to dominate every other facet. If $\tau \cap \rho \ne \varnothing$, then for every $y \in \tau$ one can choose $z \in \tau \cap \rho$ such that

$$\|y - z\| \le K_{\rho\tau} h_\rho(y), \tag{11.20.2}$$

with a fixed finite constant. Indeed, write y as a convex combination of the vertices of τ, keep the vertices in ρ, and replace all other vertices by one fixed vertex $z_0 \in \tau \cap \rho$. One may take the largest ratio $\|v - z_0\|/h_\rho(v)$ over vertices outside ρ. Since $\widetilde{\ell}(z) \le g(z)$ and the function $\widetilde{\ell} - g$ is 3ϵ-Lipschitz on τ,

$$\widetilde{\ell}(y) - g(y) \le 3K_{\rho\tau}\epsilon h_\rho(y).$$

If the two facets are disjoint, h_ρ has a positive minimum on τ, and the uniform bounds above give the same inequality with another fixed constant. Thus, independently of the branch and the boundary subdivision, there is $K_\rho \ge 0$ such that every modified branch is dominated on the boundary after subtracting $C_\rho h_\rho$, where C_ρ is any rational number in $[K_\rho\epsilon, (K_\rho + 1)\epsilon]$.

Take the maximum of these penalized branches over all facets. It extends g exactly and retains the coefficient conditions. Every branch has gradient within $M_1\epsilon$ of ∇A, where M_1 depends only on the chosen facet barriers. Hence $G - A$, a maximum of these affine differences, is $M_1\epsilon$-Lipschitz on

Q. Each branch is at most A at the vertices, so $G \le A$ throughout Q. Comparing with any boundary point gives $A - G \le (1 + M_1 D)\epsilon$. Taking $M_Q = \max\{1, M_1, 1 + M_1 D\}$ proves the lemma. □

Corollary 11.20.2 (Cellwise Lipschitz approximation)**.** *For a compatible finite compact complex Π, every $F \in V(\Pi)$ and every $\delta > 0$ admit a continuous coefficient-compatible PL function G, convex on each original cell, such that*

$$0 \le F - G \le \delta, \qquad \max_{\sigma \in \Pi} \operatorname{Lip}_\sigma(G - F) \le \delta. \tag{11.20.3}$$

Its subdivision may depend on δ.

Proof. Repeat the skeleton induction of Proposition 11.19.13, now using Lemma 11.20.1. Let $M \ge 1$ bound its constants for all positive-dimensional cells and let $d = \dim \Pi$. Choose the vertex errors at most δ/M^d. At step k, both the uniform error and the facetwise Lipschitz error are at most $M^{k-1}\delta/M^d$, and the lemma bounds both errors on the new cell by $M^k\delta/M^d$. The functions agree on shared faces by construction. The finite-max presentations give rational slopes and value-group constants on a finite refinement. If $d = 0$, the vertex choices alone suffice. □

11.20.2 Preserving the relative supports

Lemma 11.20.3 (Stability near a strict PL function)**.** *Let $F_0 \in V(\Pi)$ have strict face supports. There is $\delta_0 > 0$ such that every continuous G, a finite maximum of real affine functions on each cell, has local relative affine lower supports whenever*

$$\max_{\sigma \in \Pi} \operatorname{Lip}_\sigma(G - F_0) \le \delta_0$$

holds. More quantitatively, if $F_0 = F + tH$ with $F \in C(\Pi)$ and fixed H having strict face supports, one may take $\delta_0 = t/(4K_H)$ for a constant $K_H \ge 1$ independent of F and $t > 0$.

Proof. Choose the strict support a_ρ for a face ρ. On any coface σ, put $D_{\rho\sigma} = F_0 - a_\rho$. It is affine and nonnegative, with zero set exactly ρ. The vertex replacement argument used in (11.20.2) gives, for every $y \in \sigma$, a point $z \in \rho$ with $\|y - z\| \le K D_{\rho\sigma}(y)$, for one finite $K \ge 1$ over all proper incidences.

Take $x \in \operatorname{relint}(\rho)$ and an active affine branch supporting $G|_\rho$ at x. Its tangential gradient differs from that of $F_0|_\rho$ by a vector e of norm at most

$\delta := \max_\sigma \operatorname{Lip}_\sigma(G - F_0)$. This follows by testing the supporting inequality in both tangent directions near x. Regard e as a tangent vector in the ambient Euclidean space and set

$$b(y) = a_\rho(y) + e \cdot (y - x) + G(x) - F_0(x).$$

Then $b \le G$ on ρ and $b(x) = G(x)$. For $y \in \sigma \supseteq \rho$, use the point z above and the Lipschitz estimate within σ to obtain

$$\begin{aligned} G(y) - b(y) &= (G - F_0)(y) - (G - F_0)(z) + G(z) - b(z) \\ &\quad + D_{\rho\sigma}(y) - e \cdot (y - z) \\ &\ge D_{\rho\sigma}(y) - 2\delta\|y - z\| \\ &\ge (1 - 2\delta K) D_{\rho\sigma}(y). \end{aligned}$$

Thus $\delta \le 1/(4K)$ suffices. A small neighbourhood of x meets only cofaces of ρ, so b is the required relative support. If ρ is maximal, the active branch alone suffices.

For the quantitative statement, add a support of F to t times a strict support of H. The gap on each coface is at least t times the corresponding gap for H. The same vertex replacement construction therefore gives the distance bound with constant K_H/t, which may itself be less than one. This proves the stated bound without using a uniform bound on the values of $G - F_0$. □

Theorem 11.20.4 (Relative rational approximation with moving subdivisions)**.** *Let $\Gamma \ne 0$ and let Π be a finite compact polytopal complex whose cells are defined by rational-slope, $\Gamma_{\mathbf{Q}}$-constant affine inequalities. Every continuous cellwise-affine F with local relative affine lower supports has continuous coefficient-compatible PL approximants F_j on the same support $S = |\Pi|$, themselves admitting such supports, with*

$$F_{j+1} \le F_j, \qquad 0 \le F_j - F \le 3\rho 8^{-j} \quad (\rho \in \Gamma_{>0} \text{ fixed}). \tag{11.20.4}$$

The subdivisions of the approximants may vary with j. No continuity-closure condition $F \in V_\Gamma(\Pi)$ is required.

Proof. Use the fixed arrangement refinement Π^* and strict function H from Theorem 11.19.8. The function F is still affine on each refined cell and has relative supports. Set $B = \max\{1, \|H\|_\infty\}$ and $\eta_j = \rho 8^{-j}$. Choose

$$t_j = \frac{\eta_j}{2B}, \qquad 0 < \delta_j \le \min\left\{ \frac{\eta_j}{2}, \frac{t_j}{4K_H} \right\}.$$

Apply Corollary 11.20.2 to the real PL target $F+t_jH$ with error δ_j, obtaining G_j. Lemma 11.20.3 gives relative affine supports for G_j, and

$$\|G_j - F\|_\infty \le \delta_j + t_j\|H\|_\infty \le \eta_j.$$

Put $F_j = G_j + 2\eta_j$. This is an allowed value-group shift, preserving the supports and coefficients. The inequalities $F + \eta_j \le F_j \le F + 3\eta_j$ imply (11.20.4). Every construction takes place on the same S. The arrangement refinement is fixed once; only the further finite-max subdivisions used to build G_j vary. □

The same proof applies termwise to a decreasing sequence of such real PL targets u_j on the same compact support, even if their compatible complexes differ. Choose supported rational G_j with $|G_j - u_j| \le \eta_j$ and add $2\eta_j$. Then $G_{j+1} + 2\eta_{j+1} \le u_{j+1} + 3\eta_{j+1} \le u_j + \eta_j \le G_j + 2\eta_j$. The limit is the original pointwise limit of u_j; uniform convergence is claimed only when the targets themselves converge uniformly.

11.20.3 The source interface still to be checked

On an actual ordinary unit chart, the analytic consequences in Section 11.19.7 now apply to every relatively supported real PL target whose finite compact complex has the stated coefficient-compatible geometry. Actual Q-PL identification, nontrivial valuation, nef-residue comparison and integral-projective original-smooth transfer remain separate cited inputs. The arithmetic normalization and original tests are unchanged.

This does not yet cover the arbitrary real intercepts allowed by APW26, nor an arbitrary smooth target without a suitable PL approximation on a common domain. The argument also does not extend the current calculus to arbitrary positive backgrounds or prove first-stage closure. These distinctions are part of the theorem: the new result removes the fixed-subdivision obstruction by controlled moving subdivisions within the compatible-polyhedral class. It is an elementary reconstruction assembled from the explicit extension and support estimates above, not a claim that an unverified source theorem has been proved in its full generality.

Section 11.21 goes further for rational-direction PL germs and for families with an explicit common transport domain. Section 11.21.4 isolates an earlier issue in the literal APW26 PL convention; the gap is not resolved merely by replacing real intercepts with value-group constants.

11.21 Real intercepts, moving germs and common domains

A real intercept can be an obstruction to keeping a subdivision fixed without being an obstruction to approximating the function. There is a local way to remove it: move the centre of a PL star inside the stratum of the original support. The support remains fixed, whereas the break loci move. We prove this germ statement first. We then give a separate transport criterion that works on a prescribed compact set, and explain why the germ statement alone cannot be applied termwise to a source approximation on one neighbourhood.

Section 11.22 gives a subsequent replacement for the fixed-domain approximation question: continuous relative supports suffice, without rational directions or a one-scale input subdivision. The present constructions retain their explicit geometric interpretation and illustrate why termwise germ arguments alone do not control a common domain.

11.21.1 Moving a centre within its stratum

Throughout this section $\Gamma \subset \mathbf{R}$ is a nonzero additive subgroup. A compatible polyhedron is one defined by rational-slope affine inequalities with constants in $\Gamma_{\mathbf{Q}}$. A rational polyhedron, without the word compatible, may have arbitrary real constants. All complexes used locally are finite after restriction to a sufficiently small neighbourhood. Relative supports always mean ambient affine lower supports in the relative topology of the specified support.

Lemma 11.21.1 (Compatible points in a face)**.** *If τ is a nonempty compatible polyhedron, then* $\operatorname{relint}(\tau) \cap \Gamma_{\mathbf{Q}}^r$ *is dense in* $\operatorname{relint}(\tau)$*. Its tangent space $L = T\tau$ is rational.*

Proof. The affine hull is specified by those rational equations that hold identically on τ. Gaussian elimination gives a particular solution $a \in \Gamma_{\mathbf{Q}}^r$ and a basis $e_1, \dots, e_d \in \mathbf{Q}^r$ for the homogeneous solutions. Thus $\operatorname{aff}(\tau) = a + \sum_k \mathbf{R} e_k$. Since $\Gamma_{\mathbf{Q}}$ contains $\rho\mathbf{Q}$ for some $\rho > 0$, points $a + \sum_k b_k e_k$ with $b_k \in \Gamma_{\mathbf{Q}}$ are dense in this affine hull and have compatible coordinates. Intersect with the relatively open set $\operatorname{relint}(\tau)$. The case $d = 0$ is included. □

Lemma 11.21.2 (A fixed support near a stratum)**.** *Let S be the support of a locally finite compatible complex, and let $x \in \operatorname{relint}(\tau)$. There are $R > 0$ and a finite union C of rational polyhedral cones such that*

$$S \cap B(x,R) = (x + C) \cap B(x,R), \qquad C + L = C, \quad L = T\tau.$$

In particular, $b + C = x + C$ for every $b \in \operatorname{aff}(\tau)$. If F is continuous and affine on a finite rational polyhedral subdivision near x, then, after decreasing R,

$$F(x+v) = F(x) + f(v), \qquad v \in C, \quad \|v\| < R, \tag{11.21.1}$$

where f is continuous and homogeneous of degree one, affine on a finite rational conical subdivision of C. If F has relative supports near x, then f has relative supports on all of C.

Proof. Only cells containing x meet a sufficiently small ball. In each such cell, inequalities that are strict at x remain strict in a smaller ball; the active inequalities become homogeneous after translating x to the origin. Their normals are rational, and vanish on L, because they vanish on the face τ. Their tangent cones form the asserted union C, invariant under both signs of every vector in L. This also proves the equality after changing the centre to b.

Apply the same active-constraint construction to the finite rational subdivision of F, together with the original complex. On a cell containing x, its affine expression becomes $F(x) + p_\sigma \cdot v$. The expressions agree on overlaps, first near zero and then everywhere by homogeneity. They define f on C. To transfer a relative support to a point $v \in C$, choose $s > 0$ so small that sv and a neighbourhood of it lie in the ball where (11.21.1) holds. A support a for f near sv gives the support $s^{-1}a(s\,\cdot)$ near v. At zero use the given support directly. □

Theorem 11.21.3 (Rational approximation of a real-intercept PL germ)**.** *Let S be locally the support of a compatible complex and let F be continuous, affine on a locally finite rational polyhedral subdivision of S, with local relative affine lower supports. For every $x \in S$ there is a compact neighbourhood K of x in S and continuous coefficient-compatible PL functions F_j on K, themselves having relative supports, such that*

$$F + \eta_j \le F_j \le F + 3\eta_j, \qquad F_{j+1} \le F_j, \qquad \eta_j = \rho 8^{-j}, \quad \rho \in \Gamma_{>0}. \tag{11.21.2}$$

The intercepts of the subdivision of F need not belong to $\Gamma_{\mathbf{Q}}$. The neighbourhood K depends on the germ F; the theorem makes no uniform-domain assertion for a family of different germs.

Proof. Use Lemma 11.21.2. Choose a closed box B with coordinate endpoints in $\Gamma_{\mathbf{Q}}$ such that $x \in \operatorname{int}(B)$ and $B \subset B(x, R/4)$, and put $K = S \cap B = (x + C) \cap B$. For $b \in \operatorname{relint}(\tau) \cap \Gamma_{\mathbf{Q}}^r$ close to x, define

$$H_b(t) = F(x) + f(t - b), \qquad t \in K.$$

The equality $b + C = x + C$ makes this a function on exactly the same K. It has relative supports, and its cells are intersections of B with translates by b of rational cones. These cells are compatible. Thus H_b satisfies the hypotheses of Theorem 11.20.4, although its function coefficients can still be real.

There is a constant $M < \infty$ with $|H_b - F| \le M\|b - x\|$ on K. Indeed, the segment from $t - x$ to $t - b$ lies in C, since its direction belongs to L. Partition that segment at the finitely many conical cells of f. On each piece its slope is bounded by the norm of a chosen ambient slope of that cell; take M to be the largest of these norms. Lemma 11.21.1 now gives b_j so close to x that this error is at most $\eta_j/2$.

Theorem 11.20.4 supplies a supported coefficient-compatible G_j on K with $\|G_j - H_{b_j}\|_\infty \le \eta_j/2$. Hence $\|G_j - F\|_\infty \le \eta_j$. Set $F_j = G_j + 2\eta_j$. The shift is in $\Gamma_{\mathbf{Q}}$ and gives (11.21.2), including decrease because $3\eta_{j+1} < \eta_j$. No affine map of an analytic space has been introduced: only the real function used in a fixed set of coordinates has changed. □

11.21.2 Transport on a prescribed compact set

For a single germ the preceding construction is enough. For a sequence, a useful alternative is to move an entire one-scale presentation on a domain fixed in advance. The scale below is a real geometric parameter; it is not the normalization of a field valuation.

Theorem 11.21.4 (One-scale transport)**.** *Let C be a finite union of rational cones, let $L \subset \mathbf{R}^r$ be a rational subspace with $C + L = C$, and let $a \in \Gamma_{\mathbf{Q}}^r$. Let U be relatively open in $S = a + C$. Let B be a closed compatible box with nonempty $K = S \cap B \subset U$. Suppose F is continuous, has relative supports*

on U, and is affine on a finite polyhedral structure in a neighbourhood of K, whose cells are defined by inequalities

$$q \cdot (t - a - w) \geq \lambda c, \qquad q \in \mathbf{Q}^r, \quad c \in \mathbf{Q}, \quad w \in L, \quad \lambda > 0. \tag{11.21.3}$$

Here the same w and λ are used for all cells, and equalities are allowed. Then $F|_K$ has decreasing coefficient-compatible relative PL approximants satisfying (11.21.2) on this prescribed K. Neither w nor λ is required to have value-group coordinates.

Proof. Choose $w_j \in L \cap \Gamma_{\mathbf{Q}}^r$ and $\lambda_j \in \Gamma_{\mathbf{Q},>0}$ tending to w and λ, respectively, and define

$$T_j(t) = a + w_j + \frac{\lambda_j}{\lambda}(t - a - w).$$

The maps T_j preserve S bijectively and converge to the identity, as do their inverses, uniformly on compact sets. Choose a relatively open neighbourhood N of K with compact closure in U, contained in the neighbourhood where the stated finite presentation is valid. Sufficiently close choices ensure $T_j^{-1}(K) \subset N$. On K put $H_j = F \circ T_j^{-1}$. Supports are transported by this invertible affine map in the real coordinate space. The transformed cell inequalities are

$$q \cdot (t - a - w_j) \geq \lambda_j c.$$

They are compatible, since only rational numbers multiply elements of $\Gamma_{\mathbf{Q}}$. Their intersections with B form a compatible compact complex with support exactly K. Uniform continuity of F on $\overline{N}$ allows the choices to satisfy $\|H_j - F\|_K \leq \eta_j/2$. Apply Theorem 11.20.4 with error $\eta_j/2$, and add $2\eta_j$ as in the previous proof. □

Corollary 11.21.5 (An edge-connected simplicial certificate)**.** *In Theorem 11.21.4, the one-scale presentation condition follows if F is affine on a finite compact simplicial complex covering a neighbourhood of K in S, every maximal simplex has dimension at least two, every edge has rational direction, the maximal simplices are connected by shared edges, and one vertex p belongs to $a + L$. The vertices need not have value-group coordinates.*

Proof. Use the geometric part of the proof of Proposition 11.19.10, before its value-group step. It gives one positive real λ such that all vertices lie in $p + \lambda\mathbf{Q}^r$. Indeed, within a simplex the rational directions of its edges force the edge scales to have rational ratios; a shared nonzero edge propagates the

ratio between simplices. Each simplex is therefore $p + \lambda$ times a polytope with rational vertices, allowing lower-dimensional affine-hull equations. Its defining inequalities have the form (11.21.3), with $w = p - a \in L$. Apply Theorem 11.21.4. This is a consequence of the earlier scale-propagation proof and the new transport argument, rather than a separate density theorem. □

This certificate is deliberately checkable. It does not apply merely because a source uses the word simplicial: unbounded polyhedra, pieces joined only at vertices, one-dimensional cells, and a missing lineality anchor require additional arguments. In an ambient vector space one may take $L = \mathbf{R}^r$, so the anchor condition is automatic; on a branching support it is a real restriction.

Corollary 11.21.6 (Families with a common transport domain)**.** *Let u_j decrease pointwise on the same $U \subset S$. Suppose each u_j satisfies the hypotheses of Theorem 11.21.4 near the same K, with its own finite structure, scale and lineality translation. Then there are supported coefficient-compatible PL functions v_j on K with*

$$u_j + \eta_j \le v_j \le u_j + 3\eta_j, \qquad v_{j+1} \le v_j.$$

The pointwise limit is unchanged. If instead u_j converges uniformly to a finite function u on K, without monotonicity, a subsequence and the same error-shift construction give decreasing supported coefficient-compatible PL approximants to u on K.

Proof. For the first assertion choose G_j with $\|G_j - u_j\|_K \le \eta_j$ and set $v_j = G_j + 2\eta_j$. Then $v_{j+1} \le u_{j+1} + 3\eta_{j+1} \le u_j + \eta_j \le v_j$. For the second, select u_{k_j} with $\|u_{k_j} - u\|_K \le \eta_j/2$ and approximate that term within $\eta_j/2$. The resulting G_j lies within η_j of u, so the same shift proves the claim. Parameters may be chosen separately for each target; no uniform slope bound or common subdivision is used. □

11.21.3 Why the germ quantifiers matter

Example 11.21.7 (Shrinking stars despite uniform control)**.** Take $\Gamma = \mathbf{Z}$ and let p_j be the secant interpolation of t^2 at the dyadic nodes of $[-1, 1]$, with mesh $h_j = 2^{-j}$. On $[kh_j, (k+1)h_j]$ one has

$$p_j(t) - t^2 = (t - kh_j)((k+1)h_j - t), \qquad 0 \le p_j(t) - t^2 \le h_j^2/4.$$

The slopes $(2k+1)h_j$ increase with k, so p_j is convex. Refining each interval inserts a point of the convex graph below its old chord, hence $p_{j+1} \le p_j$. Also $\mathrm{Lip}(p_j) \le 2$. Nevertheless, the maximal centred interval on which $p_j(t) = p_j(0) + f_j(t)$ for a degree-one homogeneous PL function f_j is $[-h_j, h_j]$: there $p_j = h_j|t|$, and the slope changes at $\pm h_j$. Thus no positive-radius star works for all j. Pullback by the first-coordinate projection gives the same phenomenon in every positive dimension.

This is not a failure of approximation: the functions p_j are already coefficient-compatible, convex and decreasing uniformly to a smooth convex target. It disproves only the inference from termwise PL stars, uniform convergence and a uniform Lipschitz bound to a common star radius. The domain in Theorem 11.21.3 therefore cannot simply be intersected over the approximants furnished by a source theorem.

Corollary 11.21.8 (Original smooth approximation of a rational-direction PL germ)**.** *Let K be complete and nontrivially valued, let X be an integral projective K-variety of positive dimension, and let $W \subset X^{\mathrm{an}}$ be ordinary open. On W fix analytic units $g_1, \dots, g_r$ and the map $\tau = (-\log|g_1|, \dots, -\log|g_r|)$. Let $x \in W$. Suppose near $\tau(x)$ that the actual image is contained in a support S of a locally finite $\Gamma_{\mathbf{Q}}$-compatible complex, where $\Gamma = -\log|K^\times|$, and*

$$u = F \circ \tau,$$

where F is finite continuous, affine on a locally finite rational subdivision of S, and has local relative affine lower supports. Then some ordinary open neighbourhood $V \subset W$ of x carries original smooth psh functions $b_j \downarrow u|_V$. Convergence is uniform on compact subsets of V.

Open proof obligation (RC2). Prove the analytic germ bridge using the required curvewise-to-model implication; GRPSH Theorem 4.3.

For a family on a prescribed compatible box, Corollary 11.21.6 can replace the germ theorem in this proof, after its geometric presentation conditions are checked term by term. Neither route changes the chosen valuation, extends the ground field, enlarges the support of an actual analytic test, or replaces original CLD tests. The auxiliary real support S must be specified in the hypothesis; no unsupported extension of F from the actual image is being asserted. These are consequences of the displayed real constructions and the named model and smoothing inputs, not a full comparison with the generated source classes.

11.21.4 The PL convention in the source regularization

There is a logically earlier issue than the value-group constants. In the fixed version [APW26, Section 1.6; Sections 2.1, 2.1.4–2.1.6], affine functions have real coefficients, rational half-spaces have integral normals and arbitrary real intercepts, and polyhedral structures are declared rational and simplicial unless specified otherwise. The last step of Proposition 5.12, printed page 38, invokes a continuous finite-selection argument to conclude PL membership. The following two examples explain why that step needs an explicit convention or an additional geometric argument. They do not disprove the existence statements of Propositions 5.12 or 5.21.

The examples below concern finite or locally finite subdivisions, as explicitly stated. The displayed definition in the source Section 2.1.6 does not itself list local finiteness. This convention also needs clarification when that definition is used: we do not infer a statement about arbitrary non-locally-finite decompositions from the finite-boundary argument below.

Example 11.21.9 (A maximum with an irrational break direction)**.** On $\mathbf{R}^2$, the affine functions $\ell_1(x, y) = x$ and $\ell_2(x, y) = \sqrt{2}\, y$ are affine on every rational triangulation. Their maximum

$$m(x, y) = \max\{x, \sqrt{2}\, y\}$$

is not affine on the cells of any locally finite rational polyhedral structure near the origin. Indeed, each full-dimensional affine cell must lie on one side of the break line $D = \{x = \sqrt{2}\, y\}$. Hence an open segment of D would lie in the finite union of rational supporting lines of the cells near the origin. One such line would have to contain an open segment of D, and therefore equal D. But D has no nonzero rational tangent vector. This is a contradiction. The function m is nevertheless an ordinary real-polyhedral PL function and is ambient convex. Products with $\mathbf{R}^{r-2}$ give the same distinction in every dimension $r \geq 2$.

Proposition 11.21.10 (Uniform density does not give Lipschitz-small errors)**.** *Let $m(x, y) = \max\{x, \sqrt{2}\, y\}$ and let B be a closed ball of positive radius centred at the origin. If G is continuous and affine on a locally finite rational polyhedral subdivision of a neighbourhood of B, then*

$$\mathrm{Lip}_B(G - m) \geq \frac{\sqrt{3}}{2}.$$

This holds even when the affine coefficients of G are real. Nevertheless, rational numbers $q_j \to \sqrt{2}$ give coefficient-compatible convex functions $\max\{x, q_j y\}$ converging uniformly to m on B.

Proof. A nontrivial segment of the irrational line $D = \{x = \sqrt{2}\, y\}$ inside B cannot be covered by the finitely many rational boundary lines of the subdivision. Choose a point z on that segment in the interior of a full-dimensional cell. Near z, the function G is one affine function with gradient p. On the two open sides of D, the gradients of $G - m$ are respectively $p - (1, 0)$ and $p - (0, \sqrt{2})$. Its Lipschitz seminorm on B bounds both norms, by evaluating differences in small line segments lying in the corresponding open side. The triangle inequality gives

$$\sqrt{3} = \|(1,0) - (0,\sqrt{2})\| \le \|p - (1,0)\| + \|p - (0,\sqrt{2})\| \le 2\,\mathrm{Lip}_B(G - m).$$

For uniform approximation, the maximum operation is 1-Lipschitz in the sup norm of its two entries, so the error is at most $|q_j - \sqrt{2}| \max_B |y|$. The same obstruction holds in every ambient dimension at least two by restricting to the rational plane where the other coordinates vanish. The lower bound is sharp among rational-subdivision PL functions with real affine coefficients: the single affine function $G = (x + \sqrt{2}\, y)/2$ has $G - m = -|x - \sqrt{2}\, y|/2$ and Lipschitz error $\sqrt{3}/2$. Among coefficient-compatible functions the infimum is the same, by approximating this affine gradient by rational vectors; an allowed constant can be chosen independently because the Lipschitz seminorm ignores constants. □

Thus the cellwise Lipschitz estimates used in Section 11.20 cannot simply be demanded for arbitrary real-polyhedral targets on a preassigned rational complex. A rational subdivision of the input was a substantive hypothesis of the germ construction. This obstruction concerns the stronger error norm only; it neither obstructs uniform rational approximation nor disproves the source regularization statement.

The same proof applies to the maximum of two affine functions with gradients p_1, p_2 whenever their break hyperplane cannot be a facet in the permitted subdivision class; the bound is $\|p_1 - p_2\|/2$. This also distinguishes value-group intercepts from rational directions. For example, with $\Gamma = \mathbf{Z}$, on $[-2, 2]$ every coefficient-compatible PL approximation G to $|t - \sqrt{2}|$ has $\mathrm{Lip}(G - |t - \sqrt{2}|) \ge 1$: its finitely many rational breakpoints miss $\sqrt{2}$, so G is affine there. Yet $|t - a_j|$ converges uniformly when $a_j \in \mathbf{Q}$ tends to

$\sqrt{2}$. Thus moving the centre in Theorem 11.21.3 is compatible with uniform error control, without implying Lipschitz convergence. Products give this intercept phenomenon in every positive dimension.

Example 11.21.11 (Compatible coefficients without rational triangulability)**.** Let $\Gamma = \mathbf{Z} + \sqrt{2}\mathbf{Z}$. Each of the four functions $|x|$, $|x-1|$, $|y|$ and $|y-\sqrt{2}|$ admits a rational simplicial conical subdivision of $\mathbf{R}^2$, translated to a point on its break line. Their sum

$$P(x,y) = |x| + |x-1| + |y| + |y-\sqrt{2}|$$

has rational slopes and $\Gamma_{\mathbf{Q}}$ constants on a compatible polyhedral complex. But it admits no locally finite rational simplicial subdivision on a neighbourhood of $[0,1] \times [0,\sqrt{2}]$. Its gradient changes across each of the four bounding lines. No full-dimensional cell of an affine presentation can cross any of those lines. Thus the cells inside the rectangle would give a finite rational-direction triangulation of it, contradicting Example 11.19.11. All the cells contained in the bounded rectangle are compact simplices, irrespective of how simplicial unbounded polyhedra are defined outside it.

The first example concerns rational directions, independently of any valuation. The second retains rational directions and compatible coefficients, but concerns the extra simplicial requirement. Neither example is a counterexample to approximation by supported rational functions: the first is ambient convex and admits such approximations by Section 11.12.4, while the second is already coefficient-compatible. They identify the category in which a finite-selection proof is valid.

Lemma 11.21.12 (Coefficient-compatible finite selections)**.** *On the support of a finite compatible complex, a continuous selection from finitely many affine functions $q_i \cdot t + c_i$, with $q_i \in \mathbf{Q}^r$ and $c_i \in \Gamma_{\mathbf{Q}}$, is coefficient-compatible PL on a finite compatible refinement. The same conclusion holds for a continuous selection from finitely many coefficient-compatible PL functions. No simplicial refinement is asserted.*

Proof. Cut each cell by all equations $(q_i - q_k) \cdot t = c_k - c_i$. These are compatible hyperplanes. On the relative interior of a resulting cell, two branches are either identical or everywhere distinct, with a fixed strict order. A continuous selection must choose one of these distinct branches on each connected relative interior: locally it cannot change to a different branch across a positive value gap. Continuity extends that affine expression to the closed cell.

For PL inputs first take their finite common compatible refinement and apply the same argument to their affine branches there. □

With arbitrary real affine coefficients the same proof produces a real-polyhedral refinement, whose face directions may be irrational. Thus there are two honest ways to use the last step of the source Proposition 5.12: either specify the unrestricted real-polyhedral PL category and separately prove the later rational/model interface, or establish coefficient and subdivision control during the construction. Merely citing a finite-selection theorem does not supply that control. The germ theorem above assumes a rational subdivision of the input and therefore does not silently cover the first alternative. Section 11.22 supplies the second route for continuous relative-support inputs on a fixed compact set. The companion mixed-calculus Theorem 6.13 remains unverified here because its primary full text has not been obtained.

The primary-file check also confirms the localization correction already proved in Lemma 11.11.11. On the compact neighbourhood used in APW Proposition 5.10, the intersection of the closures of its shrinking sets is $\{g - \ell_g = 0\} = \{x\}$, not the printed zero set of $f - \ell_f$. This is a recheck of that earlier repair, not an additional result of the present section.

11.22 Rational affine bumps on a fixed compact support

The coefficient problem can be treated before the PL subdivision is produced. The local modification and finite-cover argument of [APW26, Propositions 5.10 and 5.12] suggest the following replacement: approximate the raised affine supports by coefficient-compatible affine functions, then perform the gluing. A small quadratic term supplies the strict separation needed to absorb that perturbation. The proof below is given in full, including the common domain and the last finite-selection step. It is an elementary reconstruction of that argument with coefficient control, not a claim of a new regularization principle.

11.22.1 Local modifications with controlled coefficients

Fix a nonzero additive subgroup $\Gamma \subset \mathbf{R}$, and set $\Gamma_{\mathbf{Q}} = \Gamma \otimes_{\mathbf{Z}} \mathbf{Q} \subset \mathbf{R}$. An allowed affine function is $a(t) = q \cdot t + c$ with $q \in \mathbf{Q}^r$ and $c \in \Gamma_{\mathbf{Q}}$. Let $S \subset \mathbf{R}^r$

be nonempty and compact. A continuous $F : S \to \mathbf{R}$ has relative affine lower supports if, for every $x \in S$, some ambient affine ℓ_x satisfies $\ell_x(x) = F(x)$ and $\ell_x \le F$ on a relative neighbourhood of x. No polyhedrality of S is needed until the polyhedral conclusion is stated.

Lemma 11.22.1 (A rational affine local bump)**.** *Suppose that $g : S \to \mathbf{R}$ is continuous and has relative affine lower supports. Fix $x \in S$, $r, t > 0$ and an ambient affine ℓ such that*

$$\ell(x) = g(x), \qquad g(y) - \ell(y) \ge t\|y - x\|^2 \quad (y \in S \cap \overline{B}(x, 2r)).$$

For every $0 < \delta \le tr^2/16$ there is an allowed affine function a and a continuous function $b : S \to \mathbf{R}$ with relative affine lower supports, satisfying

$$g \le b \le g + 5\delta/4, \qquad b(x) - g(x) \ge 3\delta/4, \tag{11.22.1}$$
$$b = g \quad \text{on } S \setminus B(x, r/2), \qquad b(y) > g(y) \Longrightarrow b(y) = a(y).$$

Proof. The groups $\mathbf{Q}$ and $\Gamma_{\mathbf{Q}}$ are dense in $\mathbf{R}$. Approximate the coefficients of $\ell + \delta$ so closely that

$$|a - (\ell + \delta)| \le \delta/4 \quad \text{on } \overline{B}(x, 2r).$$

This is possible by coefficientwise approximation on a bounded ball; the centre x and the radius r need not be compatible. At x one has $a - g \ge 3\delta/4$. On $S \cap \overline{B}(x, 2r)$ one has $a - g \le 5\delta/4$. If also $\|y - x\| \ge r/2$, then

$$a(y) - g(y) \le 5\delta/4 - tr^2/4 < 0.$$

Define $b = \max\{g, a\}$ on $S \cap B(x, r)$ and $b = g$ elsewhere. On an annulus around the patching boundary both formulas equal g. Hence the definition is continuous and gives (11.22.1). Locally it is either g or a maximum of g and an affine function. A support of an active term supports the maximum at that point; this proves the support assertion, including the tie locus. No smooth cutoff is used. □

Lemma 11.22.2 (A finite active cover removes the background)**.** *Let $g, b_1, \dots, b_N$ be continuous functions on compact S, with $b_i \ge g$. Suppose that $\{b_i > g\}$ cover S, and that $b_i = a_i$ on $\{b_i > g\}$ for allowed affine functions a_i. Then $P = \max_i b_i$ is a continuous selection from $a_1, \dots, a_N$. Moreover, near each point of S, it is the restriction of a maximum of a fixed subset of these affine functions. In particular, it has relative affine lower supports.*

Proof. At $y \in S$, one has $P(y) > g(y)$. Every maximizing index therefore has $b_i(y) = a_i(y)$. Let $I_y = \{i : b_i(y) = P(y)\}$. For these indices, continuity keeps $b_i > g$ near y, so $b_i = a_i$ there. For the other indices, the strict inequalities $b_i(y) < P(y)$ persist on a sufficiently small common neighbourhood, because the list is finite. Consequently $P = \max_{i \in I_y} a_i$ near y. The covering also gives $\min_S(P - g) > 0$, although no uniform lower bound independent of the approximation is needed. □

The local and global assertions in this lemma are different. An affine branch a_i may exceed P outside the patch on which it was used; the construction does not give $P = \max_i a_i$ on all of S. Near a point, however, every active modification is strictly above the background and therefore equals its affine branch. This is the precise reason why the local maximum conclusion survives the gluing.

11.22.2 Coefficient-compatible density and fixed-domain sequences

Theorem 11.22.3 (Density by rational finite selections)**.** *Let $S \subset \mathbf{R}^r$ be nonempty and compact and let $F : S \to \mathbf{R}$ be continuous with relative affine lower supports. For every $\varepsilon > 0$ there is a continuous function $P : S \to \mathbf{R}$, locally a finite maximum of allowed affine functions and globally a selection from one finite list of them, such that*

$$F \le P \le F + \varepsilon \quad \text{on the same } S. \tag{11.22.2}$$

If S is the support of a finite coefficient-compatible polytopal complex, then P is coefficient-compatible PL on a finite refinement. No rational subdivision, differentiability or PL hypothesis is imposed on F. The refinement is not asserted to be simplicial.

Proof. Set $Q(y) = \|y\|^2$ and choose $t > 0$ so that $t \max_S Q \le \varepsilon/4$. The function $g = F + tQ$ is continuous and has relative supports. More precisely, if ℓ_x^F supports F near x, then

$$\ell_x(y) = \ell_x^F(y) + t\big(Q(x) + 2x \cdot (y - x)\big)$$

satisfies $g(y) - \ell_x(y) \ge t\|y - x\|^2$ in that neighbourhood. Choose $r_x > 0$ so that this holds on $S \cap \overline{B}(x, 2r_x)$, and choose

$$0 < \delta_x \le \min\{\varepsilon/4, tr_x^2/16\}.$$

Lemma 11.22.1 gives b_x, and the relatively open sets $\{b_x > g\}$ cover S. Take a finite subcover and set P equal to the maximum of its modifications. Then

$$F \le g \le P \le g + 5\varepsilon/16 \le F + 9\varepsilon/16 < F + \varepsilon.$$

Lemma 11.22.2 gives the local maxima and the global finite selection. If S is coefficient-compatible polyhedral, apply Lemma 11.21.12: cut by the equations $a_i = a_k$, whose slopes are rational and constants lie in $\Gamma_{\mathbf{Q}}$. The original balls and the possibly nonpolyhedral sets $\{a_i > g\}$ disappear from this final presentation. It is therefore unnecessary to make their radii or boundaries compatible. □

Corollary 11.22.4 (Decreasing approximation on the same support)**.** *Under the hypotheses of Theorem 11.22.3, fix $\rho \in \Gamma_{>0}$ and put $\eta_j = \rho 8^{-j}$. There are functions P_j of the type constructed there such that*

$$F + \eta_j \le P_j \le F + 2\eta_j, \qquad P_{j+1} \le P_j. \tag{11.22.3}$$

Thus $P_j \downarrow F$ uniformly on S. The local maximum neighbourhoods may vary with j; their domains of definition are all S.

Proof. Approximate F from above within η_j and add the allowed constant η_j. This gives the displayed bounds, and $2\eta_{j+1} < \eta_j$ gives decrease. Adding a constant preserves every support and every local maximum presentation. This is the geometric-error shift used earlier, now applied after the rational bump construction. □

Corollary 11.22.5 (Continuous supported families)**.** *Let F_j be continuous functions with relative affine lower supports on the same compact S. If $F_j \downarrow F$ pointwise, then there are rational finite selections P_j, each locally a maximum of allowed affine functions, with*

$$F_j + \eta_j \le P_j \le F_j + 2\eta_j, \qquad P_j \downarrow F.$$

If instead $F_j \to F$ uniformly with no monotonicity, then a subsequence and suitable allowed shifts give such a decreasing approximation of F. In the polyhedral case all these functions are coefficient-compatible PL. No common subdivision or common local maximum radius is needed.

Proof. For decreasing targets, apply Theorem 11.22.3 to the jth target with error η_j, then add η_j. The bounds imply $P_{j+1} \le F_{j+1} + 2\eta_{j+1} \le F_j + \eta_j \le P_j$. For uniformly convergent targets, choose F_{k_j} within $\eta_j/4$ of F, approximate it from above within $\eta_j/4$, and add η_j. Then $F + 3\eta_j/4 \le P_j \le F + 3\eta_j/2$; the same geometric ratio gives decrease. The pointwise statement does not assert uniform convergence to a discontinuous or infinite limit. □

Lemma 11.22.6 (Smooth cellwise convex inputs have relative supports)**.** *Let S be the support of a locally finite polyhedral complex in $\mathbf{R}^r$, and let f be C^1 on an ambient neighbourhood of S. Assume that its restriction to every cell is locally convex. Then $f|_S$ has relative affine lower supports. It is enough, for C^2 functions, that the Hessian be positive semidefinite on the tangent space of each cell at its relative interior points.*

Proof. Fix $x \in S$. By local finiteness and closedness, a sufficiently small ball meets only cells containing x. On each of the finitely many incident cells, local convexity at x gives convexity on its intersection with a sufficiently small ball. Take a common such ball; every segment from x to a point in that cell stays in the convex intersection. The one-variable tangent inequality gives

$$f(y) \ge f(x) + df_x(y - x).$$

The right side is one ambient affine function, independent of the cell, and it equals f at x. This proves the assertion. In the C^2 case the tangential Hessian condition extends to cell boundaries by continuity, and its restriction to each segment gives the required convexity. In affine coordinates the support is $y \mapsto f(x) + df_x(y - x)$, not $y \mapsto f(x) + df_x(y)$ unless the coordinates have first been centred at x. □

This is the local tangent-support argument used in [Wu26, Appendix A, p. 53], with its affine translation written explicitly and local finiteness included. Combined with Theorem 11.22.3, it gives coefficient-compatible approximation on any fixed compact compatible support inside the ambient domain. It does not assume, without a separate comparison theorem, that positivity of an arbitrary CLD current supplies this cellwise Hessian hypothesis.

Corollary 11.22.7 (Finite ordered families)**.** *Let $\{F_\alpha\}_{\alpha\in A}$ be a finite family satisfying Theorem 11.22.3, indexed by a finite partially ordered set, with $F_\alpha \le F_\beta$ whenever $\alpha \le \beta$. The decreasing rational approximants may be chosen to preserve all these inequalities simultaneously.*

Proof. Choose approximants $Q_{\alpha,j}$ from Corollary 11.22.4, with the same η_j for all α. Set $P_{\alpha,j} = \max_{\gamma\le\alpha} Q_{\gamma,j}$. The index sets are nested when $\alpha \le \beta$, so the order is preserved. Also $F_\alpha + \eta_j \le P_{\alpha,j} \le F_\alpha + 2\eta_j$, because the term $\gamma = \alpha$ is present and $F_\gamma \le F_\alpha$. Finite maxima preserve the local affine-maximum presentations and decrease in j. □

11.22.3 The actual analytic consequence

Theorem 11.22.8 (Continuous relative-support potentials on unit charts)**.** *Let K be complete and nontrivially valued, let X be an integral projective K-variety of positive dimension, and let $W \subset X^{\mathrm{an}}$ be ordinary open. Fix analytic units $g_1, \dots, g_r$ on W and $\tau = (-\log|g_1|, \dots, -\log|g_r|)$. Suppose that $u = F \circ \tau$, where $F : \tau(W) \to \mathbf{R}$ is continuous and has ambient affine lower supports locally in the relative topology of the actual image. Then, for every $x \in W$, there is one ordinary neighbourhood $V \subset W$ carrying original smooth psh functions $b_j \downarrow u|_V$. Convergence is uniform on compact subsets of V.*

Open proof obligation (RC2). Establish the analytic chart replacement and positivity inputs for the regularization; the proof applies GJR and GRPL.

Corollary 11.22.9 (Ordered families in one actual chart)**.** *In Theorem 11.22.8, replace F by continuous relatively supported functions F_j on the same actual image, and assume $F_j \downarrow F$ pointwise. Then $F \circ \tau$ has original smooth psh approximation on one ordinary neighbourhood of each point. The limit may be $-\infty$; compact-uniform convergence is asserted only when the analytic limit is finite continuous. The same conclusion holds for locally uniform limits of such F_j, after restriction to a compact image.*

Proof. Use the same affinoid A and the same $S = \tau(A)$ for every term, apply Corollary 11.22.5, and repeat the local unit-logarithm maximum argument and the fixed-domain transfer steps in the preceding proof. □

There is also a consistent longer route: Proposition 11.11.5 gives Q-PL membership from finite selections, and Theorem 11.11.6 gives nef residues

from relative supports. The latter uses [GRPSH, Theorem 4.3], whose hypotheses are a good strictly analytic space over a nontrivially valued field and an already R-PL function. The direct maximum argument above is sufficient here because the new approximants have the stronger local maximum presentation. Neither route infers PL membership from current positivity alone.

For a finite continuous endpoint u, the conclusion also gives $d'd''[u] \geq 0$ on every original CLD positive test. Indeed, for such a compactly supported test η, compact-uniform convergence gives $[b_j](d'd''\eta) \to [u](d'd''\eta)$, by the finite signed measure defined by the top-degree form $d'd''\eta$. This is the passage in Lemma 11.9.1. The endpoint is not thereby asserted to be PL, nor is an arbitrary-background BT product being defined.

This proves a local forward implication for the stated continuous relative-support presentations. It does not identify every original positive current with such a presentation, treat arbitrary positive-current backgrounds, remove integral projectivity from the transfer input, or settle the discontinuous predecessor and first-stage closure issues in CLD25 Proposition 8.1.11. The complete Wu Theorem A.3 is not deduced. The ground field and valuation normalization are unchanged, and the conclusion concerns original CLD smooth functions and tests.

11.22.4 What the construction does not preserve

Example 11.22.10 (A balanced branching support without an ambient convex extension)**.** In $\mathbf{R}^2$, take the rays with primitive directions $e_1, e_2, e_1 + e_2, -e_1 - e_2$ and weights $1, 1, 1, 2$. They form a balanced one-dimensional fan. Define $F(s(e_1 + e_2)) = s$ for $s \geq 0$ and $F = 0$ on the other three rays. This continuous coefficient-compatible PL function has relative affine lower supports: zero supports it at the origin, and away from the origin it is affine on a single local ray. But it is not the restriction of an ambient convex function on any neighbourhood of the origin. Indeed, for small $s > 0$,

$$s(e_1 + e_2) = \tfrac{1}{2}(2se_1) + \tfrac{1}{2}(2se_2),$$
$$F(s(e_1 + e_2)) = s > 0 = \tfrac{1}{2}F(2se_1) + \tfrac{1}{2}F(2se_2).$$

On a compact compatible truncation, Theorem 11.22.3 nevertheless applies. Its local ambient-convex neighbourhoods must be allowed to shrink with the approximation. Taking a product with $\mathbf{R}^{d-1}$ gives the same example on a balanced support in every positive dimension d.

Example 11.22.11 (Relative supports need not survive a uniform limit at a boundary)**.** On $[0,1]$, set $f_\epsilon(t) = \sqrt{\epsilon} - \sqrt{t+\epsilon}$ for $\epsilon > 0$. Each function is smooth on a neighbourhood of the interval and convex there, hence has affine lower supports at every point of the interval. As $\epsilon \downarrow 0$, the functions decrease uniformly to $f(t) = -\sqrt{t}$, with error between zero and $\sqrt{\epsilon}$. Yet f has no affine lower support at zero: such a support would be at, and $at \leq -\sqrt{t}$ for all sufficiently small positive t is impossible. Products give the same boundary phenomenon in every dimension.

This is a statement about relative supports on a compact polyhedral boundary, not a counterexample to an analytic regularization theorem. It explains why Corollary 11.22.5 treats limits directly instead of silently assuming that the limit still satisfies the input support definition.

The local bump proof controls values, not Lipschitz differences. Proposition 11.21.10 remains valid, including its irrational-intercept variant. The construction also uses $\Gamma \neq 0$ essentially for coefficient approximation: on $S = \{0\}$ with $\Gamma = 0$, every allowed affine function has value zero, so even the constant function one cannot be approximated in this coefficient class. This does not assert failure of original smooth regularization over a trivially valued field.

For the local analytic purpose, Theorem 11.22.8 supersedes the rational-direction and one-scale restrictions in Section 11.21, once the continuous relative-support input is verified. The earlier proofs remain useful for their explicit geometry and, in Section 11.20, their stronger error estimates. The present proof does not repair the global twisted, simplicial or sedentary formulations of the source by redefining their terminology. It supplies a coefficient-controlled local replacement and leaves those comparisons separate.

For comparison of conventions, [BBS22, Definition 2.1] explicitly requires a locally finite closed polyhedral cover; its real Euclidean framework should not be read as imposing value-group constants. The finite-selection characterization in [FL00, p. 74, equation (1.1)] likewise concerns real affine data. Our rational conclusion comes from choosing the branches before gluing, not from attributing a rationality assertion to either source.

11.22.5 Continuous supports at vanishing coordinates

The Euclidean quadratic in the first proof cannot simply be used at an infinite tropical coordinate. There is, however, a bounded strictifying function on

each compact extended image. We now give the argument separately, with the precise boundary support convention. This treats continuous inputs by constructing new locally finite-max approximants; it does not identify every pre-existing relative PL presentation at the boundary.

Put $\mathbb{T} = \mathbf{R} \cup \{+\infty\}$ with the topology for which $t \mapsto e^{-t}$, with $e^{-\infty} = 0$, is a homeomorphism onto $[0, \infty)$. At $x \in \mathbb{T}^r$, an admissible affine germ is a function $c + \sum_{i \in I_x} q_i t_i$ on a neighbourhood of x, where $I_x = \{i : x_i < \infty\}$. For a real affine germ the coefficients are real; for an allowed germ $q_i \in \mathbf{Q}$ and $c \in \Gamma_{\mathbf{Q}}$. Thus an affine germ used at a boundary point is independent of every coordinate that is infinite at that point. Relative lower supports below must be admissible real affine germs, with equality at the point.

Theorem 11.22.12 (Rational bumps on compact extended images)**.** *Let $\Gamma \neq 0$, let $S \subset \mathbb{T}^r$ be nonempty compact, and let $F : S \to \mathbf{R}$ be continuous with relative admissible affine lower supports. For every $\varepsilon > 0$, there is continuous $P : S \to \mathbf{R}$ with $F \leq P \leq F + \varepsilon$, such that S has a finite relative open cover on each member of which P is a finite maximum of allowed admissible affine functions. The decreasing, decreasing-family and uniformly-convergent-family conclusions of Corollaries 11.22.4 and 11.22.5 hold on this same S, with this local presentation.*

Proof. Write $z(t) = (e^{-t_1}, \dots, e^{-t_r})$ and $Q(t) = \sum_i e^{-t_i}$. The function Q is continuous and bounded on S. At $x \in S$ put

$$L_x(t) = \sum_{i \in I_x} e^{-x_i}\big(1 - (t_i - x_i)\big).$$

On a neighbourhood where all coordinates in I_x stay finite, this is an admissible affine function, $L_x(x) = Q(x)$, and

$$Q(t) - L_x(t) = \sum_{i \in I_x} e^{-x_i}\big(e^{-(t_i - x_i)} - 1 + (t_i - x_i)\big) + \sum_{i \notin I_x} e^{-t_i} \geq 0.$$

Equality holds exactly at $t = x$: the first summands vanish exactly when $t_i = x_i$, and the last ones exactly when $t_i = +\infty$. Choose $a > 0$ with $a \max_S Q \leq \varepsilon/4$ and set $g = F + aQ$. If ℓ_x^F supports F relatively near x, then $\ell_x = \ell_x^F + aL_x$ supports g, with strictly positive gap off x in that neighbourhood.

Use the metric $d(s,t) = \|z(s) - z(t)\|$. Choose $r_x > 0$ so that $S \cap \overline{B}_d(x, 2r_x)$ lies in the support neighbourhood and all its coordinates in I_x stay in bounded real intervals. On the compact annulus

$$A_x = \{t \in S : r_x/2 \le d(x,t) \le 2r_x\}$$

the continuous gap $g - \ell_x$ has a positive minimum m_x, if the annulus is nonempty. If it is empty, choose any $m_x > 0$. Take $0 < \delta_x \le \min\{\varepsilon/4, m_x/2\}$. Approximate $\ell_x + \delta_x$ within $\delta_x/4$ on the closed ball by an allowed affine a_x using only coordinates in I_x. Their boundedness makes coefficient approximation uniform; no infinite-coordinate term is introduced.

Define $b_x = \max\{g, a_x\}$ on $B_d(x, r_x) \cap S$ and $b_x = g$ outside. On A_x, $a_x - g \le 5\delta_x/4 - m_x < 0$. Thus the patching is continuous, equals g outside $B_d(x, r_x/2)$, raises the value at x by at least $3\delta_x/4$, and changes g by at most $5\varepsilon/16$. As before, a finite positive cover yields $P = \max b_x$ with $F \le P \le F + 9\varepsilon/16$.

At a point y, every active modification is strictly above g, so its affine branch is defined on a neighbourhood of y. Each coordinate on which that branch depends is finite there. The active-index argument of Lemma 11.22.2 therefore gives a local finite maximum of admissible affine functions. Compactness gives a finite open cover by such presentations. The affine branches have specified local domains; no evaluation of an inactive branch at a point where it is undefined is needed. Finally the geometric shifts and subsequence arguments of Corollaries 11.22.4 and 11.22.5 apply without change. □

Corollary 11.22.13 (The analytic transfer through zeros)**.** *In Theorem 11.22.8, allow $g_1, \dots, g_r$ to be analytic functions, possibly vanishing, set $-\log 0 = +\infty$, and impose the admissible relative-support hypothesis of Theorem 11.22.12 on the actual image. The same original smooth decreasing approximation exists on one ordinary neighbourhood of every point. The corresponding decreasing and locally uniformly convergent continuous families on the same extended chart also satisfy Corollary 11.22.9.*

Proof. Take one compact strict affinoid neighbourhood $A \subset W$, put $S = \tau(A) \subset \mathbb{T}^r$, and apply Theorem 11.22.12. This image is compact by continuity; polyhedrality is not needed. For each local maximum presentation of an approximant near $\tau(y)$, all coordinates used in its active branches are finite. The corresponding g_i are nonvanishing near y, and hence analytic

units after restriction to an ordinary neighbourhood. The denominator and unit-logarithm calculation in Theorem 11.22.8 applies there. Thus each approximant is actual Q-PL with nef residues on the same $\mathrm{Int}(A)$. Apply the fixed-domain transfer, and use the same compact image for families. The neighbourhoods used to verify individual PL germs are not intersected over the sequence. □

The support condition at the boundary is essential to this statement. It is a condition on a real-valued function on the actual extended image, expressed by affine germs independent of the infinite coordinates. It is not obtained merely by checking separate finite strata, taking their closures, or allowing cancellation of infinite affine terms. The construction does not alter the original field or its absolute value. General source-class identification, the first-stage closure problem and the full comparison theorems remain separate.

11.22.6 Single smooth inputs and sequences

Proposition 11.22.14 (Local rational approximation of one original smooth psh function)**.** *In the integral-projective, nontrivially valued setting of Theorem 11.22.8, let h be an original CLD smooth function on W with $d'd''[h] \geq 0$. For each $x \in W$ there is one ordinary neighbourhood U and a sequence of actual Q-PL functions p_j with nef residues on U, decreasing to $h|_U$ uniformly. Each p_j is locally a finite maximum of rational unit logarithms. The neighbourhood and the tropical presentation in this assertion may depend on h.*

Open proof obligation (RC2). Supply the local boundary-separation and approximation steps used to pass from one original smooth input; GRPL Theorem 7.7 argument and section 7.2.

For a sequence of different smooth inputs h_i, this proposition supplies neighbourhoods U_i and presentations that may depend on i. Their intersection need not be a neighbourhood. Corollaries 11.22.9 and 11.22.13 apply when the continuous supported inputs are already presented on one common actual chart; they do not manufacture such a chart for an arbitrary smooth sequence. Thus the single-input comparison above does not close the full family comparison in Wu Theorem A.3 or the first-stage closure issue in CLD25 Proposition 8.1.11.

For finitely many $h_1, \dots, h_m$, intersect their presentation neighbourhoods, take the product unit chart and add boundary-separating coordinates once. Each ambient H_i remains smooth; the same integration argument gives relative supports on the common image away from the boundary. One compact affinoid A' therefore works for all inputs. Corollary 11.22.7 also preserves any prescribed finite order in the rational approximants. This uses finite intersections and products; it supplies no countable common chart.

The common-domain replacement for arbitrary original smooth families in this projective setting is completed in Theorem 11.24.3. It uses finite extended presentations on each prescribed affinoid, rather than a countable product of unit charts. The remaining sheaf-level decreasing closure is distinguished in Section 11.24.4.

11.23 Varying unit charts on one affinoid neighbourhood

A fixed finite chart is stronger than the approximation argument requires. It is enough that the charts of the individual terms be defined on one affinoid neighbourhood: boundary-separating coordinates can then be chosen once, while the other coordinates vary. We prove this criterion first. We then give a decreasing smooth psh sequence with a finite continuous uniform limit for which the criterion's presentation hypothesis fails on every neighbourhood of a rational point. Thus the criterion advances the common-domain argument but does not remove its general gluing problem.

11.23.1 Separating the boundary before choosing the terms

Throughout this section, K is complete and nontrivially valued, X is an integral projective K-variety of positive dimension, and $W \subset X^{\mathrm{an}}$ is ordinary open. Interiors are taken in X^{an}; ∂B denotes the analytic boundary of an affinoid domain B over K. A global unit presentation on A means an equality $h|_A = H \circ \tau$, where $\tau = (-\log|g_1|, \dots, -\log|g_r|)$ for finitely many $g_i \in \mathcal{O}(A)^\times$, and H is C^∞ on an ambient open neighbourhood of $\tau(A)$. This is a hypothesis on the whole of A, stronger than original smoothness at each point.

Lemma 11.23.1 (A boundary separator independent of the input)**.** *Let $A \subset W$ be a compact strictly affinoid neighbourhood of x. There are compact strictly affinoid neighbourhoods $B \subset A$ and $A' \subset \mathrm{Int}(B)$ of x, and a unit tropicalization $\beta : B \to \mathbf{R}^s$, such that, for every finite unit tropicalization τ on A, the product $\gamma = (\tau|_B, \beta)$ satisfies*

$$\gamma(A') \subset \gamma(B) \setminus \gamma(\partial B). \tag{11.23.1}$$

The choices of B, A' and β depend only on (A, x), not on τ or on the number of charts subsequently considered.

Open proof obligation (RC2). Supply boundary separation by analytic functions in the given setup; the proof applies GRPL's Theorem 7.7 construction.

The lemma fixes the analytic domain, not the tropical image. With infinitely many input charts the sets $\gamma_j(A')$ may have different dimensions and subdivisions. They need not embed into one finite-dimensional common chart. The estimates below are imposed after pullback to the same A', where they can be compared.

Theorem 11.23.2 (Simultaneous rational replacement on a common affinoid)**.** *Let h_j be original CLD smooth psh functions on W, and suppose that every h_j has a global unit presentation on the same compact strictly affinoid neighbourhood A of x. The finite tuples of units and the ambient smooth functions may depend on j, with no uniform bound on their number or derivatives. There is one compact strictly affinoid neighbourhood A' of x such that, for every sequence $\varepsilon_j > 0$, there are continuous functions q_j on A' satisfying*

$$h_j \le q_j \le h_j + \varepsilon_j \quad \text{on } A', \tag{11.23.2}$$

and each $q_j|_{\mathrm{Int}(A')}$ is actual Q-PL with nef residue classes, locally a finite maximum of rational unit logarithms. The same A' works before the errors ε_j are prescribed.

Open proof obligation (RC2). Supply the uniform chart replacement with the asserted error and positivity in the stated scope; GRPL (7.7.1).

11.23.2 Decreasing families and continuous uniform limits

Corollary 11.23.3 (A family transfer without a common finite chart)**.** *Under the hypotheses of Theorem 11.23.2, assume either that $h_j \downarrow h$ pointwise on W, with values of h in $\mathbf{R} \cup \{-\infty\}$, or that $h_j \to h$ locally uniformly on W with h finite and continuous. Then one ordinary neighbourhood U of x carries decreasing actual Q-PL functions with nef residues and pointwise limit $h|_U$. On one further neighbourhood $V \subset U$, there are original smooth psh functions $b_j \downarrow h|_V$. In the second case, and whenever the endpoint in the first case is finite and continuous, convergence is uniform on compact subsets of V.*

Proof. Fix $0 < \rho \in \Gamma$ and $\eta_j = \rho 8^{-j} \in \Gamma_{\mathbf{Q}}$. In the decreasing case apply Theorem 11.23.2 with error η_j and put $p_j = q_j + \eta_j$. On A' one has

$$h_j + \eta_j \le p_j \le h_j + 2\eta_j, \qquad p_{j+1} \le h_j + 2\eta_{j+1} \le p_j.$$

Thus $p_j \downarrow h$ on $U = \mathrm{Int}(A')$. Adding η_j preserves Q-PL membership and nef residues because $\eta_j \in \Gamma_{\mathbf{Q}}$.

In the locally uniform case, choose increasing indices n_j with $\sup_{A'} |h_{n_j} - h| \le \eta_j/4$. Replace h_{n_j} with error $\eta_j/4$ and again add η_j. The resulting functions satisfy

$$h + \tfrac{3}{4}\eta_j \le p_j \le h + \tfrac{3}{2}\eta_j, \qquad \tfrac{3}{2}\eta_{j+1} < \tfrac{3}{4}\eta_j,$$

so they decrease to h on the same U. In both cases Theorem 11.10.11 supplies the required original smooth sequence on one final $V \subset U$. For a finite continuous endpoint, Dini's theorem on each compact subset gives the stated convergence. No change of ground field, normalization or original test class occurs. □

For an already decreasing original smooth sequence, the last original-smooth conclusion by itself is tautological. The substantive assertion is its replacement by decreasing actual Q-PL functions with nef residues on one fixed domain. For a locally uniform, nonmonotone sequence, the argument additionally produces a decreasing sequence. These are consequences of the stated presentation hypothesis, not an identification of all sheaf-generated classes.

11.23.3 Why a common affinoid presentation is a genuine condition

Lemma 11.23.4 (Unit logarithms on a closed polydisc)**.** *Let $D_s^n = \{|T_i| \le s\ (1 \le i \le n)\} \subset \mathbf{A}_K^{n,\mathrm{an}}$, with $s \in |K^\times|$. Every $g \in \mathcal{O}(D_s^n)^\times$ has constant absolute value on D_s^n. Consequently, if an affinoid neighbourhood A of 0 contains D_s^n, every function given by any finite unit presentation on A is constant on this same D_s^n. The statement holds for any number of such functions, even when their tuples of units differ.*

Open proof obligation (RC2). Prove the analytic Tate-algebra unit criterion used in the argument; Bosch14 Section 2.1, Corollary 4.

Example 11.23.5 (Uniform decreasing approximation without common unit presentations)**.** For every $n \ge 1$, on $W = \{|T_i| < 1\ (1 \le i \le n)\} \subset \mathbf{P}_K^{n,\mathrm{an}}$ there is a decreasing sequence of original smooth psh functions converging uniformly to the finite continuous function $u = |T_1|^2$, but no affinoid neighbourhood of 0 carries global unit presentations for every term of the sequence.

Proof. Fix $0 < \delta < 1$, and let κ be a nonnegative even C^∞ function supported in $(-\delta, \delta)$ with integral one. Define, for $z \ge 0$,

$$\psi(z) = \int_{-\delta}^{\delta} \max\{z, 1+a\}\kappa(a)\,da.$$

This is smooth, convex and nondecreasing, equals 1 for $z \le 1-\delta$, and equals z for $z \ge 1+\delta$. Moreover

$$0 \le \psi(z) - z \le 1 + \delta,$$
$$\psi(z) - z\psi'(z) = \int_{a > z-1} (1+a)\kappa(a)\,da \ge 0.$$

Choose any $r_j \downarrow 0$ and put

$$h_j(T) = r_j \psi\big(|T_1|^2 / r_j\big).$$

Each h_j equals r_j on a neighbourhood of 0. On $\{T_1 \ne 0\}$, it is an ambient smooth function of the unit logarithm $t = \log|T_1|$. With $z = e^{2t}/r_j$, its second derivative is

$$\frac{d^2}{dt^2}\big(r_j\psi(e^{2t}/r_j)\big) = 4r_j\big(z\psi'(z) + z^2\psi''(z)\big) \ge 0.$$

Thus h_j is original smooth and psh on W, using a constant presentation near $\{T_1 = 0\}$ and the unit chart elsewhere; the displayed nonnegative Hessian

pulls back to a positive $(1,1)$-form. For fixed $v \geq 0$, differentiation in $r > 0$ gives

$$\frac{d}{dr}\big(r\psi(v/r)\big) = \psi(v/r) - (v/r)\psi'(v/r) \geq 0.$$

Consequently h_j decreases, and $0 \leq h_j - u \leq (1+\delta)r_j$ on all of W. This proves uniform convergence, including at 0.

Suppose a common affinoid neighbourhood A supplied the claimed unit presentations. It contains a polydisc D_s^n with $s \in |K^\times|$ and $s > 0$. Lemma 11.23.4 would make every h_j constant on this same disc. For j large enough that $(1+\delta)r_j < s^2$, however, $h_j(0) = r_j$ whereas at the Gauss point ζ_s with all radii equal to s one has $h_j(\zeta_s) = s^2$. This is a contradiction. □

This is a counterexample only to automatic simultaneous global unit presentations. It is not a counterexample to regularization: the functions h_j themselves are the required regularization. They share the extended coordinate $-\log|T_1|$, with an admissible constant germ at $T_1 = 0$, as permitted in Corollary 11.22.13. It also shows that local uniform convergence does not, by itself, give a uniform radius for the original smooth presentations. The same obstruction occurs in every positive dimension, although it is already detected by the first coordinate.

A common-domain argument must therefore do more than ask for global units on a smaller affinoid. The next section allows global analytic functions with zeros outside their local patches. It proves that these extended presentations suffice to handle arbitrary original smooth psh families on a fixed affinoid in the stated setting. The counterexample above remains valid for global unit presentations.

11.24 Gluing presentations on a fixed affinoid

The obstruction in Example 11.23.5 concerns global units. It disappears if a global analytic function is allowed to vanish outside the patch on which its logarithm is used. The following argument exploits this distinction. On a Laurent domain, a sufficiently accurate rational approximation to a unit has exactly the same absolute value. Finitely many such replacements, together with the functions defining the domains, place all local presentations in one extended tropical image. Relative affine supports then pass to that image. This gives rational approximation on a prescribed compact affinoid, before a sequence of inputs is chosen.

11.24.1 Exact absolute values from rational approximation

Lemma 11.24.1 (Replacing local units by global fractions)**.** *Let $A = \mathcal{M}(\mathscr{A})$ be strictly affinoid, and let*

$$C = \{y \in A : |a_i(y)| \le 1, |b_k(y)| \ge 1\}$$

be a Laurent domain, where $a_i, b_k \in \mathscr{A}$. For every $g \in \mathcal{O}(C)^\times$ there are $P, Q \in \mathscr{A}$, both nonvanishing on C, such that

$$|g(y)| = |P(y)/Q(y)| \qquad (y \in C). \tag{11.24.1}$$

One can take Q to be a product of nonnegative integral powers of the b_k. No equality of analytic functions with g is asserted.

Proof. If C is empty, take $P = Q = 1$. Otherwise the Laurent-domain algebra is

$$\mathcal{O}(C) = \mathscr{A}\langle U_i, V_k\rangle/(U_i - a_i, b_k V_k - 1).$$

This is the affinoid localization of Section 2.1; see also [Bosch14, Section 3.3, Proposition 11]. Truncation in the Tate algebra shows that the image of $\mathscr{A}[b_1^{-1}, \dots, b_s^{-1}]$ is dense in $\mathcal{O}(C)$. In particular its elements approximate g in the supremum seminorm on C. Since g is a unit, $m = \min_C |g| > 0$. Choose a fraction P/Q in this dense subalgebra with $\sup_C |g - P/Q| < m$. The ultrametric equality proves (11.24.1) at every Berkovich point. The denominator is a product of the b_k, hence is nonvanishing on C; the equality makes P nonvanishing there as well. □

We also need the ordinary topology, rather than just an affinoid-domain cover. For any point of A and any relative ordinary neighbourhood, choose finitely many strict inequalities $|f| < c$ and $|g| > d$ defining a smaller neighbourhood. Nontriviality makes $|K^\times|^{\mathbf{Q}}$ dense in $\mathbf{R}_{>0}$. The thresholds can therefore be chosen in this group, with strict inequalities at the point and with their closed versions still inside the prescribed neighbourhood. Raising to positive integral powers and dividing by constants in $K^\times$ writes the resulting compact domain in the form C above. Its strict locus

$$V = \{y \in A : |a_i(y)| < 1, |b_k(y)| > 1\}$$

is a relative ordinary neighbourhood of the point. Both C and V are determined by absolute values of global analytic functions on A. This elementary construction does not say that every member of an arbitrary affinoid-domain cover contains an ordinary neighbourhood.

11.24.2 A finite extended presentation with relative supports

Call a finite continuous function h locally unit-supported if, near each point in the ordinary topology, it has a unit tropical presentation $h = H \circ \sigma$, where H is continuous on the actual image and has relative affine lower supports. The ambient affine slopes in these supports may be real. This definition includes local finite maxima of rational unit logarithms. In our integral-projective, nontrivially valued setting, it also includes every original smooth psh function: the boundary-adapted positivity argument in the proof of Proposition 11.22.14 supplies precisely these local supports.

Proposition 11.24.2 (Globalizing a finite local presentation)**.** *Let K be complete and nontrivially valued, let A be compact strictly affinoid, and let $h : A \to \mathbf{R}$ be continuous and locally unit-supported in its relative ordinary topology. Then finitely many global analytic functions $f_1, \dots, f_N \in \mathcal{O}(A)$ give an extended tropicalization*

$$\tau : A \longrightarrow \mathbb{T}^N, \qquad \tau = (-\log|f_1|, \dots, -\log|f_N|), \quad S = \tau(A),$$

such that $h = F \circ \tau$ for a continuous $F : S \to \mathbf{R}$ having relative admissible affine lower supports in the sense of Theorem 11.22.12. In particular, at a point where a coordinate is infinite, its supporting affine germ does not use that coordinate. No global-unit assertion is made for the f_i.

Proof. At each point choose a local supported presentation, then a Laurent domain C_i inside its ordinary presentation domain whose strict locus V_i contains the point, as constructed above. Compactness yields finitely many V_i covering A. Write the presentation on C_i as

$$h = H_i \circ \sigma_i, \qquad \sigma_i = (-\log|g_{i1}|, \dots, -\log|g_{im_i}|).$$

Apply Lemma 11.24.1 to each unit g_{ik} on C_i, obtaining $P_{ik}, Q_{ik} \in \mathcal{O}(A)$ with the same absolute-value ratio. Include all these numerators and denominators, and every global function defining the inequalities of the C_i, in the finite list defining τ. Identically zero constraint functions are harmless; unused coordinates can be omitted.

Because the strict inequalities defining V_i are recorded among the coordinates, there is an open $O_i \subset \mathbb{T}^N$ such that $V_i = \tau^{-1}(O_i)$. These O_i cover S. On C_i, the coordinates of σ_i are differences of the finite coordinates corresponding to P_{ik} and Q_{ik}. Denote this linear map on that finite-coordinate

locus by L_i. If two points of A have the same τ-image, choose V_i containing one; saturation puts both in V_i, and $h = H_i \circ L_i \circ \tau$ gives equal values. Thus h defines a function F on S. The map $\tau : A \to S$ is a continuous surjection from a compact space to a Hausdorff space, hence a quotient map; consequently F is continuous.

Finally fix $w \in S \cap O_i$. Every P_{ik} and Q_{ik} is nonvanishing on C_i, so all coordinates used by L_i are finite near w. A relative affine lower support ℓ of H_i at $L_i(w)$, restricted to $\sigma_i(C_i)$, pulls back to $\ell \circ L_i$. On a sufficiently small relative neighbourhood of w in $S \cap O_i$, this affine function is at most F and equals it at w. It only uses coordinates finite at w, so is admissible. This proves the asserted support property at every point, including the extended boundary. □

Only the presentations are glued. The fractions need not agree as analytic functions on overlaps, because equality of their absolute values with the prescribed local units is enough. The functions $H_i \circ L_i$ agree on the actual image by their common pullback h; no ambient extension across all patches is asserted. Polyhedrality of the global extended image is also unnecessary for Theorem 11.22.12.

11.24.3 Fixed-domain replacement and first decreasing stages

Theorem 11.24.3 (Rational approximation on a prescribed affinoid)**.** *Let K, X, W have the hypotheses of Section 11.23, and fix a compact strictly affinoid domain $A \subset W$ with nonempty ordinary interior U. If h is finite continuous and locally unit-supported on W, then for every $\varepsilon > 0$ there is a continuous $q : A \to \mathbf{R}$ with*

$$h \le q \le h + \varepsilon \quad \text{on } A,$$

and $q|_U$ is locally a finite maximum of rational unit logarithms, hence actual Q-PL with nef residues. This applies in particular to every original smooth psh h on W. The affinoid A is fixed independently of h and ε.

Proof. Restrict the local supported presentations of h to A and apply Proposition 11.24.2. Apply Theorem 11.22.12 to the resulting compact image S, with $\Gamma = -\log|K^\times|$. Pull back its approximant to A. At every point of U, each active affine branch uses only coordinates finite there. Their global analytic functions are therefore units on an ordinary neighbourhood of

that point. The denominator calculation and finite-maximum semipositivity argument of Theorem 11.22.8 give the asserted rational PL and nef properties. The domain was never reduced in this construction. For original smooth psh inputs, local supported presentations come from the already verified boundary-adapted argument, as stated above. □

Corollary 11.24.4 (First-stage comparison in the stated projective setting)**.** *For an ordinary open $O \subset X^{\mathrm{an}}$, let $\mathcal{H}(O)$ be its finite original smooth psh functions, let $\mathcal{C}(O)$ be its finite continuous locally unit-supported functions, let $\mathcal{G}(O)$ be its functions locally expressible as finite maxima of rational unit logarithms with constants in $\Gamma_{\mathbf{Q}}$, and let $\mathcal{S}_{\mathbf{Q}}(O)$ have the meaning of Section 11.10.6. For one of these classes $\mathcal{E}$, write $D_x(\mathcal{E})$ for germs at x representable as $e_j \downarrow u$ on one ordinary neighbourhood of x, with all e_j in that class on that neighbourhood. Allow endpoints in $\mathbf{R} \cup \{-\infty\}$. Then*

$$D_x(\mathcal{H}) = D_x(\mathcal{C}) = D_x(\mathcal{G}) = D_x(\mathcal{S}_{\mathbf{Q}}). \tag{11.24.2}$$

If a sequence in $\mathcal{C}(W)$ converges locally uniformly to a finite continuous u, then its germ also belongs to these equal classes. The resulting decreasing original smooth approximation converges uniformly on compact subsets of one neighbourhood.

Proof. The local supported-presentation argument gives $\mathcal{H} \subset \mathcal{C}$. Let $h_j \in \mathcal{C}(W)$ decrease to u, and fix a compact strictly affinoid neighbourhood $A \subset W$ of x once. Apply Theorem 11.24.3 to every h_j, with error $\eta_j = \rho 8^{-j} \in \Gamma_{\mathbf{Q}}$, and add η_j. The inequalities in the proof of Corollary 11.23.3 give a decreasing sequence $p_j \in \mathcal{G}(\mathrm{Int}(A))$ with limit u. Thus $D_x(\mathcal{H}) \subset D_x(\mathcal{C}) \subset D_x(\mathcal{G})$. The local unit-log residue and maximum statements give $\mathcal{G} \subset \mathcal{S}_{\mathbf{Q}}$. Finally Theorem 11.10.11 gives $D_x(\mathcal{S}_{\mathbf{Q}}) \subset D_x(\mathcal{H})$, closing the chain. For a locally uniform sequence use the subsequence and separated errors from Corollary 11.23.3, now with Theorem 11.24.3 in place of the common-unit-presentation hypothesis. Dini's theorem gives compact-uniform convergence at a finite continuous endpoint. □

Equation (11.24.2) is an equality of explicitly defined first-stage germ classes over the fixed nontrivially valued field and integral projective variety. It does not assert that this class is already closed under every further locally defined decreasing operation, or under the full transfinite procedure in CLD25. Identifying Wu's precise analytic/algebraic generator conventions

and all of its field hypotheses remains separate. No arbitrary-positive-current Bedford–Taylor product, new field descent, or verification of the unavailable mixed-calculus Theorem 6.13 is used or obtained. The proof is a synthesis of affinoid localization, the local positivity input, compact extended-image density, and the existing projective transfer; no independent priority claim is made.

11.24.4 A second diagonal when all rows have one domain

The first-stage equality leaves a separate question: can a decreasing limit of first-stage germs again be represented on one neighbourhood? The following elementary diagonal argument settles the case in which all rows already have a common domain. It does not manufacture that domain. Unlike the uniform-error diagonal, it permits discontinuous and $-\infty$ row limits.

Lemma 11.24.5 (Compact diagonal for ordered row limits)**.** *Let Q be compact, and let $f_{j,k} : Q \to \mathbf{R}$ be continuous. Suppose $f_{j,k} \downarrow u_j$ as $k \to \infty$, and $u_j \downarrow u$ as $j \to \infty$, allowing limits in $\mathbf{R} \cup \{-\infty\}$. Fix any positive strictly decreasing $\eta_j \to 0$. There are integers $m_j \geq j$ such that*

$$a_j = f_{j,m_j} + \eta_j \downarrow u \quad \text{on } Q.$$

No metrizability, countable dense subset, continuity of u_j, or uniform convergence of the rows is assumed.

Proof. Choose m_j inductively so that, in addition to $m_j \geq j$,

$$f_{j,m_j} + \eta_j \leq a_{j-1} \qquad (j > 1), \tag{11.24.3}$$

$$f_{j,m_j} \leq f_{k,\ell} + \eta_j \qquad (1 \leq k, \ell \leq j). \tag{11.24.4}$$

For every pair in the second line, $u_j \leq u_k \leq f_{k,\ell} < f_{k,\ell} + \eta_j$. For the first line the inductive lower bound $a_{j-1} \geq u_{j-1} + \eta_{j-1}$ gives $u_j < a_{j-1} - \eta_j$ wherever u_{j-1} is finite. Where it equals $-\infty$, also $u_j = -\infty$, so the same strict inequality holds. For any one of these finitely many continuous upper bounds b, the open sets $\{f_{j,m} < b\}$ increase with m and cover Q. Compactness makes one of them equal to Q. Taking the largest of finitely many resulting indices imposes all the inequalities simultaneously. This constructs m_j and proves decrease of a_j.

Since $a_j \geq u_j \geq u$, its limit a satisfies $a \geq u$. For each fixed (k, ℓ), inequality (11.24.4) holds for all sufficiently large j, so $a \leq f_{k,\ell}$. Taking the

infimum first in ℓ, then in k, gives $a \le u$. Thus $a = u$. The finite upper bounds were used only as constraints in the selection; their minimum is not used as an approximating function. □

For original smooth psh rows on one open W, restrict to a compact affinoid neighbourhood $Q \subset W$ and then to its ordinary interior. Each selected a_j remains original smooth psh. For rows in $\mathcal{G}$ or $\mathcal{S}_{\mathbf{Q}}$, choose the shifts in $\Gamma_{\mathbf{Q}}$ and obtain the same conclusion in that generator class. This is a common-domain second-stage closure statement. Merely knowing, for each j, that the germ of u_j belongs to $D_x(\mathcal{H})$ provides possibly different row domains; it does not satisfy this lemma's hypothesis. That ordinary-neighbourhood/sheafification issue, together with the precise transfinite predecessor requirement, is the next comparison task.

Corollary 11.24.6 (Full collapse of the raw compact hierarchy)**.** *Let Q be compact Hausdorff and let $\mathscr{S} \subset C(Q, \mathbf{R})$ be nonempty and stable under addition of real constants. For the raw hierarchy of Definition 11.6.2,*

$$D_\alpha(\mathscr{S}) = D_1(\mathscr{S}) \qquad (\alpha \ge 1).$$

This equality includes discontinuous and $-\infty$-valued endpoints. It concerns actual functions on the same compact domain, without sheafification.

Proof. If $u_j \in D_1(\mathscr{S})$ decreases to u, choose a row $f_{j,k} \in \mathscr{S}$ decreasing to each u_j on Q. Lemma 11.24.5 gives $f_{j,m_j} + \eta_j \downarrow u$. Stability under constants places every selected term in $\mathscr{S}$, so $D_1(\mathscr{S})$ is closed under decreasing sequences. Since constant sequences give $\mathscr{S} \subset D_1(\mathscr{S})$, transfinite induction in the stated recursion proves the equality: successor steps use this closure, and limit steps take unions. □

Theorem 11.6.4 remains useful for its uniform-closure characterization at continuous endpoints. The present corollary strengthens only its raw, fixed-domain conclusion. A local sheaf section may be produced on changing neighbourhoods before any compact representation is available; that operation is absent from the recursion used here. Thus this corollary does not supply the missing representation property in Corollary 11.6.5.

Chapter 12

Regularized maxima, approximation and barriers

12.1 The normalized regularized maximum

A regularized maximum must do more than approximate a nonsmooth function. In a gluing argument it must agree exactly with a branch which dominates the others. For logarithmic branches it must also ignore a branch near its zero set. We prove these properties with one normalization.

Definition 12.1.1. Fix an even nonnegative function $\theta \in C_c^\infty((-1,1))$ with integral one. For $m \geq 1$ and $\varepsilon > 0$ set

$$M_{\varepsilon,m}(s) = \int_{\mathbb{R}^m} \max_{1\leq i\leq m} (s_i + \varepsilon t_i) \prod_{i=1}^m \theta(t_i)\, dt_1 \cdots dt_m.$$

The subscript m is retained when branches are removed. For $m = 1$, the zero mean gives $M_{\varepsilon,1}(s) = s$.

Theorem 12.1.2. *The function $M = M_{\varepsilon,m}$ is smooth, convex, symmetric in its coordinates, and nondecreasing in each coordinate. It satisfies*

$$M(s + a\mathbf{1}) = M(s) + a, \tag{12.1.1}$$

$$\max_i s_i \leq M(s) \leq \max_i s_i + \varepsilon, \tag{12.1.2}$$

$$|M(s) - M(r)| \leq \max_i |s_i - r_i|. \tag{12.1.3}$$

If $s_i < \max_{j\neq i} s_j - 2\varepsilon$, then on a neighbourhood of s the function is independent of s_i and equals the regularized maximum of the remaining coordinates. Furthermore,

$$\partial_i M \geq 0, \qquad \sum_i \partial_i M = 1, \qquad (\partial_i \partial_j M)_{ij} \geq 0, \qquad D^2 M\, \mathbf{1} = 0.$$

Proof. Put $F(s) = \max_i s_i$. After changing variables, M is the convolution of the locally integrable function F with the smooth compactly supported probability kernel $\varepsilon^{-m} \prod_i \theta(t_i/\varepsilon)$. Differentiating that kernel proves smoothness. For $0 \leq \lambda \leq 1$, apply the convexity inequality for F to $\lambda(s+\varepsilon t)+(1-\lambda)(r+\varepsilon t)$ and integrate. This proves convexity. Monotonicity and permutation symmetry follow directly from the integral.

Translation by $a\mathbf{1}$ adds a inside the maximum, and the kernel has mass one. Jensen's inequality gives the lower bound in (12.1.2), since $\int t_i \theta(t_i) dt_i = 0$. The upper bound follows from $|t_i| < 1$. The pointwise estimate $|F(s+\varepsilon t) - F(r+\varepsilon t)| \leq \|s-r\|_\infty$ proves (12.1.3).

For the deletion assertion choose $j \neq i$ realizing the other maximum. Then $s_i + \varepsilon t_i < s_j + \varepsilon t_j$ throughout the kernel support. The maximum does not use the ith coordinate; integrating out t_i contributes the factor one. The strict gap persists near s. Finally, monotonicity and convexity give the derivative inequalities. Differentiate (12.1.1) once in a, then once in s, to obtain the two remaining identities. □

The factor ε^{-m} is essential if the kernel is written as $\prod_i \theta(t_i/\varepsilon)$. Without it the mass is ε^m, and translation adds $a\varepsilon^m$. This is the normalization error in the displayed regularization in CLD25, Proposition 16.9.1, p. 466. Formula (12.1.1) supplies a direct check independent of any positivity argument.

12.2 Composition and gluing

The smoothness just proved is an ordinary real statement. To use it in CLD geometry, all functions involved must first be represented on a common refinement of their charts. The following chain rule then descends to actual forms.

Proposition 12.2.1. *Let $u_1, \dots, u_m$ be original smooth functions on an analytic open set, and let F be smooth near their joint image. Then*

$$\mathrm{d}'\mathrm{d}''F(u) = \sum_i F_i(u)\mathrm{d}'\mathrm{d}''u_i + \sum_{i,j} F_{ij}(u)d'u_i \wedge d''u_j.$$

If every $\mathrm{d}'\mathrm{d}''u_i$ is positive, F is convex, and $F_i \geq 0$, then $\mathrm{d}'\mathrm{d}''F(u)$ is positive. In particular $M_{\varepsilon,m}(u)$ is smooth psh.

Proof. Apply d' to $d''F(u) = \sum_i F_i(u)d''u_i$ and use the product rule. At a point, factor the positive semidefinite Hessian as $D^2F = B^{\mathsf{t}}B$. The second sum becomes $\sum_k \alpha_k \wedge J\alpha_k$, where $\alpha_k = \sum_i B_{ki}d'u_i$. This is a positive $(1,1)$-form. The first sum is positive because its scalar coefficients are nonnegative. These identities commute with the pullbacks defining the sheaf. □

Corollary 12.2.2 (Gluing with a collar)**.** *Let $V \subset U$ be open, let u be smooth psh on U, and let v be smooth psh on V. Suppose an open neighbourhood O of the relative boundary of V in U satisfies $u > v + 2\varepsilon$ on $O \cap V$. Then*

$$w = \begin{cases} M_{\varepsilon,2}(u,v) & \text{on } V, \\ u & \text{on } U \setminus V \end{cases}$$

is smooth psh on U, and equals v wherever $v > u + 2\varepsilon$.

Proof. Deletion and $M_{\varepsilon,1}(u) = u$ show equality on the collar, so the definitions agree on an open neighbourhood of every interface point. Composition proves positivity on V, and the old function supplies it elsewhere. The last assertion follows by deleting the other branch. □

A partition of unity does not replace this argument. Although it glues unrestricted smooth functions, derivatives of its factors introduce mixed terms of no fixed sign. The collar inequality is the geometric input that makes positive gluing possible.

12.3 Logarithmic branches and finite barriers

Proposition 12.3.1. *Let $f_1, \dots, f_m$ be analytic functions on an analytic open set U, let a_i and c be real constants, and put*

$$q = \max\{c, \log|f_1| + a_1, \dots, \log|f_m| + a_m\}.$$

Interpret $\log 0 = -\infty$. Applying M_ε to the finite branches and deleting the branches equal to $-\infty$ defines a global original smooth psh function q_ε satisfying $q \le q_\varepsilon \le q + \varepsilon$.

Proof. Fix x. If $f_i(x) = 0$, continuity of $|f_i|$ gives a neighbourhood on which $\log|f_i| + a_i < c - 2\varepsilon$. Delete that branch throughout this neighbourhood. For every remaining branch, shrink the neighbourhood so that f_i is a unit. Its logarithmic absolute value is then an original smooth function with zero $\mathrm{d}'\mathrm{d}''$. The constant branch remains finite everywhere. Proposition 12.2.1 therefore proves smoothness and positivity locally. On overlaps the deletion identity shows that the local formulas coincide. The estimates follow from (12.1.2). □

Theorem 12.3.2 (A barrier from nested rational domains)**.** *Let V be an affinoid domain in a good Hausdorff analytic space X. Let $f_1, \dots, f_m, g \in \mathcal{O}(V)$ have no common zero and let $\lambda_i > 0$. For real $a < b$, define*

$$W_t = \{y \in V : |f_i(y)| \le e^t \lambda_i |g(y)| \text{ for all } i\}.$$

Suppose $W_b \subset \mathrm{Int}_X(V)$, and let x satisfy all the inequalities for W_a strictly. There exist an open neighbourhood U of W_a, an original smooth psh function ρ on U, and an open neighbourhood U_0 of x such that

$$\rho < 0 \text{ on } U_0, \qquad \{y \in U : \rho(y) \le 0\} \text{ is compact in } U.$$

Proof. The no-common-zero assumption implies $g \neq 0$ on every W_t: otherwise every f_i would vanish there. These sets are compact rational domains. Choose $c < a$ and set

$$q = \max\{c, \log|f_i/g| - \log\lambda_i : 1 \le i \le m\}$$

on the locus $D(g)$ in V. It is finite and continuous. Choose c so that $q(x) < a$, and put $U = \{q < b\} \subset D(g)$. This subset is contained in W_b, hence in the ordinary interior of V; it is therefore open in X. It contains W_a. For $c \le t < b$, its sublevel $\{q \le t\}$ is exactly W_t.

Choose $\varepsilon > 0$ and a real s with $q(x)+\varepsilon < s < a$. The preceding proposition applies to the analytic functions f_i/g on U. Put $\rho = q_\varepsilon - s$. Then $\rho(x) < 0$. Its nonpositive sublevel is closed in U and contained in $W_s \subset W_a$. As a closed subset of the compact set W_a, it is compact. Continuity gives the required U_0. □

The theorem is deliberately stated with the nested-domain input visible. Establishing such rational data near every point uses the local domain theorems of analytic geometry. The analytic construction above proves what follows once those data have been supplied. It also distinguishes the larger domain U from the smaller set on which ρ is negative; these two sets must not be identified.

12.4 Uniform approximation and decreasing sequences

The domain of approximation is part of the assertion. The useful elementary conversion below does not change that domain with the accuracy parameter.

Lemma 12.4.1. *Let u be continuous on U and let $\mathcal{F}(U) \subset C^0(U)$ be stable under addition of real constants. Suppose u is a locally uniform limit of functions in $\mathcal{F}(U)$. For every relatively compact $V \Subset U$, there is a sequence in $\mathcal{F}(U)|_V$ decreasing to $u|_V$.*

Proof. Choose $v_j \in \mathcal{F}(U)$ with $\sup_{\overline{V}} |v_j - u| \le 4^{-j}$. Set $w_j = v_j + 2 \cdot 4^{-j}$. Then

$$u + 4^{-j} \le w_j \le u + 3 \cdot 4^{-j}, \qquad w_{j+1} \le u + \tfrac{3}{4}\, 4^{-j} < w_j.$$

The squeeze proves the limit. Every function remains defined on the common set V. □

Conversely, decreasing continuous functions with a continuous limit converge uniformly on every compact subset, by Dini's theorem. Neither direction proves that a continuous section at an arbitrary transfinite decreasing-limit stage admits continuous approximants in the preceding stage. That is the missing replacement step discussed in the source concordance, not a consequence of Dini's theorem.

Chapter 13

Continuous Bedford–Taylor products

13.1 Continuous products and the role of the potential

The mixed product of Theorem 11.1.5 can be understood through two operations: multiplication of a positive current by a continuous function, and distributional differentiation. Their domains explain why the notation $d'd''u \wedge T$ is not an unrestricted wedge product of currents.

13.1.1 A recursive construction with stated regularity

Proposition 13.1.1 (Multiplication and weak convergence)**.** *Let T_j be ordinary positive currents of one fixed bidegree converging weakly to an ordinary positive current T. Let u_j be continuous functions converging locally uniformly to a continuous function u. Then*

$$u_j T_j \longrightarrow uT$$

as currents. The products are defined through the Radon measures obtained by testing the positive currents against smooth complementary forms.

Open proof obligation (RC2). Prove uniform approximation near the test support in the required category; the proof explicitly identifies CLD12 Corollaries 5.4.7–5.4.8 as the density input.

Definition 13.1.2 (One continuous potential acting on a closed current)**.** Let T be an ordinary positive current with $d'T = d''T = 0$, and let $u \in \mathcal{C}_{25}$. Define

$$d'd''u \wedge T := d'd''(uT). \tag{13.1.1}$$

At this point the right side, and therefore the construction, uses the specified function u. Dependence only on its curvature current is a separate question.

Proposition 13.1.3 (Positivity and closedness)**.** *The current in* (13.1.1) *is ordinary positive and is killed by both d' and d''. If u is smooth, it is the usual product of the smooth form $d'd''u$ with T.*

Open proof obligation (RC2). The argument uses multiplier convergence, whose native density premise is open.

This argument uses the continuous generated sheaf directly. It does not require the disputed all-stage equality with $C^0 \cap \mathcal{P}_{25}$.

Proposition 13.1.4 (Iteration and local uniform stability)**.** *Let T have bidegree (p,p) and satisfy the preceding positivity and closedness assumptions. For $u_1, \dots, u_q \in \mathcal{C}_{25}$, with $p+q \le n$, the recursive expression*

$$d'd''\big(u_1 d'd''(u_2 \cdots d'd''(u_q T)\cdots)\big) \tag{13.1.2}$$

is a positive closed current of bidegree $(p+q, p+q)$. If $T_j \to T$ weakly through positive closed currents and each $u_{i,j} \to u_i$ locally uniformly through $\mathcal{C}_{25}$, the corresponding recursive products converge weakly to (13.1.2).

Open proof obligation (RC2). The induction uses one-step positivity and multiplier convergence. The cited CLD25 recursion is explanatory here and its citation does not discharge either open native premise.

Open proof obligation (RC3). For $u_i \in \mathcal{U}$, the symmetry and independence of smooth approximations in Theorem 11.1.5 remain pending. For smooth approximants on a common smaller neighbourhood, the smooth products are symmetric. Passing this identity to the recursive products requires the local uniform stability in Proposition 13.1.4, which in turn depends on the open multiplier-convergence assertion in Proposition 13.1.1. Strongly positive forms need not span all symmetric forms.

13.1.2 Independence of the potential is another assertion

Definition 13.1.5 (The continuous Bedford–Taylor property)**.** A positive closed current T has the continuous Bedford–Taylor property on a specified class of continuous potentials if, locally,

$$d'd''[u] = d'd''[v] \quad \Longrightarrow \quad d'd''(uT) = d'd''(vT) \tag{13.1.3}$$

for all potentials u, v in that class. This is the continuous interpretation of the property singled out in [CLD25, Definition 8.6.2].

Remark 13.1.6 (A proved case and a missing inference). The integration current $[1]$ has this property: $u[1] = [u]$, so (13.1.3) is exactly its hypothesis. For an arbitrary positive closed T, the implication also holds if $u - v$ is smooth with $d'd''(u - v) = 0$, by the Leibniz calculation above. If $u - v$ is merely continuous and its current Hessian vanishes, the same argument is unavailable. This is why the potential-independence condition is stated separately in [CLD25, §8.6.1].

Similarly, a positive continuous scalar multiplier preserves positivity of a current but need not preserve either closedness or the Bedford–Taylor property. Example A.1.3 disproves the unrestricted multiplication assertion printed in Corollary 8.6.7 of that text.

13.1.3 Metrics, measures, and actual norms

For a line bundle with continuous local weights in $\mathcal{U}$, the products of its curvature currents are defined locally by the preceding construction and glue: changes of frame add the smooth pluriharmonic function $-\log|f|$ for an analytic unit f. This is a legitimate use of the smooth case in Remark 13.1.6. The argument concerns currents and their products; it does not forget the normalization of the original metric.

Remark 13.1.7 (Constants are invisible to curvature). If $\|\cdot\|' = e^{-c}\|\cdot\|$, then its weights satisfy $\varphi'_e = \varphi_e + c$, and

$$c_1(L, \|\cdot\|') = c_1(L, \|\cdot\|).$$

The two norms are nevertheless different for $c \neq 0$. Equality of currents or of top-degree measures therefore cannot identify actual metrics. This distinction persists when currents are used in Deligne pairings or in adelic intersection theory.

The passage to unbounded potentials requires an integrability domain for products such as uT. The continuous recursion above supplies no automatic product when that multiplication is undefined. In particular, it supplies neither a general non-pluripolar product nor a finite-energy theory by notation alone. Those constructions require their own definitions and comparison theorems.

13.2 The estimates and identities behind continuous products

13.2.1 What a Chern–Levine–Nirenberg estimate controls

Fix an ordinary positive closed current T, a relatively compact test region, and a compactly supported smooth complementary form ω. A local CLN estimate bounds expressions of the shape

$$\left|\left\langle u_0\, \mathrm{d}'\mathrm{d}''u_1 \wedge \cdots \wedge \mathrm{d}'\mathrm{d}''u_q \wedge T, \omega \right\rangle\right| \leq C \prod_{i=0}^{q} \|u_i\|_K,$$

for smooth psh functions on a fixed larger neighbourhood, with the usual choice of nested compact sets and cutoffs. The constant depends on the region, the fixed tests and cutoffs, and the relevant local mass of T. It is not uniform over an unbounded family of background currents.

The estimate is striking because the left side contains second derivatives of every u_i, while the right side contains only their values. Positivity is the reason derivatives can be removed without losing control. It also explains why an estimate for arbitrary signed currents would need a different argument.

13.2.2 The induction mechanism

Choose nested compact neighbourhoods of the support of ω and cutoffs equal to one on the smaller neighbourhoods. Positive-cone domination bounds the coefficients of the test by finitely many positive tests. For one curvature factor, integration by parts moves $\mathrm{d}'\mathrm{d}''$ from u_1 to a cutoff times the test. The derivatives now fall on fixed smooth data. Their coefficients are bounded on the larger compact set, so ordinary positivity bounds the resulting pairing by a fixed local mass of T, times $\|u_1\|_K$.

Repeat this step for the remaining factors, enlarging the compact region at each stage. The closedness of the inner mixed current removes derivatives of that current. Positivity allows the same coefficient estimate at the next step. The scalar u_0 is controlled directly by its sup norm. This is the structure of the CLN argument in CLD25 Chapter 8; the technical formulation keeps track of the degrees and support sets.

There is a printed degree slip in Proposition 8.4.1: the symbol p must be read as the bidimension of the initial current for the displayed pairing to have the stated complementary degree. The estimate is used here with explicitly complementary test degrees, as explained in Appendix A.

13.2.3 Symmetry on the continuous generated class

The recursive expression in the preceding section is written in an order. Its symmetry is a theorem. For smooth potentials, it follows from the wedge algebra. For two continuous generated potentials u, v, first fix a smooth u and pass to the generated continuous class in v: the identity

$$\mathrm{d}'\mathrm{d}''(u\,\mathrm{d}'\mathrm{d}''(vT)) = \mathrm{d}'\mathrm{d}''(v\,\mathrm{d}'\mathrm{d}''(uT))$$

is local and stable under the uniform limits allowed in the definition, by the multiplier-convergence theorem. Now fix such a v and make the same argument in u. This proves the two-factor symmetry on the continuous class. Adjacent transpositions give symmetry for any finite number of factors.

This argument does not require replacing every generated function by one globally chosen sequence of original smooth psh functions. It uses the defining closure property of the continuous sheaf. It also does not establish the separate kernel property: if two different potentials have the same ambient Hessian, their actions on an arbitrary background current still need comparison.

13.2.4 Differences of psh functions

CLD25 calls the real vector sheaf generated by its continuous psh functions the dpsh class. Locally one can write a member as a difference of continuous psh functions. Products extend multilinearly by expanding such differences. Independence of the chosen positive decomposition follows from linearity of the scalar multiplication and distributional differentiation in the recursive construction, together with the established symmetry.

For example, a smooth function on a relatively compact real chart can be written as

$$u = (u + C|x|^2) - C|x|^2$$

with both terms convex when C dominates the negative part of the Hessian. Pulling back this local argument explains why original smooth functions belong to the dpsh class. PL and G-smooth functions require the corresponding piecewise convex decomposition and the source's local chart hypotheses.

The word dpsh does not assert positivity. A dpsh curvature is generally a difference of positive currents. It is a useful domain for multilinear calculus, just as differences of semipositive metrics are useful in arithmetic intersection theory.

13.2.5 Projection formulas and the direction of functoriality

For a proper morphism in the category where smooth pullback and current pushforward are defined, the elementary identity

$$f_*(f^*u\, S) = u\, f_*S$$

comes from evaluating both sides on the same test and using scalar multiplication. Commuting f_* with the distributional derivatives then gives

$$f_*\big(\mathrm{d}'\mathrm{d}''(f^*u) \wedge S\big) = \mathrm{d}'\mathrm{d}''u \wedge f_*S$$

for continuous potentials in the admitted class and positive closed S. Iteration gives the mixed version. The support/properness hypothesis ensures that pulled-back tests have the support needed to evaluate S.

This is a pushforward theorem with pulled-back potentials. It is not a general pullback construction for arbitrary currents. The latter would require defining the action on tests in the opposite direction and controlling singular intersections. This distinction is important when interpreting the functorial psh condition of GK and the analytic curve tests of Gubler–Rabinoff.

13.3 Polar sets, integrability, and the boundary of the BT theorem

13.3.1 The precise input in the polar-negligibility theorem

Theorem 8.12.1 assumes the local existence of suitable smooth psh sublevel neighbourhoods. Its mixed measure is constructed from continuous locally approachable potentials $u_1, \dots, u_n$. The auxiliary function V is itself locally approachable psh and locally integrable. The conclusion is that V is locally integrable for the mixed measure.

The analytic version is Theorem 16.9.2. For the good boundaryless analytic setting used in these notes, the preceding sublevel construction provides the needed local geometry. A formula error in the printed smoothing kernel is corrected in Appendix A; the normalization and domain of the regularized maximum are made explicit there.

These hypotheses are narrower than a theorem about every generated psh function and every positive closed background current. In particular, the theorem is not a full statement of capacity theory for arbitrary discontinuous bounded potentials.

13.3.2 Why integrability implies no polar mass

Suppose $V \le 0$ near a compact set and $\int (-V)\, d\mu < \infty$. For $M > 0$,

$$M\, \mu\{V < -M\} \le \int_{\{V<-M\}} (-V)\, d\mu \le \int (-V)\, d\mu.$$

The sets $\{V < -M\}$ decrease to $\{V = -\infty\}$ as $M \to \infty$. Hence the latter has zero μ-mass. This elementary argument is the final step; the mathematical work lies in proving the integrability bound for the mixed measure.

The source obtains that bound by combining CLN estimates with decreasing smooth approximants of V and uniform smooth approximants of the continuous u_i. A compactly supported psh barrier controls the localization. Positivity and monotone convergence then pass the estimate to V. Each approximation has a specific role; a general weak limit of measures would not by itself preserve the desired integrability bound.

13.3.3 Polar sets and small tropical dimension are different criteria

CLD25 Chapter 16 also proves a support theorem for positive closed currents. Under the nontrivial valuation and boundaryless hypotheses, Theorem 16.8.5 says that a positive closed current of bidimension (p, p) does not charge, after pairing with a smooth (p, p)-form, a closed set whose image in every relevant tropical chart has zero p-dimensional Hausdorff measure.

This criterion is geometric and dimension-theoretic. Polar-negligibility is formulated through a potential taking the value $-\infty$. One should not identify the two notions without another theorem. A set may be small in one chosen tropical image while being visible in another; the support theorem requires all the prescribed charts.

13.3.4 What a complete bounded theory would add

Continuous scalar multiplication is canonical because positive currents have measure coefficients. If a bounded potential is discontinuous, multiplication remains meaningful once a measurable representative is fixed, but the continuity theorem needed for iteration changes. Locally uniform convergence is no longer available. One must control decreasing limits, exceptional sets, and the dependence on the representative.

In complex pluripotential theory, capacities, quasi-continuity, and monotone convergence make these operations compatible. A corresponding non-Archimedean theory must specify its psh class and its test space before claiming the analogy. The toric theory of BGJK and global variational theories provide important established cases, treated in Chapter 21; they should be compared on their actual domains. The continuous arguments above are a foundation for that comparison, not a proof of every bounded or finite-energy statement.

References. [CLD25, §§8.4–8.12, 16.8–16.9].

13.4 Local mass estimates

The first product theorem proves positivity by approximation. Once positivity is known, integration by parts gives a mass estimate depending on the

potential itself, not on derivatives of its approximants. This is the estimate needed for repeated products.

Lemma 13.4.1. *For a smooth real function χ, the coefficient matrix of $\mathrm{d}'\mathrm{d}''\chi \wedge \beta_{q-1}$ satisfies*

$$\left\| H_{\mathrm{d}'\mathrm{d}''\chi\wedge\beta_{q-1}} \right\|_{\mathrm{op}} \le q \left\| D^2\chi \right\|_{\mathrm{op}}.$$

Proof. At the point in question, diagonalize the real symmetric Hessian by an orthogonal basis change, with eigenvalues $\lambda_1, \dots, \lambda_n$. Such a change preserves ω and all the exterior Euclidean norms. The coefficient matrix of the wedge is diagonal; its entry indexed by a q-element set I is $\sum_{i\in I} \lambda_i$. This follows by expanding β_{q-1} and observing that only indices different from the Hessian index survive. The absolute value of each entry is at most $q \max_i |\lambda_i|$. □

Proposition 13.4.2 (One-step mass bound)**.** *Let $T, u, R = \mathrm{d}'\mathrm{d}''(uT)$ satisfy Theorem 9.8.1. Choose $0 \le \chi \in C_c^\infty(\Omega)$ equal one near K, and a compact L containing* $\operatorname{supp}\chi$*. For any $c \in \mathbb{R}$,*

$$\mu_R(K) \le q \left\| D^2\chi \right\|_{\infty,\mathrm{op}} \|u - c\|_{L,\infty}\, \mu_T(L). \tag{13.4.1}$$

Proof. Since R is positive and $\chi = 1$ on K,

$$\mu_R(K) \le R(\chi\beta_{q-1}) = T(u\,\mathrm{d}'\mathrm{d}''\chi \wedge \beta_{q-1}).$$

Here β_{q-1} is constant and (9.7.1) is valid on the continuous product uT. Closedness of T gives $T(\mathrm{d}'\mathrm{d}''(\chi\beta_{q-1})) = 0$, so u may be replaced by $u - c$. Now apply (9.3.5) and Lemma 13.4.1; all coefficients of the test are supported in L. □

The constant in this bound depends on the cutoff and on the bidimension, not on the rate of approximation of u. Subtracting a constant is legitimate because the background is closed. In applications one may take $c = \inf_L u$, replacing the potential norm by its oscillation on L.

13.5 Mixed products in the approximation class

We now prove iteration and symmetry for the explicit approximation class used above. This result is deliberately stated with that class in its hypotheses; it makes no identification with a larger generated or current-psh class.

Definition 13.5.1. Write $\mathcal{U}(\Omega)$ for the continuous functions that locally admit smooth approximants with positive Hessian, converging locally uniformly on one fixed neighbourhood.

Theorem 13.5.2. *Let T be positive and closed of bidimension (q,q), and let $u_1,\dots,u_k \in \mathcal{U}(\Omega)$ with $k \le q$. The recursively defined current*

$$R(u_1,\dots,u_k;T) = \mathrm{d}'\mathrm{d}''\big(u_1\,\mathrm{d}'\mathrm{d}''(u_2\cdots \mathrm{d}'\mathrm{d}''(u_kT)\cdots)\big)$$

is positive and closed of bidimension $(q-k,q-k)$, local in the potentials and background, and symmetric in the u_i. If $T_j \rightharpoonup T$ are positive closed currents and $u_{i,j}\to u_i$ locally uniformly with all $u_{i,j},u_i\in\mathcal{U}(\Omega)$, then

$$R(u_{1,j},\dots,u_{k,j};T_j) \rightharpoonup R(u_1,\dots,u_k;T).$$

Proof. Existence, positivity and closedness follow inductively from Theorem 9.8.1. Each multiplication and derivative commutes with restriction, giving locality.

We prove continuity before symmetry. For $k=0$ it is the assumed convergence of T_j. Suppose it is proved for $k-1$. Let $S_j = R(u_{2,j},\dots,u_{k,j};T_j)$ and $S = R(u_2,\dots,u_k;T)$. By induction $S_j \rightharpoonup S$, and these currents are positive. Theorem 9.6.3 gives $u_{1,j}S_j \rightharpoonup u_1 S$. Differentiation gives the claimed convergence for k. This argument does not require derivative bounds on $u_{i,j}$.

Symmetry is local. Around any point, intersect the finitely many approximation neighbourhoods and choose simultaneous smooth approximants $u_{i,j}$ there. For smooth potentials, Proposition 9.7.2 identifies the recursion with

$$\mathrm{d}'\mathrm{d}''u_{1,j}\wedge\cdots\wedge\mathrm{d}'\mathrm{d}''u_{k,j}\wedge T.$$

All the smooth factors have even total degree, so they commute. Apply the continuity just proved to this expression in either order. The two limits agree on each neighbourhood and hence globally. □

Corollary 13.5.3 (Mixed local mass bound)**.** *Let $K \Subset \operatorname{int} L$ with $L \Subset \Omega$ compact. For $k \le q$ there is a constant C depending on K, L, k, q, n and chosen intermediate cutoffs, such that*

$$\mu_{R(u_1,\dots,u_k;T)}(K) \le C\,\mu_T(L)\prod_{i=1}^{k}\operatorname{osc}_L(u_i).$$

Proof. Choose nested compact sets $K = K_0 \subset \operatorname{int} K_1 \subset \cdots \subset \operatorname{int} K_k \subset L$, with smooth cutoffs equal one on K_{i-1} and supported in K_i. Apply Proposition 13.4.2 first to the outermost product and then to its background, continuing inward. At each step subtract $\inf_L u_i$. The bidimension factors and the Hessian bounds of the finitely many cutoffs multiply into C. □

The same proof shows that the mixed product is separately additive when the potentials involved and their sums belong to $\mathcal{U}$, and is homogeneous for nonnegative scalars. Positivity remains attached to this admitted class. A proof that a different psh definition belongs to $\mathcal{U}$ is a comparison theorem, not part of the formal recursion.

13.6 Intrinsic limits and admitted potentials

Theorem 13.6.1. *In the algebraic scope of Section 8.8, let $T_j \rightharpoonup T$ be ordinary positive currents of fixed bidimension on W, and let $f_j \to f$ locally uniformly with all f_j, f continuous. Then $f_j T_j \rightharpoonup fT$.*

Proof. Fix an actual symmetric compactly supported test η and choose an actual positive control θ and M such that $M\theta \pm \eta \geq 0$. For the corresponding signed measures,

$$|\mu_{T_j,\eta}| \leq M \mu_{T_j,\theta}, \qquad \mu_{T_j,\theta}(W) = T_j(\theta) \longrightarrow T(\theta).$$

Hence their total variations are uniformly bounded and their supports lie in the fixed compact $\operatorname{supp} \eta$. For smooth scalar ϕ, weak convergence of currents gives

$$\int \phi \, d\mu_{T_j,\eta} = T_j(\phi\eta) \longrightarrow T(\phi\eta).$$

One may insert a cutoff equal one near $\operatorname{supp} \eta$ if ϕ is not compactly supported. Scalar density on that compact set and the uniform variation bound extend this convergence to every continuous scalar function on a neighbourhood of the compact set. Finally split

$$(f_j T_j - fT)(\eta) = \int (f_j - f) \, d\mu_{T_j,\eta} + \int f \, d(\mu_{T_j,\eta} - \mu_{T,\eta}).$$

The first term tends to zero by uniform convergence and the variation bound; the second by the continuous-scalar convergence just proved. Symmetrization treats arbitrary tests. □

Definition 13.6.2. Let $\mathcal{U}_X(W)$ denote the continuous functions locally uniformly approximable, on one fixed neighbourhood of each point, by original smooth functions u_j such that the actual smooth form $\mathrm{d}'\mathrm{d}''u_j$ is ordinary positive.

This is an explicitly admitted class. No equivalence with all continuous functions whose curvature current is positive is asserted. In particular, Proposition 8.12.2 does not prove membership in this class.

Theorem 13.6.3. *Let T be an ordinary positive closed current of bidimension (q,q) on W. For $u_1,\dots,u_k \in \mathcal{U}_X(W)$, $k \le q$, the recursive product*

$$R_X(u_1,\dots,u_k;T) = \mathrm{d}'\mathrm{d}''\big(u_1\,\mathrm{d}'\mathrm{d}''(u_2\cdots\mathrm{d}'\mathrm{d}''(u_kT)\cdots)\big)$$

is an intrinsic ordinary positive closed current. It is symmetric in the potentials and commutes with locally uniform convergence of admitted potentials and simultaneous weak convergence of positive closed backgrounds of fixed degree.

Proof. The first product is defined by Theorem 8.14.1 and distributional differentiation. If u_j are smooth positive-curvature approximants on a fixed neighbourhood, Theorem 13.6.1 gives $u_jT \rightharpoonup uT$. Smooth Leibniz on actual tests and closedness of T give

$$\mathrm{d}'\mathrm{d}''(u_jT) = \mathrm{d}'\mathrm{d}''u_j \wedge T \rightharpoonup \mathrm{d}'\mathrm{d}''(uT).$$

Wedge positivity is checked after a common refinement of the smooth form and the test. It follows from Proposition 7.5.2 face by face. Thus the approximating currents are positive, and their limit is positive. It is closed by the differential identities. This argument works locally; a nonnegative partition of unity gives the global assertion.

Iterate this construction. To prove convergence, induct on the number of potentials. The inner products converge by induction and are positive. Apply Theorem 13.6.1 to their multiplication by the outer potentials, then differentiate. For symmetry, choose simultaneous smooth approximants locally for the finitely many potentials. The smooth product is the wedge of their curvature forms with T, hence unchanged by permutation. The convergence just proved identifies its limits in any order. All operators commute with restriction, so the local equalities glue. □

This theorem supplies the intrinsic version of the Euclidean mixed-product argument in Section 13.5 for $\mathcal{U}_X$. The continuous-scalar relations are handled by Theorem 8.14.1. Equality of two nonsmooth potentials modulo the curvature kernel is still a different question, and has not been used in the proof.

13.7 Quantitative continuity of mixed products

Weak convergence of currents is convergence of their values on each fixed smooth compactly supported test. It does not measure the distance between their coefficient measures in total variation. A quantitative version of the local continuity theorem makes this distinction precise and explains which derivatives must be controlled.

We first work on an open real domain $\Omega \subset \mathbb{R}^n$, with the conventions and trace measures of Chapter 9. Let T be ordinary positive and closed of bidimension (q,q). All potentials belong to $\mathcal{U}(\Omega)$, and $R(\mathbf{u};T)$ denotes the product of Theorem 13.5.2. The Euclidean estimate below is not asserted on an arbitrary analytic space by simply choosing one tropical chart: an analytic test can involve further refinements. Its intrinsic qualitative counterpart is Theorem 13.6.3.

Proposition 13.7.1 (A telescoping identity)**.** *For two k-tuples $\mathbf{u},\mathbf{v}$, where $1 \le k \le q$, put*

$$S_i = R(v_1,\dots,v_{i-1},u_{i+1},\dots,u_k;T).$$

Then, as currents,

$$R(\mathbf{u};T) - R(\mathbf{v};T) = \sum_{i=1}^{k} \mathrm{d}'\mathrm{d}''\big((u_i - v_i)S_i\big). \tag{13.7.1}$$

Proof. Replace u_1 by v_1, then u_2 by v_2, and continue. At the ith replacement, symmetry moves the changing factor to the outside of the recursion. Linearity of continuous scalar multiplication and of $\mathrm{d}'\mathrm{d}''$ identifies the difference with $\mathrm{d}'\mathrm{d}''((u_i-v_i)S_i)$. Adding these differences cancels every intermediate product. This proof uses the chosen potentials; it does not replace their differences by abstract curvature classes. □

Theorem 13.7.2 (A bound on each fixed test)**.** *Fix a smooth compactly supported test η of bidegree $(q-k, q-k)$ and a compact $L \Subset \Omega$ whose interior contains its support. There is a constant $C_{\eta,L}$, depending also on the chosen intermediate cutoffs, such that*

$$\begin{aligned}&|\langle R(\mathbf{u};T) - R(\mathbf{v};T), \eta\rangle| \\ &\quad \le C_{\eta,L}\mu_T(L) \sum_{i=1}^{k} \|u_i - v_i\|_L \prod_{j<i} \operatorname{osc}_L(v_j) \prod_{j>i} \operatorname{osc}_L(u_j).\end{aligned}$$

An empty product is one. Only the fixed test and cutoffs, not the varying potentials, are differentiated in this estimate.

Proof. We may symmetrize η, since all currents being paired are symmetric. Choose a compact neighbourhood K of $\operatorname{supp}\eta$ in $\operatorname{int} L$. The telescoping identity gives

$$\langle R(\mathbf{u};T) - R(\mathbf{v};T), \eta\rangle = \sum_i S_i\big((u_i - v_i)\mathrm{d}'\mathrm{d}''\eta\big).$$

The form $\mathrm{d}'\mathrm{d}''\eta$ has bidegree $(q-k+1, q-k+1)$, exactly the bidimension of S_i. Its symmetric coefficient matrix has a finite operator-norm bound A_η. The trace-measure estimate of Chapter 9 therefore gives

$$|S_i((u_i - v_i)\mathrm{d}'\mathrm{d}''\eta)| \le A_\eta \|u_i - v_i\|_L \, \mu_{S_i}(K).$$

Apply Corollary 13.5.3 to the $k-1$ potentials defining S_i, using intermediate compact sets between K and L. There are finitely many positions i, so a common maximum of the cutoff constants suffices. This proves the formula. For $k = 1$, there are no inner potentials and the argument is simply the trace estimate for T. □

Corollary 13.7.3. *If all the oscillations in the preceding theorem are bounded by M and $\mu_T(L) \le B$, then*

$$|\langle R(\mathbf{u};T) - R(\mathbf{v};T), \eta\rangle| \le C_{\eta,L} B\, M^{k-1} \sum_i \|u_i - v_i\|_L.$$

For $k = 1$ the factor M^{k-1} is one, also when $M = 0$. Thus on a bounded family the product is Lipschitz on each fixed smooth test, with respect to uniform distance of the potentials.

The constant depends on the second derivatives of η and on the localization. It is not uniform over all continuous tests of sup norm one. Consequently this corollary gives no total-variation convergence. Nor does weak convergence $T_j \to T$ alone give a numerical rate for the background error. The simultaneous-background theorem is obtained by continuity of scalar multiplication and induction, rather than by assigning a norm distance to arbitrary currents.

13.8 Locality, maxima and contact sets

The maximum operation connects regularization to local comparison arguments. It is useful to record exactly what follows from locality before invoking any comparison principle. Work either in the real setting above or in the intrinsic algebraic setting of Theorem 13.6.3.

Proposition 13.8.1. *Let u, v belong to the admitted local uniform approximation class and put $w = \max(u, v)$. Then w belongs to that class. For fixed additional admitted potentials* $\mathbf{a}$*,*

$$R(w, \mathbf{a}; T)|_{\{u>v\}} = R(u, \mathbf{a}; T)|_{\{u>v\}},$$
$$R(w, \mathbf{a}; T)|_{\{v>u\}} = R(v, \mathbf{a}; T)|_{\{v>u\}}.$$

Proof. On a common approximation neighbourhood choose smooth psh approximants u_j, v_j. Apply the normalized regularized maximum of Chapter 12, with smoothing parameter tending to zero. Convexity and coordinatewise monotonicity preserve positivity of the Hessian. Its uniform error from the ordinary maximum tends to zero, while

$$|\max(u_j, v_j) - \max(u, v)| \le \max(|u_j - u|, |v_j - v|).$$

This proves membership in the admitted class. On the open set $\{u > v\}$ the functions w and u agree, so locality of scalar multiplication and distributional differentiation identifies the products. The second equality is the same argument. □

Example 13.8.2 (The contact contribution)**.** On the real line take $u(t) = t$ and $v(t) = -t$. Their Hessians vanish, but

$$\mathrm{d}'\mathrm{d}'' \max(u, v) = \mathrm{d}'\mathrm{d}''|t| = 2\delta_0.$$

Thus the two restrictions in Proposition 13.8.1 do not determine the product on $\{u = v\}$. For a test χ, integration by parts separately on the two half-lines gives $\int |t|\chi''(t)\, dt = 2\chi(0)$, which proves the formula and its normalization. In a tropical annulus coordinate the same local calculation applies with the relevant lattice calibration.

For a truncation $u_c = \max(u, c)$, locality gives $\mathrm{d}'\mathrm{d}''u_c = \mathrm{d}'\mathrm{d}''u$ on $\{u > c\}$ and $\mathrm{d}'\mathrm{d}''u_c = 0$ on $\{u < c\}$. The level set $\{u = c\}$ can carry mass. Removing that mass by restricting to a strict sublevel complement is an additional operation; it is not the original product. This distinction underlies the separate definitions of truncated and non-pluripolar products in theories where the latter are available.

References. [CLD12, Section 5.6]; [CLD25, Sections 8.4–8.7]. The quantitative estimate combines the local mass bound with the telescoping identity; the maximum statements use regularized maxima and locality. These are consequences in the stated admitted classes, not extensions to arbitrary current-psh potentials.

13.9 Symmetry without choosing simultaneous smooth approximants

The continuous generated sheaf $\mathcal{C}_{25}$ was defined by local uniform closure from smooth psh functions. Its sections need not come with one common one-step approximation. Nevertheless the recursive products are symmetric. The proof uses the defining closure property separately in the two variables of an adjacent interchange.

For the concrete analytic assertions below, use the algebraic scope of Section 8.8: an algebraically closed complete nontrivially valued field and paracompact open subsets of analytifications of separated integral algebraic varieties. The background currents are ordinary positive and closed, and Theorem 13.6.1 supplies multiplication and joint continuity on actual original smooth tests. The closure arguments also apply abstractly in any calculus where these same inputs have been established. For $u \in \mathcal{C}_{25}$ write

$A_u T = \mathrm{d}'\mathrm{d}''(uT)$. The preceding construction gives a positive closed current, and

$$u_j \to u \text{ locally uniformly}, \quad T_j \rightharpoonup T \quad \Longrightarrow \quad A_{u_j} T_j \rightharpoonup A_u T.$$

All currents in this implication have the same degree and are positive closed.

Lemma 13.9.1. *Suppose a property of continuous functions is local, holds for smooth psh functions, and is preserved under locally uniform limits. Then the property holds for every section of $\mathcal{C}_{25}$, provided it is imposed on restrictions to every open subset.*

Proof. The functions satisfying the property form a subsheaf of continuous functions, contain the starting sheaf of smooth psh functions, and are closed under the prescribed limit operation. The minimality in the definition of the generated sheaf gives the conclusion. No countable-stage or fixed-neighbourhood representation of an arbitrary section is asserted. □

Theorem 13.9.2. *For $u, v \in \mathcal{C}_{25}$ and an ordinary positive closed current T of the appropriate degree,*

$$A_u A_v T = A_v A_u T.$$

Consequently every iterated product $A_{u_1} \cdots A_{u_q} T$ is symmetric in the potentials.

Proof. First fix a smooth psh function v. For smooth psh u, the identity is the commutativity of the two smooth curvature factors. Consider the property that the identity holds for every positive closed T on every open restriction. It is local. If $u_j \to u$ locally uniformly, joint continuity gives $A_{u_j} A_v T \to A_u A_v T$ and $A_v A_{u_j} T \to A_v A_u T$. Hence the property is closed under these limits. Lemma 13.9.1 proves it for all $u \in \mathcal{C}_{25}$ and smooth v.

Now consider the property of v that the identity holds for every $u \in \mathcal{C}_{25}$ and every such T, on every open restriction. The first step gives it for smooth psh v. If $v_j \to v$ locally uniformly, then $A_{v_j} T \to A_v T$; applying joint continuity with the fixed continuous multiplier u gives $A_u A_{v_j} T \to A_u A_v T$. The other side converges to $A_v A_u T$ by the same theorem. A second application of the closure principle gives the desired identity for all $v \in \mathcal{C}_{25}$.

In an iterated product the factors inside an adjacent pair produce another positive closed current. The two-factor identity therefore allows every adjacent interchange. Such interchanges generate all permutations. □

This proof distinguishes two types of independence. The product is independent of an approximation used to construct it and of the order of its potential factors. It has not thereby been shown to depend only on the ambient curvature currents $\mathrm{d}'\mathrm{d}''[u_i]$. That latter statement is the kernel property of Chapter 14.

13.10 Chern operators with continuous generated weights

Proposition 13.10.1. *Let a metrized line bundle $\overline{L}$ have local weights in $\mathcal{C}_{25}$. For every ordinary positive closed current T, the local currents $\mathrm{d}'\mathrm{d}''(\varphi_e T)$ glue to a global positive closed current, denoted $c_1(\overline{L}) \wedge T$. These operators commute for different such metrized line bundles.*

Proof. For frames $e' = ge$, one has $\varphi_{e'} - \varphi_e = -\log|g|$. This difference is original smooth and has zero $\mathrm{d}'\mathrm{d}''$ because g is an analytic unit. The two closedness conditions on T give

$$\mathrm{d}'\mathrm{d}''\big((\varphi_{e'} - \varphi_e)T\big) = \mathrm{d}'\mathrm{d}''(-\log|g|) \wedge T = 0.$$

Thus the local currents agree on overlaps. Positivity and closedness are local and were proved for $A_u T$. Commutativity is Theorem 13.9.2 on a common trivializing neighbourhood. □

The gluing uses a very specific kernel: logarithms of analytic units. It therefore remains valid even when an arbitrary-current theorem for all current-harmonic continuous functions is unavailable. This is why line-bundle intersection calculus can be established on a useful class before the general harmonic-kernel problem is settled.

13.11 Proper pushforward and projection

Let $f : Y \to X$ be a proper map between the chosen analytic opens induced by an algebraic morphism over the same field, in the scope just specified. Both spaces are pure dimensional. We index the next statement by bidimension, which is preserved by current pushforward. If T has bidimension (q, q) on Y, then $f_* T$ acts on (q, q)-tests on X.

Lemma 13.11.1. *For an ordinary positive current T and a continuous function u on X,*

$$f_*((u \circ f)T) = u\, f_*T.$$

Proof. For smooth u, evaluate both sides on a compactly supported test η and use $f^*(u\eta) = (u \circ f)f^*\eta$. For continuous u, uniformly approximate it by smooth functions near the compact support of η. Properness makes the inverse image of that support compact. The order-zero estimates on both spaces pass the smooth identity to the limit. This also proves the identity when f is merely proper over the support involved. □

Theorem 13.11.2. *If T is ordinary positive closed and $u_1, \dots, u_s \in \mathcal{C}_{25}(X)$ with $s \le q$, then*

$$f_*\big(A_{u_1 \circ f} \cdots A_{u_s \circ f} T\big) = A_{u_1} \cdots A_{u_s}(f_*T).$$

Proof. Pullback preserves smooth psh functions and locally uniform convergence; the closure principle therefore gives $u_i \circ f \in \mathcal{C}_{25}(Y)$. Pullback preserves ordinary positive test forms, so f_*T is ordinary positive. It is closed because the differentials commute with pullback on tests. For one factor, commutation of current pushforward with distributional differentiation and Lemma 13.11.1 give

$$f_*\mathrm{d}'\mathrm{d}''((u \circ f)T) = \mathrm{d}'\mathrm{d}'' f_*((u \circ f)T) = \mathrm{d}'\mathrm{d}''(u f_*T).$$

Apply this successively to the positive closed inner products to obtain the formula for s factors. □

For a finite flat same-field map of degree d, apply the theorem with $T = [Y]$ and the calibrated identity $f_*[Y] = d[X]$. It gives the degree-d projection formula for these mixed products. If instead one integrates a scalar extension over its new native ground field, Chapter 23 gives $p_*[X_L]_L = [X]_K$ and the corresponding formula has no extra degree factor. The recursive argument uses the supplied calibration identity and does not choose that normalization itself.

This theorem is a statement about currents. It does not say that proper pushforward of an actual delta-form is an actual delta-form, or that an alteration preserves an exact support complement. Those are the distinct representative questions discussed in Chapter 23.

13.12 A monotone consequence and its limit

Proposition 13.12.1. *Suppose $u_{i,j} \in \mathcal{C}_{25}$ decrease pointwise to finite continuous functions u_i, for $1 \le i \le s$. On each compact subset, convergence is uniform. The limits belong locally to $\mathcal{C}_{25}$, and the mixed products converge weakly, also with a weakly convergent sequence of ordinary positive closed background currents.*

Proof. For a compact set K and $\epsilon > 0$, the open sets $\{u_{i,j} - u_i < \epsilon\}$ increase with j and cover K. A finite subcover is contained in one of them. This is Dini's argument and proves uniform convergence. Local compactness and the generated-sheaf closure give the membership assertion. The product convergence is then the locally uniform stability theorem already proved. □

Continuity of the limit is essential to this argument. Without it, the sets used in the compactness proof need not be open. A general bounded-potential monotone theorem requires more than relabelling pointwise convergence as uniform convergence.

Example 13.12.2 (Pointwise multipliers do not suffice)**.** On $\mathbb{R}$, let $T_j = \delta_{1/j}$ and $T = \delta_0$. Choose continuous bumps u_j of height one at $1/j$, supported in intervals of radius $1/(10j^2)$ around $1/j$. Then $u_j \to 0$ pointwise, whereas $u_j T_j = T_j \rightharpoonup \delta_0$. Thus multiplication does not converge to $0T$. The bumps are not psh; this is a counterexample to the bare pointwise multiplier argument, not to a separately proved psh monotone theorem.

References. The generated-class construction is compared with [CLD25, Sections 8.5–8.7]. The proofs above use the ordinary-positive estimates and current operations established in Chapters 8–9; no full strong-cone spanning statement is used.

13.13 Comparison on a continuous global domain

A comparison principle can be separated from the harder problem of defining products for all bounded psh functions. We prove the continuous statement from locality, positivity, and the total mass formula. This identifies a useful consequence of an established calculus without claiming the full bounded-potential theory.

Let X be compact and let $\mathcal{P} \subset C(X)$ be a specified class of continuous potentials in one fixed background class θ. Assume that $\mathcal{P}$ is stable under addition of constants and finite maxima. Suppose its Monge–Ampère operator assigns positive Radon measures of the same finite mass V, is unchanged by adding constants to a potential, and is local on open sets: if two potentials agree on an open set, their measures agree there. These hypotheses are part of the statement. They must be checked in the chosen analytic theory.

Theorem 13.13.1. *For $u, v \in \mathcal{P}$,*

$$\int_{\{u<v\}} \mathrm{MA}(v) \leq \int_{\{u<v\}} \mathrm{MA}(u).$$

Proof. Fix $\varepsilon > 0$ and put $w = \max(u, v - \varepsilon)$. On the disjoint open sets $A_\varepsilon = \{u < v - \varepsilon\}$ and $B_\varepsilon = \{u > v - \varepsilon\}$, locality gives $\mathrm{MA}(w) = \mathrm{MA}(v)$ and $\mathrm{MA}(w) = \mathrm{MA}(u)$, respectively. Positivity and equality of total masses therefore imply

$$\begin{aligned} \mathrm{MA}(v)(A_\varepsilon) &= \mathrm{MA}(w)(A_\varepsilon) \leq V - \mathrm{MA}(w)(B_\varepsilon) \\ &= V - \mathrm{MA}(u)(B_\varepsilon) = \mathrm{MA}(u)(\{u \leq v - \varepsilon\}). \end{aligned}$$

As ε decreases to zero through a sequence, both sets in the final inequality increase to $\{u < v\}$. Continuity from below for finite positive measures proves the result. No assertion about the measure of the equality set $\{u = v\}$ is needed. □

Remark 13.13.2. This proof applies, for example, after the three stated properties have been established for a continuous semipositive metric class on a proper variety. It does not derive those properties from the single condition $\mathrm{d}'\mathrm{d}''[u] + \theta \geq 0$ on original smooth tests. In particular, the maximum must belong to the admitted domain and its measure must be local there. The theorem should not be cited as a regularization theorem or as an extension of the domain of MA.

13.13.1 Why finite maxima preserve a generated class

For the continuous generated class used in Chapter 13, maximum stability follows by the same two-variable closure argument as symmetry. The start-

ing step uses a smooth convex regularized maximum, nondecreasing in each argument. Its Hessian chain rule is

$$\mathrm{d}'\mathrm{d}''F(u,v) = F_1\mathrm{d}'\mathrm{d}''u + F_2\mathrm{d}'\mathrm{d}''v + \sum_{i,j=1}^{2} F_{ij}\, d'u_i \wedge d''u_j, \quad (u_1,u_2) = (u,v).$$

For smooth psh inputs all three contributions are positive: $F_i \geq 0$ and the Hessian matrix (F_{ij}) is positive semidefinite. The regularized maxima converge uniformly to the maximum. Keeping one input fixed and passing through local uniform closure, then doing the same for the other input, proves maximum stability on the generated class. The estimate

$$\|\max(u,v) - \max(\widetilde{u},\widetilde{v})\|_\infty \leq \max(\|u-\widetilde{u}\|_\infty, \|v-\widetilde{v}\|_\infty).$$

For metrics on a fixed line bundle, carry out this argument on local weights. Changing a frame adds the same pluriharmonic function to both weights; maximum commutes with that common addition, so the resulting local metric weights glue. One must still use the global degree theorem to identify their total masses.

13.14 A capacity estimate on the same domain

Assume additionally that $0 \in \mathcal{P}$, that convex combinations remain in $\mathcal{P}$, and that symmetric multilinear positive mixed measures are defined, with the usual expansion for $\theta + \mathrm{d}'\mathrm{d}''(tv)$. These assumptions hold only on the specified domain. For a Borel set $E \subset X$, define

$$\mathrm{Cap}_{\mathcal{P}}(E) = \sup_{v\in\mathcal{P},\, -1\leq v\leq 0} \int_E \mathrm{MA}(v).$$

This definition records its testing class in the subscript. Different classes may give different capacities, even when their operators agree on the intersection.

Proposition 13.14.1. *For $u \in \mathcal{P}$ with $u \leq 0$, $s \geq 0$ and $0 < t \leq 1$,*

$$t^n\,\mathrm{Cap}_{\mathcal{P}}(\{u < -s-t\}) \leq \int_{\{u<-s\}} \mathrm{MA}(u),$$

where n is the number of factors in the Monge–Ampère operator.

Proof. For an admitted v with $-1 \le v \le 0$, put $w = tv - s$. Since $0 < t \le 1$, convexity and constant stability make w admitted. Its curvature is $t(\theta + \mathrm{d}'\mathrm{d}''v) + (1-t)\theta$. The mixed expansion and positivity give $\mathrm{MA}(w) \ge t^n \mathrm{MA}(v)$. Moreover,

$$\{u < -s - t\} \subseteq \{u < w\} \subseteq \{u < -s\}.$$

The comparison theorem therefore yields

$$t^n \int_{\{u<-s-t\}} \mathrm{MA}(v) \le \int_{\{u<w\}} \mathrm{MA}(w) \le \int_{\{u<w\}} \mathrm{MA}(u) \le \int_{\{u<-s\}} \mathrm{MA}(u).$$

Take the supremum over the admitted test potentials v. □

Monotonicity, countable subadditivity and continuity along increasing Borel sets follow directly from the definition: each test supplies a positive measure, and increasing suprema commute. Also $\mathrm{Cap}_{\mathcal{P}}(X) = V$, since $v = 0$ is an allowed test and all test measures have mass V. Continuity along decreasing compact sets does not follow from this argument.

Example 13.14.2. On $[0,1]$, the set function $c(E) = \sup_{k\ge1} \delta_{1/k}(E)$ is a supremum of positive measures of mass one. Yet for $K_j = [0, 1/j]$ one has $c(K_j) = 1$ for every j, while $c(\bigcap_j K_j) = c(\{0\}) = 0$. Thus the measure properties of individual tests do not by themselves make their supremum a Choquet capacity. This example concerns the abstract inference, not a counterexample to a capacity theorem proved for a particular psh class.

The continuous comparison and sublevel estimate are therefore available consequences once their explicit inputs have been verified. Quasicontinuity, pluripolar-set characterizations, monotone convergence for discontinuous bounded potentials, and a Dirichlet existence theorem require further results. The elementary arguments above do not remove those obligations.

References. The proofs combine maximum locality and the fixed-mass identity, followed by the positive mixed expansion. Their analytic inputs are discussed in Chapters 13, 19 and 20; compare the model-based pluripotential framework of [BFJ15].

Chapter 14

Harmonic kernels and potential independence

14.1 Skeletal currents and harmonic charts

14.1.1 The quantifier in the definition

Let T have bidimension (p, p). A calibrated skeletal subset P describes T relative to a chart f if

$$\langle T, \rho\omega \rangle = \int_P \rho\, \omega|_P$$

for every smooth form ω tropicalized by f and every compactly supported smooth scalar ρ. In Definition 7.5.1, the current is skeletal when such a local description exists relative to *every* chart. The describing subset and calibration may depend on the chart.

This last quantifier is the essential point. Being supported on one skeleton only says where a current vanishes. Being skeletal specifies how it acts and how that action transforms when more tropical coordinates are introduced. The integration current of the ambient tropical space is skeletal because every chart has a canonically calibrated locus describing its top-dimensional integration.

Skeletal currents are symmetric and of order zero in the source construction. Positive describing calibrations give a correspondingly strong positivity statement. These conclusions come from their geometric description, inde-

pendently of the false general implication from weak positivity to order zero discussed in Appendix A.

14.1.2 A simple example and a misleading near-example

On a weighted graph, integration over a collection of edges with constant compatible weights is a skeletal current. Multiplying by a nonconstant smooth scalar gives a current with the same support, but its edge density is no longer locally constant. It need not remain skeletal in this particular sense, and it need not remain closed. Thus support, order zero, skeletal representability, and closedness are four different properties.

Similarly, a Radon measure supported on a compact skeleton may have a singular continuous density or an arbitrary atomic distribution. It is a perfectly legitimate measure. It does not follow that it is a skeletal current of the required calibrated type. A theorem about the latter cannot be applied solely from the support of the former.

14.1.3 What harmonicity asks to vanish

The harmonic charts of CLD25 are built from the source's PL-generated harmonic functions and current conditions. Their coordinates have vanishing appropriate Hessian currents, but their ordinary CLD smoothness is not assumed. Harmonicity is intended to preserve the integration and balancing needed for differential operations when the coordinate class is enlarged.

For a skeletal current, a coordinate h interacts with the calibration through $\mathrm{d}'\mathrm{d}''(hT)$. If this vanishes, the weighted slopes of h cancel in the relevant skeletal description. This is a stronger compatibility with T than merely $\mathrm{d}'\mathrm{d}''[h] = 0$ on the ambient integration current. That difference is exactly why the Bedford–Taylor property later appears in the harmonic product theorem.

14.1.4 The mechanism of the harmonic product formula

Proposition 8.11.1 assumes that T is skeletal and has the Bedford–Taylor property. For a G-form α locally obtained from harmonic coordinates, it proves the expected differential identities

$$d'(T \wedge \alpha) = T \wedge d'\alpha, \qquad d''(T \wedge \alpha) = T \wedge d''\alpha.$$

The proof applies Stokes to the skeletal pieces. The internal boundary terms involve the outgoing derivatives of the harmonic coordinate functions. The Bedford–Taylor property turns their ambient Hessian vanishing into $\mathrm{d}'\mathrm{d}''(hT) = 0$, which forces the required weighted cancellation. Thus the hypothesis has a concrete job: it makes the new coordinates harmonic for the current being multiplied.

Corollary 8.11.2 then identifies certain recursively defined BT products with products by the corresponding G-forms. Its skeletal and BT hypotheses are retained here. The subsequent Corollary 8.11.3 is stated for an arbitrary positive closed current but cites this restricted comparison. Section 14.2 gives an explicit counterexample in the abstract tropical category. The restricted theorem cannot be extended by simply dropping those hypotheses.

14.2 The kernel problem: a complete tropical calculation

14.2.1 The equality one wants to descend

For an admitted continuous potential u and a positive closed current T, the expression $\mathrm{d}'\mathrm{d}''(uT)$ is defined. To say that it depends only on $\mathrm{d}'\mathrm{d}''[u]$ asks for

$$\mathrm{d}'\mathrm{d}''[h] = 0 \quad \Longrightarrow \quad \mathrm{d}'\mathrm{d}''(hT) = 0 \tag{14.2.1}$$

for differences h of admitted potentials. This is a statement about the kernel of the ambient Hessian acting on T. It does not follow from approximation independence, which says that two approximating sequences for the *same function* give the same product.

For smooth h, closedness of T gives $\mathrm{d}'\mathrm{d}''(hT) = \mathrm{d}'\mathrm{d}''h \wedge T$, so the implication holds. For a smooth analytic-unit logarithm, this proves exactly the gluing needed for line-bundle weights. For a nonsmooth current-harmonic h, the same Leibniz proof is not available.

14.2.2 An admissible reducible tropical space

Let $H = \mathbb{R} \times \{0\}$, $V = \{0\} \times \mathbb{R}$, and $X = H \cup V$. Give each of the four rays weight one. Use the refined affine structure of CLD25 Example 6.1.4: affine functions are locally restrictions of ambient affine functions on $\mathbb{R}^2$. In particular, not every PL function is declared affine.

Here are the category checks, since the example is meant to test an abstract tropical theorem. The underlying polyhedral structure has the G-tropical and skeletal structures of Examples 5.1.4 and 5.2.3. It is pure of dimension one and has the required richness. Ambient coordinates separate points and differential directions. An affine germ on a polyhedral domain extends from its ambient affine expression, and such domains are locally Boolean combinations of affine inequalities; these give the two decency conditions in Definition 6.3.1. The calibration balances at the vertex because

$$e_1 - e_1 + e_2 - e_2 = 0.$$

Every local affine chart preserves this equation. Boundaries of local polyhedral domains have zero one-dimensional measure. Thus Definition 6.6.2 permits the empty boundary. The larger boundary allowed as a general choice in Example 6.6.3 does not force the vertex to be a boundary point in this balanced example.

Smooth tests for this structure are locally restrictions of ambient smooth superforms. In particular, their restrictions to each whole line are smooth through the origin, and scalar tests have one common value at the vertex.

14.2.3 Two potentials with the same ambient curvature

Put $u = |x||_X$ and $v = |y||_X$. The restrictions of

$$\sqrt{x^2 + \varepsilon^2}, \qquad \sqrt{y^2 + \varepsilon^2}$$

are smooth psh functions decreasing uniformly to u, v as $\varepsilon \downarrow 0$. Thus both belong to the one-stage continuous approximation class. For every smooth compactly supported scalar test ϕ,

$$\langle \mathrm{d}'\mathrm{d}''[u], \phi\rangle = \int_{\mathbb{R}} |x| \frac{d^2}{dx^2}\phi(x,0)\, dx = 2\phi(0,0),$$
$$\langle \mathrm{d}'\mathrm{d}''[v], \phi\rangle = \int_{\mathbb{R}} |y| \frac{d^2}{dy^2}\phi(0,y)\, dy = 2\phi(0,0).$$

Hence $\mathrm{d}'\mathrm{d}''[u] = \mathrm{d}'\mathrm{d}''[v] = 2\delta_0$ on the same actual test space.

Now let $T = \delta_H$, integration of $(1,1)$-tests along the horizontal line. This is a positive current, and Stokes on the whole line proves $d'T = d''T = 0$. Multiplication by the continuous functions gives

$$\mathrm{d}'\mathrm{d}''(uT) = 2\delta_0, \qquad \mathrm{d}'\mathrm{d}''(vT) = 0. \tag{14.2.2}$$

The current T is therefore positive closed but fails the BT kernel property. All identities use the same tests; no tensor-product-only testing or change of category is hidden in the calculation.

14.2.4 The consequence for harmonic pullback

The function $h = u - v$ is PL and satisfies $\mathrm{d}'\mathrm{d}''[h] = 0$. It is harmonic by CLD25 Definition 7.8.2. Take the harmonic map $f = -h : X \to \mathbb{R}$ and the convex function $w(t) = t$. Then $f^*w = -h$ is a difference of the admitted psh potentials, but

$$\mathrm{d}'\mathrm{d}''\big((f^*w)T\big) = -2\delta_0.$$

This is not positive. Thus Corollary 8.11.3 is false in its unrestricted abstract-tropical formulation. The missing skeletal/BT hypothesis in its cited argument is not merely cosmetic. This calculation strengthens the hypothesis-transfer observation in the preceding audit section to a counterexample in the explicitly verified category.

The example does not satisfy the hypotheses of a smooth Berkovich local-potential problem. It does not refute a separate analytic theorem based on residual geometry. Its conclusion is confined to the stated abstract tropical generality.

14.2.5 The graph-support statement also detects the problem

On $X \times \mathbb{R}$, with coordinate t in the second factor, put $S = \delta_{H\times\mathbb{R}}$ and use $f = h$. The graph-intersection construction of §9.5 is

$$S \cap \Gamma_f = \mathrm{d}'\mathrm{d}''\big(\max\{h, t\}\, S\big).$$

On the open set

$$W = \big(X \cap \{|x|, |y| < 1/4\}\big) \times (-5/4, -3/4)$$

we have $h > t$. Hence W is disjoint from Γ_f, but the restriction of the displayed current to W is

$$2\delta_0 \boxtimes [1]_{\mathbb{R}},$$

which is nonzero. Indeed, take a test $\eta = \rho(x, y)\chi(t)\, d't \wedge d''t$ supported in W, with $\rho(0) = 1$ and $\chi \geq 0$ nonzero. Its pairing is $2\int \chi(t)\, dt > 0$.

This disproves the unrestricted harmonic graph-support assertion in Lemma 9.5.4. Its printed proof uses a BT hypothesis on S that is not in the

statement. For an affine f, the relevant potential is smooth affine off the graph and the closed-current Leibniz calculation does prove the support assertion. A version with additional BT hypotheses must verify the corresponding stability and potential class.

14.2.6 What remains a valid research question

The cross shows that arbitrary-current kernel descent cannot be proved from the abstract tropical axioms alone. A positive answer on a smooth analytic space must use extra analytic geometry or a more restrictive harmonic kernel. Possible inputs include residual numerical triviality, approximation preserving the relevant kernel, or a representation theorem for the allowed currents. Finding such an input is a substantive theorem, not a change of notation.

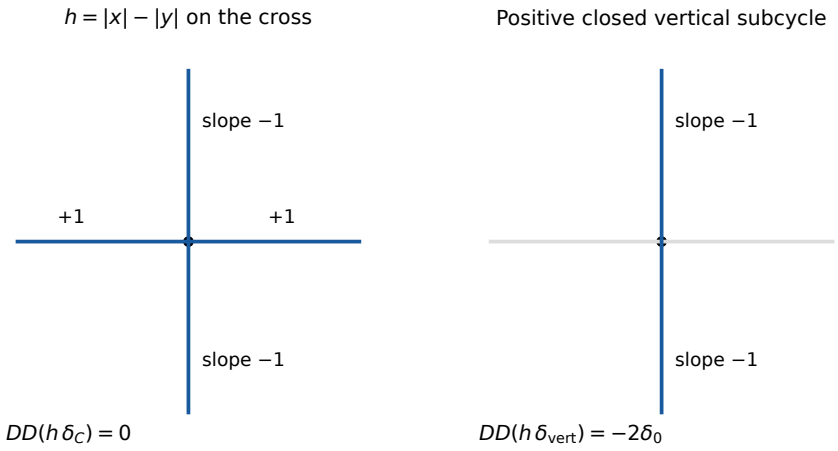

Figure 14.1: The outgoing slopes of h cancel on the whole balanced cross, but not on the positive closed vertical subcycle. This is the kernel obstruction of Section 14.2.

14.3 A local classification of the graph kernel property

The tropical cross gives a counterexample, but its mechanism is more general. On a balanced graph, the ambient Laplacian and the Laplacian weighted by another current are two linear functionals on the vector of outgoing slopes. Potential independence asks for inclusion of their kernels. This elementary linear-algebra problem can be solved completely.

Let a neighbourhood of a vertex v be a union of k rational rays with primitive outgoing vectors $u_1, \dots, u_k \in N$, parameterized by lattice length $t \geq 0$. Give them positive weights m_i satisfying $\sum_i m_i u_i = 0$. Smooth tests are restrictions of ambient smooth superforms. Let T_λ be integration along the same rays with nonnegative constant weights λ_i. We work with compactly supported tests in this neighbourhood, so artificial outer endpoints contribute no boundary terms.

Lemma 14.3.1. *The current T_λ is closed under both d' and d'' if and only if $\sum_i \lambda_i u_i = 0$. If this balancing condition holds and a continuous function h is affine on each ray near v, with outgoing slopes s_i, then its vertex contribution is*

$$d'd''(hT_\lambda) = \left(\sum_i \lambda_i s_i \right) \delta_v \quad \text{near } v.$$

Proof. Stokes on each ray expresses the boundary of its integration current as evaluation at v against the outgoing tangent. Summing with weights gives contraction with $\sum_i \lambda_i u_i$. Thus balancing is sufficient. Conversely, choose an ambient covector a and a smooth cutoff equal to one near v. The associated one-form test detects $\langle a, \sum_i \lambda_i u_i \rangle$. Vanishing for every a forces balancing. The two differentials give the same condition in their respective exterior factors.

For the second assertion, write $h_i(t) = h(v) + s_i t$. Twice integrating by parts against a scalar test ψ gives the vertex terms $\lambda_i s_i \psi(v) - \lambda_i h(v) \partial_{u_i} \psi(v)$. The terms containing $h(v)$ sum to zero by balancing. The remaining sum is the displayed atom. There is no interior term because each h_i is affine near the vertex. □

Theorem 14.3.2. *Assume T_λ is closed. The following conditions are equivalent:*

1. *For every continuous, raywise affine germ h at v, ambient harmonicity $\sum_i m_i s_i = 0$ implies $d'd''(hT_\lambda) = 0$ near v.*
2. *There is a constant $c \geq 0$ such that $\lambda_i = cm_i$ for every i.*

Thus, in this class of currents and PL germs, the full ambient harmonic kernel acts trivially precisely when the current has a common density relative to the ambient calibration.

Proof. Any vector $s = (s_1, \ldots, s_k) \in \mathbb{R}^k$ is realized by a continuous raywise affine germ with a prescribed common value at v. By Lemma 14.3.1, condition (1) is therefore

$$\ker(m_1, \ldots, m_k) \subseteq \ker(\lambda_1, \ldots, \lambda_k).$$

Fix an index j. Since $m_j > 0$, every s decomposes as

$$s = \left(s - \frac{m \cdot s}{m_j} e_j\right) + \frac{m \cdot s}{m_j} e_j,$$

with the first term in $\ker m$. Kernel inclusion gives $\lambda \cdot s = (\lambda_j/m_j)(m \cdot s)$ for all s, so $\lambda = cm$ with $c = \lambda_j/m_j \geq 0$. Conversely, proportionality gives $\lambda \cdot s = c(m \cdot s)$, proving (1). It also automatically gives balancing from that of m. □

The theorem concerns all continuous raywise affine germs. If a particular analytic theory admits a smaller harmonic class, its kernel condition can be weaker. In particular, the theorem does not assert that every such germ on every graph is the restriction of an analytic harmonic function. That realization problem involves the analytic or residual geometry absent from this linear-algebra calculation.

Corollary 14.3.3. *Let a connected finite balanced graph have positive ambient edge weights, and let a closed polyhedral integration current have constant nonnegative weights on its edges. If the local property of Theorem 14.3.2 holds at every vertex, then the current is one constant nonnegative multiple of the ambient integration current.*

Proof. At a vertex, the theorem says that the ratios of current weight to ambient weight are the same on all incident edges. An edge has one ratio

at both ends because both of its weights are constant. Connectedness propagates the ratio through the graph. The statement is componentwise if the graph is disconnected. □

14.3.1 Why ordinary closedness is weaker

An ambient affine function has slopes $s_i = \langle a, u_i \rangle$. Closedness gives $\lambda \cdot s = \langle a, \sum_i \lambda_i u_i \rangle = 0$. Thus closedness already annihilates all slopes coming from ambient affine functions. The harmonic kernel usually contains more slopes: it is the hyperplane $m \cdot s = 0$, whereas the affine slopes form the image of $N^*_{\mathbb{R}} \to \mathbb{R}^k$. Equality of these two spaces requires an additional rank condition.

Example 14.3.4. For the standard trivalent tropical line, $u_1 = (1, 0)$, $u_2 = (0, 1)$ and $u_3 = (-1, -1)$. Balancing forces $\lambda_1 = \lambda_2 = \lambda_3$. With ambient weights one, every closed current in this constant-edge class therefore satisfies the PL kernel property.

For the cross, the directions are $e_1, -e_1, e_2, -e_2$. Balancing only forces weights of the form (a, a, b, b). Theorem 14.3.2 requires $a = b$. The slopes $(1, 1, -1, -1)$ are ambient harmonic and give weighted Laplacian $2(a - b)\delta_v$. Taking $a = 1$, $b = 0$ recovers the earlier counterexample. The failure is measured by the difference between the densities on the two crossing lines.

This calculation explains the role of an extra BT property in a harmonic-coordinate theorem. Such a property is a compatibility requirement between the allowed harmonic functions and the current's calibration. It is not another name for positivity and closedness. In a Berkovich theorem, proving that compatibility may require residual geometry or a representation theorem; it cannot be replaced by the smooth Leibniz rule for coordinates which are not smooth in the original sheaf.

14.4 The obstruction to gluing local potentials

A local potential theorem and a global potential theorem are different assertions even on a smooth real affine manifold. Local potentials differ by elements of the Hessian kernel. Their differences form a cocycle, and this cocycle is the exact obstruction to choosing one global potential. This elementary description is useful when comparing Green currents, metric weights and cohomological vanishing.

Let M be a paracompact real affine manifold, with affine transition maps, and let Aff_M be the sheaf of locally affine real functions. On convex coordinate charts, Theorem 11.5.3 gives convex potentials for any ordinary positive closed $(1,1)$ current. Affine coordinate changes preserve Hessians and convexity. Choose a cover (U_i) by such charts and potentials u_i.

Proposition 14.4.1. *On every overlap, $a_{ij} = u_j - u_i$ is locally affine, and*

$$a_{ij} + a_{jk} = a_{ik}.$$

The resulting class in $\check{H}^1(M, \mathrm{Aff}_M)$ is independent of the local potentials and cover. It vanishes if and only if the current is the Hessian of a global finite locally convex function.

Proof. The difference has zero Hessian, hence is affine on each connected overlap component by Proposition 11.4.1. The cocycle identity is subtraction of three functions. If u_i is replaced by another potential, its difference from the old one is a locally affine function b_i, and the new cocycle differs by $b_j - b_i$. Refinement restricts the same cocycle. Thus the class is intrinsic.

If the class vanishes, after refinement there are locally affine b_i with $a_{ij} = b_j - b_i$. Then $u_i - b_i$ agree on overlaps and glue to a finite continuous function u. Locally it is convex and has the prescribed Hessian. Conversely, a global potential gives $b_i = u_i - u$ and makes the cocycle a coboundary. □

The coefficient sheaf is Aff_M, not the constant sheaf $\mathbb{R}$. On a singular tropical space, the kernel of the Hessian current can differ from the restrictions of affine functions. Replacing that kernel by an ambient affine sheaf would change the obstruction group. The tropical cross in Chapter 14 gives an explicit reason for retaining the actual kernel.

Example 14.4.2 (A positive curvature class on a real torus)**.** Let $M = \mathbb{R}^n/\Lambda$, and let H be a positive definite symmetric matrix. The form $\theta = \sum H_{ij} d'x_i \wedge d''x_j$ descends to M. Locally it is DDq for $q(x) = \frac{1}{2} x^{\mathsf{t}} H x$. On overlaps of lifted charts differing by $\lambda \in \Lambda$,

$$q(x+\lambda) - q(x) = x^{\mathsf{t}} H \lambda + \tfrac{1}{2} \lambda^{\mathsf{t}} H \lambda.$$

This is an affine cocycle. It cannot be a coboundary of local affine functions, because a global distributional potential u would give

$$0 = \langle DD[u], \theta^{n-1} \rangle = \int_M \theta^n > 0,$$

a contradiction. The first equality is distributional integration by parts and $DD(\theta^{n-1}) = 0$. Thus a perfectly regular positive curvature form can have local convex potentials and no global scalar potential.

14.4.1 Metric weights solve a different gluing problem

For a line bundle with local frames e_i and transitions $e_j = g_{ij}e_i$, additive metric weights satisfy

$$u_j - u_i = -\log|g_{ij}|.$$

The transition functions are prescribed by the line bundle. Their logarithms are smooth pluriharmonic where g_{ij} are analytic units, so the local currents $DD[u_i]$ glue even when the weights do not glue as scalar functions. A metrized line bundle is therefore naturally described by local potentials with a specified cocycle. The global scalar-potential problem asks for that cocycle to be trivial in the relevant kernel sheaf.

This also explains a limitation of curvature comparison. Equal local curvatures imply that the difference of weights lies in a Hessian kernel. They do not identify the metric constants or the transition cocycle without further information. In the real affine case the kernel is fully described above; in a non-Archimedean form theory its description depends on the chosen tests and regularity class.

References. The local real potential theorem is [Lag12, Proposition 1.13]. The cocycle argument is the standard gluing construction applied to its affine kernel; the torus automorphy formula is compatible with the metric setting of [BGJK25, Sections 7–8].

Part IV

Delta and harmonic calculi

Chapter 15

Polyhedral intersection calculus

15.1 Tropical preforms and their representations

Let N be a lattice, let $\widetilde{\Omega} \subset N_{\mathbb{R}}$ be open, and let C_i be tropical cycles with smooth real weights as in Chapter 5. Their currents δ_{C_i} have bidegree equal to their codimension.

Definition 15.1.1 (Tropical delta-preform)**.** A delta-preform of bidegree (p, q) on $\widetilde{\Omega}$ is a supercurrent admitting an expression

$$\alpha = \sum_{i=1}^{m} \alpha_i \wedge \delta_{C_i}, \qquad \alpha_i \in A^{p-\ell_i, q-\ell_i}(\widetilde{\Omega}), \qquad \operatorname{codim} C_i = \ell_i.$$

The vector space of these currents is denoted $P^{p,q}(\widetilde{\Omega})$. If every $\ell_i = \ell$, the expression has pure codimension ℓ; the coefficient bidegree is then $(p-\ell, q-\ell)$.

The defining data are representations of a current, rather than additional labels attached to it. The product on P combines the wedge product of the coefficients with stable intersection of tropical cycles. Its independence of the representation is a theorem [GK17, Definition 2.9 and Proposition 2.12]. It is not a product defined on arbitrary supercurrents.

Remark 15.1.2 (Codimension zero does not mean smooth). With smooth weights allowed, a codimension-zero tropical cycle on $N_{\mathbf{R}}$ is a piecewise smooth function on that space. Consequently, a codimension-zero delta-preform can have piecewise smooth coefficients [GK17, Remark 1.7 and Example 2.10]. For example, $|t|[\mathbf{R}]$ has codimension zero but is not represented by a smooth function near 0. Thus codimension and regularity are different attributes.

15.2 Recovering coefficients from a polyhedral current

The product of delta-preforms is a product of currents, not of chosen lists of generators. Its construction therefore needs a detection statement before a multiplication formula. We give the argument in fixed polyhedral codimension, as in GK17, Sections 2.11–2.12.

Lemma 15.2.1. *Let $\mathscr{C}$ be a locally finite polyhedral complex in $N_{\mathbb{R}}$, and let*

$$S = \sum_{\sigma \in \mathscr{C}_d} \alpha_\sigma \wedge \delta_\sigma,$$

where each α_σ is a smooth tangential superform on σ, extending smoothly to a neighbourhood in its affine span. If $S = 0$, then each $\alpha_\sigma = 0$. Consequently two such currents on a common complex are equal exactly when their tangential coefficients agree.

Proof. Fix a point in the relative interior of one d-cell. A sufficiently small neighbourhood avoids the other d-cells, since their intersections with this cell are proper faces and the complex is locally finite. On that neighbourhood, testing S is testing α_σ by integration on the affine span of σ.

Choose affine coordinates on this span. For any coefficient of α_σ, wedge with the complementary primed and double-primed basis elements, choosing their order to fix the sign, and multiply by an arbitrary compactly supported scalar test. Such a test extends to the ambient space by a linear projection and a normal cutoff. The vanishing of S says that the integral of the chosen coefficient against every scalar test is zero. The fundamental lemma for distributions gives that coefficient zero. All coefficients vanish on the relative interior and, by continuity, on its closure. Repeat for each cell. □

A representative $\sum_i \alpha_i \wedge \delta_{C_i}$ has, after a common subdivision, the coefficient $\sum_i m_{i,\sigma}\alpha_i|_\sigma$ on a cell σ. This coefficient is intrinsic to the current on that complex. It is a tangential form: adding an ambient form which restricts to zero on σ changes nothing. This last point is essential when the support has positive codimension.

15.3 The geometric input for stable intersection

We use the stable-intersection theorem for tropical cycles with smooth weights in GK17, Section 1.4. After common subdivision, a generic displacement computes the coefficient of a codimension $\ell+\ell'$ intersection face τ by summing over contributing pairs of faces σ, σ', of codimensions ℓ, ℓ'. A pair contributes only if it survives the displacement test and $N_\sigma + N_{\sigma'}$ has full rank. Its factor is

$$[N : N_\sigma + N_{\sigma'}]\, m_\sigma m_{\sigma'}.$$

The cycle theorem asserts that the resulting cycle is independent of the permitted sufficiently small generic displacement and of subdivision, and that the cycle product is associative and commutative. We use those assertions as geometric inputs. They are not consequences of the coefficient-detection lemma.

Theorem 15.3.1 (Representation independence)**.** *Assume the stated cycle-intersection theorem. For delta-preforms of fixed polyhedral codimensions, the formula*

$$\left(\sum_i \alpha_i \wedge \delta_{C_i}\right) \wedge \left(\sum_j \beta_j \wedge \delta_{D_j}\right) = \sum_{i,j} (\alpha_i \wedge \beta_j) \wedge \delta_{C_i \cdot D_j}$$

is independent of the chosen representations. It is bilinear, associative and graded commutative for total superform degree, and agrees with multiplication by a smooth superform.

Proof. Choose a common complex for all cycles in two proposed representations of each factor, refining further so that the displacement formula applies. Let a_σ and $b_{\sigma'}$ be the intrinsic tangential coefficients of the two currents on this complex. On an intersection face τ the proposed product has coefficient

$$\sum_{\sigma,\sigma'} [N : N_\sigma + N_{\sigma'}](a_\sigma|_\tau) \wedge (b_{\sigma'}|_\tau),$$

with the same contributing-pair rule as the cycle formula. This expression follows by expanding the finite sums and collecting the cycle weights. Lemma 15.2.1 makes $a_\sigma, b_{\sigma'}$ independent of the initial lists of generators. Restriction to τ is well defined for tangential forms, because $T\tau$ lies in both tangent spaces. Thus the coefficient of every intersection face is independent of those lists. Detection proves equality of the resulting currents.

Bilinearity is immediate. Once representation independence is established, expand a triple product using the original smooth coefficients and cycles. Associativity of wedge and of the cycle product identifies the two expansions. Swapping the factors changes the smooth coefficients by the usual total-degree sign; twice the polyhedral codimension is even and adds no sign. Finally, a smooth form is represented using the unit cycle $N_{\mathbb{R}}$, so the formula reduces to its usual multiplication with the current. □

This proof separates two independence questions. The tropical cycle theorem controls displacement and subdivision. The coefficient argument controls representations of an already defined current. Conflating them hides the main point of GK17, Proposition 2.12. Neither independence statement defines a multiplication on arbitrary distributional currents.

15.4 Transverse lines and the determinant

Proposition 15.4.1. *In $\mathbb{R}^2$ with lattice $\mathbb{Z}^2$, let L_a, L_b be distinct lines through the origin with primitive integral direction vectors a, b. With weight one on each line,*

$$\delta_{L_a} \wedge \delta_{L_b} = |\det(a, b)|\delta_0.$$

If the two lines coincide, their stable intersection is zero.

Proof. Distinct lines meet transversely. After any sufficiently small generic translation they meet at one point tending to the origin. The cycle multiplicity is $[\mathbb{Z}^2 : \mathbb{Z}a + \mathbb{Z}b] = |\det(a, b)|$. For coincident lines choose a translation transverse to the line. The displaced lines are disjoint, so no face contributes. Displacement independence makes this the stable product. □

For $u = \max(0, x)$ and $v = \max(0, x + 2y)$, the two divisor directions may be chosen as $(0, 1)$ and $(2, -1)$. Their determinant has absolute value two, so $\mathrm{d}'\mathrm{d}''[u] \wedge \mathrm{d}'\mathrm{d}''[v] = 2\delta_0$ in this calculus. In contrast, the stable square

of the straight divisor $\{x = 0\}$ is zero. These identities express geometric intersection rules; they are not prescriptions for squaring Dirac distributions in ordinary distribution theory.

15.5 Balancing as cancellation of boundary currents

The corner calculation in Chapter 10 has a useful converse. For constant weights, balancing is precisely what removes the boundary term in Stokes' formula. This gives a direct way to prove that a PL corner divisor is again balanced. Smoothly varying weights require an additional distinction, because their derivatives need not vanish.

Proposition 15.5.1. *Let C be a locally finite, pure d-dimensional rational polyhedral complex in $N_{\mathbb{R}}$ with constant real weights m_σ. Tests have compact support away from any designated boundary. The following conditions are equivalent: C is balanced; $d'\delta_C = 0$; $d''\delta_C = 0$.*

Proof. Fix a codimension-one face τ. Write $n_{\sigma,\tau}$ for an outgoing primitive normal lift and put

$$b_\tau = \sum_{\sigma \supset \tau} m_\sigma n_{\sigma,\tau} \pmod{N_{\tau,\mathbb{R}}}.$$

Apply ordinary Stokes on each maximal polyhedron to the coefficients of a superform. The interior derivatives of the weights vanish. Along τ, all tangential coordinates and the induced lattice measure agree, so the sum of the boundary contractions depends only on b_τ. A tangent change of normal has zero contraction in the normal quotient. Hence $b_\tau = 0$ makes the boundary contribution vanish. Summing over the finitely many cells meeting a test support proves both closedness assertions.

Conversely, take a point in the relative interior of τ and a small neighbourhood meeting no other codimension-one face. Choose a compactly supported scalar bump on τ whose lattice integral is one. Given any real linear functional ℓ on $N_{\mathbb{R}}/N_{\tau,\mathbb{R}}$, extend the bump to an ambient test and choose its remaining differential factors to be a tangential volume element and the normal covector ℓ. The same Stokes calculation pairs the boundary current with this test as $\ell(b_\tau)$, up to one fixed nonzero sign. If $d'\delta_C = 0$, every such pairing

vanishes, so $b_\tau = 0$. The argument for d'' is identical with the two copies of the cotangent space exchanged. □

Theorem 15.5.2 (A PL corner is balanced)**.** *Let C have constant real weights and be balanced. If u is continuous and affine on the cells of a subdivision of C, the corner weights of Proposition 10.5.1 define a balanced cycle $u \cdot C$, and*

$$\mathrm{d}'\mathrm{d}''(u\delta_C) = \delta_{u\cdot C}.$$

Proof. On a maximal cell, the second derivatives of u vanish. Integrate twice by parts in the pairing of $u\delta_C$ with $\mathrm{d}'\mathrm{d}''$ of a test. The terms containing the value of u times a normal derivative of the test cancel along each facet by continuity and balancing. The remaining coefficient on a facet τ is

$$\sum_{\sigma \supset \tau} m_\sigma \ell_\sigma(n_{\sigma,\tau}) - \ell_\tau\left(\sum_{\sigma \supset \tau} m_\sigma n_{\sigma,\tau}\right),$$

where ℓ_σ and ℓ_τ are the linear parts of u. This proves the current identity, including the tangent correction. It also proves that the result is a polyhedral current with constant facet weights. Now

$$d'\delta_{u\cdot C} = d'\mathrm{d}'\mathrm{d}''(u\delta_C) = 0, \qquad d''\delta_{u\cdot C} = 0.$$

Proposition 15.5.1 therefore proves balancing of the corner cycle. This last step uses only the differential identities and the preceding Stokes characterization. □

The proof also completes subdivision independence in this constant-weight PL setting. The distribution $\mathrm{d}'\mathrm{d}''(u\delta_C)$ is unchanged by subdivision. On a common refinement, coefficient detection identifies its facet weights. Thus two descriptions give the same weighted cycle; the new facets inside an affine piece already have zero weight by Proposition 10.5.1.

15.5.1 Smooth weights and the cellwise differential

Balancing of smooth weights is a pointwise condition along a facet. It cancels boundary contributions but does not kill derivatives inside cells. Already on $N_\mathbb{R} = \mathbb{R}$, every smooth weight $m(t)$ on the full line satisfies the codimension-zero balancing condition, whereas

$$d'(m\delta_\mathbb{R}) = m'(t)d't \wedge \delta_\mathbb{R}.$$

For $m(t) = e^t$, the right side is nonzero. Thus "balanced with smooth weights" and "closed integration current" are different assertions. The operators d'_P, d''_P record the cellwise terms. The difference between a distributional differential and its cellwise counterpart is the boundary operator. This distinction is used when selecting the universally closed generators in the GK sheaf.

15.6 Why the fan product is independent of displacement

For a finite complete rational fan Σ in a rank-r lattice N, a codimension-p Minkowski weight assigns a real number to each $(r-p)$-dimensional cone and satisfies balancing at the next lower-dimensional cones. There is a geometric reason for exactly these linear equations.

Let X_Σ be the associated complete toric variety. A cone σ of codimension p has orbit closure $V(\sigma)$ of dimension p. An operational Chow class $c \in A^p(X_\Sigma)$ consequently defines

$$m_c(\sigma) = \deg(c \cap [V(\sigma)]).$$

The dimension convention is important: the codimension of the cone is the dimension of its orbit closure. For a cone τ of codimension $p+1$ and a character $u \in M \cap \tau^\perp$, the divisor of that character on $V(\tau)$ gives the relation

$$\sum_{\substack{\sigma \supset \tau \\ \dim \sigma = \dim \tau + 1}} \langle u, n_{\sigma,\tau} \rangle [V(\sigma)] = 0 \quad \text{in } A_p(X_\Sigma).$$

Applying c and taking degree says that the weighted sum of the normal vectors pairs to zero with every such u. This is precisely balancing modulo N_τ. Thus balancing is the numerical expression of principal-divisor relations.

Theorem 15.6.1 (The toric input)**.** *For complete Σ, the assignment $c \mapsto m_c$ identifies operational Chow cohomology, with real coefficients, with Minkowski weights. Its product is computed by the fan displacement formula: at a cone γ of codimension $p+q$, sum*

$$[N : N_\sigma + N_\tau]\, m_c(\sigma) m_{\widetilde{c}}(\tau),$$

over cones of codimensions p, q containing γ whose generic displacement meets. This is the Fulton–Sturmfels theorem; the identification and the diagonal-degeneration formula are used here as inputs.

Displacement independence now has a precise proof from that input. Two generic vectors give two expressions for the same number

$$\deg\big((c\widetilde{c}) \cap [V(\gamma)]\big).$$

They must agree even though the contributing pairs may differ. Associativity and commutativity are inherited from the Chow product, not from an assertion that the displaced set-theoretic intersections are identical. A common toric subdivision compares different fans. Pullback of operational classes and the projection formula preserve the relevant degrees, which is the geometric source of refinement compatibility.

15.6.1 From constant fans to smooth polyhedral weights

Proposition 15.6.2. *Assume the toric fan product and its refinement compatibility. The displacement construction for rational polyhedral cycles with smooth weights is well defined, balanced pointwise, and compatible with subdivision. Its products are associative and commutative.*

Proof. Fix a point x in a common polyhedral complex. Replace every cell containing x by its local tangent cone at x, and freeze its weight at the value at x. The pointwise balancing equations become exactly the balancing equations for this constant-weight fan. A compatible complete fan is obtained by adding zero-weight cones and refining. For each prospective intersection face, the small-displacement incidence condition on the original cells becomes the displacement condition on these tangent cones. The local coefficient is therefore the constant-fan product coefficient. It is independent of the generic vector and of the chosen complete refinement by Theorem 15.6.1.

On any fixed face, this coefficient is a finite sum of products of restrictions of the original smooth weights, multiplied by constant lattice indices. It is therefore smooth on that face. At a lower-dimensional face, freeze the weights again at a point. The balancing equation for the product is the constant-fan balancing equation there, so it holds. The same procedure shows subdivision compatibility: both subdivisions give the same local fan product at every point.

Finally, the local fan of a product at x is the product of the local fans at x, with their frozen weights. Thus both bracketings of a triple product have the same coefficient by associativity of the constant-fan product. Swapping two

factors is treated in the same way. These are pointwise identities of smooth coefficient functions and hence identities of the weighted cycles. □

This argument uses values of weights, not derivatives of weights. It explains why stable intersection extends to smooth weights even though their integration currents need not be closed. Combining it with Theorem 15.3.1 proves representation independence of the resulting delta-preform algebra. The geometric and distributional independence statements are different steps, now linked by an explicit local construction.

15.6.2 Two displacement calculations

Example 15.6.3 (A tropical line intersects itself)**.** Let $L \subset \mathbb{R}^2$ consist of the rays generated by $e_1, e_2, -e_1 - e_2$, all with weight one. For $v = (a, b)$ with $0 < a < b$, the ray $\mathbb{R}_{\geq 0}e_2$ meets the translated diagonal ray $v + \mathbb{R}_{\geq 0}(-e_1 - e_2)$ at $(0, b - a)$. Checking the three pairs of coordinate and diagonal directions shows that this is the only transverse intersection of L and $L + v$. Its lattice index is $|\det(e_2, -e_1 - e_2)| = 1$. Replacing v by ϵv sends this point to the origin. Hence

$$L \cdot L = [0].$$

A straight tropical line has stable square zero, as in Proposition 15.4.1. The difference comes from the three-ray geometry, not from a formal rule about repeated supports.

Example 15.6.4 (Nonprimitive equations and weights)**.** Let $u = \max(0, ax)$ and $v = \max(0, by)$ for positive integers a, b. The supports of their divisors are the coordinate lines, but their weights are a, b. The determinant of the primitive line directions is one, so

$$\mathrm{d}'\mathrm{d}''[u] \wedge \mathrm{d}'\mathrm{d}''[v] = ab\delta_0.$$

Counting only the geometric intersection point loses both multiplicities. Conversely, using the nonprimitive vectors in the determinant and also retaining the weights would count them twice. Primitive directions and cycle weights must therefore be recorded separately.

References. The Stokes and corner-current framework is [GK17, Sections 2–3]. The toric input is [FS, Theorems 2.1 and 3.2]; the passage to smooth weights follows the local-fan construction of [GK17, Remark 1.4], with its pointwise steps written above.

15.7 The delta-algebra and intersection theory

15.7.1 Polyhedral curvature terms

For a smooth real function, the Hessian is a smooth $(1,1)$-form. For a PL function, the cellwise Hessian vanishes and the distributional Hessian is a corner current. A calculus limited to original smooth forms cannot treat that corner current as an ordinary smooth coefficient. GK enlarges the algebra so that certain polyhedral currents become legitimate differential objects with products.

The enlargement is controlled. A typical preform is a finite sum of smooth superforms multiplied by integration currents on weighted polyhedral cycles. Stable intersection supplies the product of the cycle factors. Differential operators have both cellwise and boundary parts. The functorial closedness conditions ensure that the construction survives refinements and pullbacks in the specified algebraic category.

This is why the detailed definition in the preceding sections is needed. Declaring every polyhedral current to be a form would not automatically make its derivatives remain in the class or make products independent of the presentation.

15.7.2 A local multiplication that ordinary distribution theory cannot supply

On $\mathbb{R}^2$, let $u = \max(0, x)$ and $v = \max(0, y)$. Their curvature currents are integration currents on the coordinate lines, with the corresponding normal differential degrees. The delta product is the point mass at the origin, with multiplicity one. Replacing y by $x+2y$ gives the determinant factor two after the correct lattice normalization.

If two divisors coincide, ordinary multiplication of their distributional densities is not defined by writing a square of a Dirac delta. Tropical stable intersection provides a geometric intersection operation in its admissible cycle class. The product belongs to that calculus because its construction includes a displacement or equivalent intersection-theoretic definition. This does not supply a product for every pair of distributions with the same supports.

15.7.3 The metric application

A model metric has PL local weights. The corner formula produces its curvature as a delta-form in the appropriate GK setting. Products of these Chern delta-forms can then be integrated and compared with model intersection numbers. Green currents and star products lead to local heights, with Poincaré–Lelong providing the divisor term.

The arithmetic importance is that the calculus retains lower-degree curvature, not only a final scalar intersection number. It gives local formulas for metric variation and intersections, while compatibility with the model theory verifies the normalization. The resulting local heights can then be assembled in global arithmetic settings with their own adelic hypotheses.

15.7.4 Mihatsch's analytic construction and the comparison boundary

Mihatsch develops delta-forms intrinsically on analytic spaces using compatible skeletal descriptions and a polyhedral-current calculus. The resulting trigrading records smooth bidegrees and polyhedral codimension. In the notation of that paper, the codimension-zero component is the piecewise smooth calculus, and the realization in CLD currents has an injectivity theorem under the stated analytic hypotheses.

These are useful improvements for actual representatives and higher-codimension Green identities. They should not be retroactively inserted into the original GK definition without a comparison argument. In particular, a property proved for the later analytic delta-sheaf does not resolve an original GK representability question solely because both are denoted by B in informal discussions.

The complete-intersection Green formula is a case where the distinction matters constructively. CLD25 states a current identity on original smooth tests. Mihatsch's theorem supplies an actual delta-form on the complement in its own category and an identity against the appropriate delta-form tests. The stronger representation and testing statement is additional mathematical content.

15.8 Products and tropical intersection in CLD25 Chapter 9

15.8.1 External products come before internal intersections

If S is a current on X and T a current on Y, their external product belongs on $X \times Y$. Formally it is obtained by integrating a test in one variable against one current and then against the other. To make this rigorous, CLD25 Chapter 9 develops integration with parameters and the continuity of the resulting test-valued operations. The construction is more general than merely writing a product of two scalar measures.

An internal intersection on X can then be related to the diagonal in $X \times X$. But pulling a current back to the diagonal is a singular restriction problem. A Gysin construction supplies such an operation in a controlled class; an arbitrary pair of distributions cannot be intersected just because their external product exists.

15.8.2 Why displacement appears

In a real vector space, translate one tropical cycle by a small generic vector. The transverse intersections have lattice-index multiplicities. Passing to the stable value gives the familiar tropical intersection. This can be interpreted through a family of currents and a diagonal or Gysin operation. The analytic formulation explains why the result is compatible with differential operations and why multiplicities are conserved under small displacements.

For two transverse lines in $\mathbb{R}^2$, the determinant computation in Chapter 5 is the entire local calculation. For nontransverse cycles, the displacement construction resolves an excess-dimensional intersection into weighted pieces of the expected dimension. The support of the result is a subset of the set-theoretic intersection, but the multiplicities require the displacement and lattice data.

15.8.3 Relation to the GK product

GK begins with polyhedral currents and stable intersections to construct a delta-algebra on analytic spaces. CLD25 develops product spaces, parameter-dependent integrals, and Gysin operations inside its abstract tropical frame-

work. These approaches have overlapping local models and related formulas. An identification on a chosen class still requires matching the calibration, the allowable generators, and the current realization. The existence of both products is not a proof that the entire algebras coincide.

This point will matter for the research questions in Chapter 24. Extending a geometric intersection product to arbitrary positive closed currents requires new analytic continuity and representation results. The tropical product explains the finite polyhedral case and provides examples, but it does not automatically supply all bounded-potential or unbounded-current products.

References. [CLD25, §§7.5–7.8, 8.10–8.11, Chapter 9]; [GK17, Sections 2–4].

15.9 Changing conventions without changing curvature

The six operators of Section 16.5 use Mihatsch's boundary convention. Cai's convention is the opposite. The current derivatives and the polyhedral derivatives agree, while

$$\partial'_{\mathrm{C}} = d' - d'_P = -\partial'_{\mathrm{M}}, \qquad \partial''_{\mathrm{C}} = d'' - d''_P = -\partial''_{\mathrm{M}}.$$

Here the subscripts label conventions, not different geometric operations. For a continuous piecewise smooth function f, both conventions give

$$\begin{aligned} d'd''f &= d'_P d''_P f + \partial'_{\mathrm{C}} d''_P f \\ &= d'_P d''_P f - \partial'_{\mathrm{M}} d''_P f. \end{aligned}$$

Thus the corner current is $+\partial'_{\mathrm{C}} d''_P f$ in Cai's notation and $-\partial'_{\mathrm{M}} d''_P f$ in Mihatsch's. For $f(t) = \max(0, t)$ it is δ_0, with positive coefficient in both descriptions. This example is a useful normalization test: changing the sign of the boundary operator must not change the sign of the Monge–Ampère mass.

References. [Mih23, Definition 3.4]; [Cai23, Theorem 4.25 and the conventions preceding Theorem 1.2].

15.10 Graph pullback and two pushforwards

Let $F : N'_{\mathbb{R}} \to N_{\mathbb{R}}$ be an integral affine map. The graph construction defines a pullback of delta-forms even when F is not surjective. If p_1, p_2 are the projections from $N'_{\mathbb{R}} \times N_{\mathbb{R}}$ and Γ_F is the graph, the defining formula is

$$F^*\beta = (p_1)_*\big([\Gamma_F] \wedge ([N'_{\mathbb{R}}] \times \beta)\big).$$

The intersection on the right is the delta-product. It is not restriction of the coefficients of an arbitrary distribution. The projection has the required properness on the graph support, locally over the source. The construction preserves total bidegree and commutes with the wedge product and all six operators. These are theorems of the polyhedral calculus, not consequences of continuity of F.

Example 15.10.1 (A non-surjective pullback)**.** Let $i : \mathbb{R} \to \mathbb{R}^2$ be $t \mapsto (t, 0)$, and let $D_x = d'd'' \max(0, x)$ and $D_y = d'd'' \max(0, y)$. Then

$$i^*D_x = \delta_0, \qquad i^*D_y = 0.$$

Indeed pullback commutes with $d'd''$ and with piecewise linear functions. The pulled-back functions are $\max(0, t)$ and 0. Although $i(\mathbb{R})$ is contained in the support of D_y, its delta-pullback is zero. A set-theoretic inverse image of supports does not determine a pullback multiplicity.

Two operations are denoted by pushforward in the literature. The current pushforward F_* is defined by duality with smooth tests; it requires properness on support, or compact support in the version used in Cai's Theorem 5.13(3). It can integrate coefficient degrees along positive-dimensional fibres. The cycle-type pushforward $\widehat{F}_*$ instead preserves the dimension of the supporting cells. A cell on which dimension drops contributes zero. For an s-dimensional cell σ mapped injectively to an s-dimensional cell it is

$$\widehat{F}_*(\alpha_\sigma[\sigma]) = [N_{F(\sigma)} : dF(N_\sigma)]((F|_\sigma)^{-1})^*\alpha_\sigma\,[F(\sigma)].$$

Cai proves a projection formula for each operation with its own domain. The formula involving $\widehat{F}_*$ on the full affine spaces does not remove the support condition from the current pushforward. When F is injective on every supporting cell the two constructions agree.

Proposition 15.10.2 (The lattice factor in dimension one)**.** *For $F : \mathbb{R} \to \mathbb{R}$, $t \mapsto mt$ with a nonzero integer m, normalized using the standard lattices,*

$$F_*[\mathbb{R}] = |m|[\mathbb{R}], \qquad F_*\delta_0 = \delta_0, \qquad F^*\delta_0 = |m|\delta_0.$$

Proof. For a compactly supported top-degree test $a(y)d'y \wedge d''y$, its pullback is $m^2 a(mt)d't \wedge d''t$. Change of variables in the real integral gives the factor $m^2/|m| = |m|$. The second formula follows by evaluation on a scalar test. For the third, write $\delta_0 = d'd'' \max(0, y)$. The slopes of $\max(0, mt)$ have jump $|m|$ at zero. □

These formulas satisfy the projection formula: pushing $F^*\delta_0 \wedge [\mathbb{R}]$ forward gives $|m|\delta_0$, as does $\delta_0 \wedge F_*[\mathbb{R}]$. They also show why the mass of a point and the weight of a one-dimensional cycle must not be normalized by the same informal "degree rule". Passing from this affine construction to analytic spaces requires compatibility of charts and their test quotients. Cai's algebraic construction, GK's original sheaf and Mihatsch's analytic sheaf must therefore still be distinguished. None of the affine formulas alone supplies a trace of arbitrary actual delta-forms through every proper analytic map.

Chapter 16

Analytic delta-forms and their positivity

An analytic domain, a closed analytic subspace and a scalar extension are different constructions; Chapter 2 supplies each of them. The quotient defining a differential object must respect precisely the maps admitted by its theory. In the original GK construction below, the universal quantifier ranges over algebraic morphisms and compatible charts. The later Mihatsch comparison uses analytic morphisms under its own hypotheses. The existence of the underlying analytic map alone does not prove that substitution respects a presentation quotient.

16.1 Delta-forms and delta-currents

Throughout this section, K is algebraically closed, complete, and nontrivially valued. Let X be an integral separated K-scheme of finite type, let $n = \dim X$, and let $W \subset X^{\mathrm{an}}$ be open. These are the hypotheses of the algebraic tropical-chart construction in [GK17, §4] and of the positivity results in [GK19, §0.1]. No hypothesis on the residue characteristic is imposed.

16.1.1 From tropical preforms to forms on the analytic space

Let N be a lattice of rank r, put $N_{\mathbf{R}} = N \otimes_{\mathbf{Z}} \mathbf{R}$, and let $\widetilde{\Omega} \subset N_{\mathbf{R}}$ be open. A tropical cycle with smooth weights is represented by a finite integral real-

affine polyhedral complex together with smooth weight functions m_σ on its maximal faces. For each codimension-one face τ and $x \in \tau$, balancing means

$$\sum_{\sigma \supset \tau} m_\sigma(x)\nu_{\sigma,\tau} \in N_{\tau,\mathbf{R}},$$

where $\nu_{\sigma,\tau}$ is a lift of the primitive outgoing normal and $N_{\tau,\mathbf{R}}$ is the tangent space of τ. If C has codimension ℓ, its integration current δ_C has bidegree (ℓ,ℓ). The weights and coefficients in the following definition are real.

The tropical preforms were defined in Chapter 15.

A tropical chart of X^{an} consists of a very affine open subvariety $U \subset X$, its canonical torus embedding $\varphi_U : U \hookrightarrow T_U$, and

$$V = \mathrm{trop}_U^{-1}(\Omega), \qquad \Omega = \widetilde{\Omega} \cap \mathrm{Trop}(U).$$

Write N_U for the cocharacter lattice of T_U. If $f : X' \to X$ is an algebraic morphism and $(V', \varphi_{U'})$ is a chart with $f(U') \subset U$ and $f^{\mathrm{an}}(V') \subset V$, the torus maps induce an integral affine map

$$F : N_{U',\mathbf{R}} \longrightarrow N_{U,\mathbf{R}}.$$

An ambient preform $\widetilde{\alpha}$ can be pulled back by F and then restricted to the tropical cycle $\mathrm{Trop}(U')$. Here restriction means the product with $\delta_{\mathrm{Trop}(U')}$.

Definition 16.1.1 (The functorial chart quotient)**.** Let $\mathcal{N}^{p,q}(V, \varphi_U)$ be the subspace of ambient preforms $\widetilde{\alpha} \in P^{p,q}(\widetilde{\Omega})$ such that

$$\left(F^*\widetilde{\alpha} \wedge \delta_{\mathrm{Trop}(U')}\right)\big|_{\mathrm{trop}_{U'}(V')} = 0$$

for every algebraic morphism $f : X' \to X$ and every compatible chart as above. Set

$$P^{p,q}(V, \varphi_U) = P^{p,q}(\widetilde{\Omega})/\mathcal{N}^{p,q}(V, \varphi_U).$$

This quotient is independent of the choice of $\widetilde{\Omega}$. It has pullbacks under compatible algebraic morphisms [GK17, Definition 4.4 and Remark 4.5]. The quantifier over all morphisms is part of the definition. It cannot be replaced by the requirement that the restriction to the one cycle $\mathrm{Trop}(U)$ vanish. Indeed, [GK17, Example 4.22] constructs a nonzero chart class whose restriction to that cycle is zero but whose pullback to a compatible chart is nonzero.

Definition 16.1.2 (Closed generators and delta-forms)**.** An element $\omega \in P^{p,q}(V, \varphi_U)$ belongs to $Z^{p,q}(V, \varphi_U)$ if, after every compatible pullback and restriction as in Definition 16.1.1, the resulting supercurrent is both d'-closed and d''-closed. Let $AZ(V, \varphi_U)$ be the algebra generated by $A^{\bullet,\bullet}(\Omega)$ and $Z^{\bullet,\bullet}(V, \varphi_U)$. Thus locally an element has the form

$$\beta = \sum_{j=1}^{s} \alpha_j \wedge \omega_j, \qquad \alpha_j \in A^{\bullet,\bullet}(\Omega), \quad \omega_j \in Z^{\bullet,\bullet}(V, \varphi_U).$$

Sheafifying the chart algebras P gives the sheaf of generalized delta-forms; sheafifying AZ gives the sheaf $B^{\bullet,\bullet}$ of delta-forms.

The universally closed condition makes

$$d'\beta = \sum_j d'\alpha_j \wedge \omega_j, \qquad d''\beta = \sum_j d''\alpha_j \wedge \omega_j$$

independent of the chosen expression. There are injective morphisms of sheaves

$$A^{\bullet,\bullet} \hookrightarrow B^{\bullet,\bullet} \hookrightarrow P^{\bullet,\bullet},$$

and B is a bigraded differential algebra [GK17, §4.6, Definitions 4.9 and 4.13, Proposition 4.15]. The differentials need not preserve the larger algebra P. This is the precise difference between a generalized delta-form and a delta-form in this construction.

16.1.2 The test topology and its dual

It is useful to spell out the continuity condition in the definition of a delta-current. On a fixed chart, freeze a finite tuple $\omega_J = (\omega_j)_{j\in J}$ of closed generators. Let $AZ(V, \varphi_U, \omega_J)$ consist of the sums $\sum_j \alpha_j \wedge \omega_j$. If $C \subset \Omega$ is compact and $s \geq 0$, write $p_{C,s}(\alpha)$ for the usual smooth coefficient seminorm, controlling derivatives up to order s. The quotient seminorm is

$$p_{C,s,\omega_J}(\beta) = \inf_{\beta = \sum_j \alpha_j \wedge \omega_j} \max_{j\in J} p_{C,s}(\alpha_j).$$

On a fixed chart covering of W, choose such tuples chart by chart and use the induced locally convex topology. Finally fix a compact subset of W containing the supports of the test forms.

Definition 16.1.3 (Delta-current)**.** A delta-current on W is a real linear functional on $B_c^{\bullet,\bullet}(W)$ whose restriction to every fixed-chart, fixed-generator, fixed-compact-support space just described is continuous. A delta-current of bidegree (p,q) acts on $B_c^{n-p,n-q}(W)$; its space is denoted $E^{p,q}(W)$.

This is [GK17, Definition 6.3 and §6.4], with bidegree indexing. The two constructions of currents fit into natural maps

$$P^{p,q}(W) \longrightarrow E^{p,q}(W) \longrightarrow D^{p,q}(W).$$

The first associates a functional by integration,

$$\langle [\alpha]_E, \beta \rangle = \int_W \alpha \wedge \beta, \qquad \beta \in B_c^{n-p,n-q}(W);$$

the second restricts a functional to the smaller space $A_c^{n-p,n-q}(W)$. In particular, enlarging the space of test forms reverses the direction of the comparison map on duals.

Proposition 16.1.4 (Functorial detection of a generalized delta-form)**.** *Let $\alpha, \beta \in P^{p,q}(W)$. Then $\alpha = \beta$ if and only if*

$$[f^*\alpha]_D = [f^*\beta]_D$$

on every open $W' \subset (X')^{\mathrm{an}}$ with $f^{\mathrm{an}}(W') \subset W$, for every algebraic morphism $f : X' \to X$.

Open proof obligation (RC2). Prove detection and its converse on actual tropical pullback tests; GK17 Proposition 6.8 supplies the criterion.

Remark 16.1.5 (Which operations have been constructed). There is a product $B^{a,b} \times E^{p,q} \to E^{a+p,b+q}$, and d', d'' act on E by transposition. Proper algebraic morphisms have pushforward on delta-currents [GK17, §6.4, §6.9 and §6.10]. These statements do not give a product of two arbitrary delta-currents or pullback of an arbitrary delta-current. Nor do the displayed comparison maps by themselves establish injectivity, surjectivity, or extension of every ordinary current to the larger test space.

16.1.3 Positivity and positive representatives

The adjectives strong, positive and weak refer to the three Lagerberg cones. They should be distinguished from the following two additional issues: which chart representatives are positive, and which test space is used by a current.

Definition 16.1.6 (Positive generalized delta-form)**.** A chart class $\beta \in P^{p,p}(V, \varphi_U)$ is positive if, for every compatible algebraic morphism and chart, its pulled-back restriction is a tropical delta-preform whose underlying supercurrent is positive. It is positively representable if it has a positive ambient representative $\widetilde{\beta} \in P^{p,p}(\widetilde{\Omega})$. A generalized delta-form on W has either property if the property holds locally on tropical charts.

There are corresponding strong and weak versions [GK19, Definitions 2.2 and 2.6]. Positive representability implies positivity, since ambient affine pullback and restriction to an effective tropical cycle preserve the relevant cones. The converse is not part of the definition or of this implication.

Definition 16.1.7 (Positive delta-current)**.** A symmetric $T \in E^{p,p}(W)$ is positive if $\langle T, \beta \rangle \geq 0$ for every positive $\beta \in B_c^{n-p,n-p}(W)$. It is weakly positive when tested against strongly positive forms, and strongly positive when tested against weakly positive forms.

Restriction of a positive delta-current is a positive ordinary current, because every positive smooth test form is a positive delta-form [GK19, Definition 2.10 and Remark 2.12]. For a generalized delta-form β, the statements proved in that paper are more specific:

$$\begin{aligned} \beta \text{ positively representable} &\implies [\beta]_E \text{ positive}, \\ \beta \text{ positive} &\iff [f^*\beta]_D \text{ positive for every algebraic } f. \end{aligned}$$

These are [GK19, Corollary 2.11 and Proposition 2.13]. In the second line the inverse image of W is the domain of the current. In the first line, positive representability is an actual hypothesis.

Remark 16.1.8 (The smooth case and the middle-degree caution). For a smooth form, positivity of the form and of either associated current agree [GK19, Remark 2.14]. In middle degree, one must not supplement this with the false assertion that strongly positive real Lagerberg forms span all symmetric forms. The counterexample in [BGJK, Example 2.3.6] also shows that the weak cone can contain a line. Thus [GK19, Remark 1.12], which repeats the older spanning assertion, is not a valid general-purpose nondegeneracy argument. In degree $(1, 1)$ the three cones agree, so this particular obstruction does not affect the curvature comparisons below.

16.2 Piecewise smooth weights and four plurisubharmonicity conditions

Definition 16.2.1 (The four conditions for a continuous weight)**.** Let $u : W \to \mathbf{R}$ be continuous.

1. u is current-psh for the original smooth test theory if $d'd''[u]_D$ is positive.
2. u is delta-psh if $d'd''[u]_E$ is positive.
3. u is functorial current-psh if $u \circ f^{\mathrm{an}}$ is current-psh on $(f^{\mathrm{an}})^{-1}(W)$ for every algebraic morphism $f : X' \to X$.
4. u is functorial delta-psh if the analogous condition holds with delta-psh in place of current-psh.

These are the conditions in [GK19, Definition 3.1 and §3.4]; the explicit label *current-psh* records which of the several uses of psh is intended. For a continuous metric on a line bundle L, the condition is imposed on each weight $-\log \|s\|$, where s is a nowhere vanishing local algebraic frame. The ordinary or delta Poincare–Lelong formula for invertible functions makes the condition independent of the frame [GK19, §3.5].

Proposition 16.2.2 (Implications requiring no comparison theorem)**.** *For continuous weights and for continuous metrics,*

$$\textit{functorial delta-psh} \implies \textit{delta-psh} \implies \textit{current-psh},$$
$$\textit{functorial delta-psh} \implies \textit{functorial current-psh} \implies \textit{current-psh}.$$

Proof. Use the identity morphism to remove the functorial quantifier. For the remaining implication, restrict the positive delta-current to smooth test forms. Apply the same argument after every morphism for the functorial version. □

The proposition states implications, not their strictness. In particular, it is not a counterexample to the converse of any arrow. For smooth metrics the arrows collapse to equivalences:

$$c_1(L, \|\cdot\|) \geq 0 \text{ as a smooth form}$$
$$\iff \text{current-psh} \iff \text{functorial delta-psh}.$$

This is [GK19, Corollary 8.9]; it also includes functorial current-psh, and delta-psh follows by Proposition 16.2.2.

Definition 16.2.3 (Delta-metric)**.** A piecewise smooth metric is a delta-metric if every point admits a tropical frame with weight φ for which the facewise $(1,1)$-form $d'_P d''_P \varphi$ is the restriction of an ambient superform with piecewise smooth coefficients. For such a metric, there is a unique $\gamma \in B^{1,1}(W)$ whose associated delta-current, after every algebraic pullback, is the curvature delta-current of the pulled-back metric. This γ is denoted $c_1(L, \|\cdot\|)$.

The local criterion and its equivalence with the functorial curvature representation are [GK17, Definition 9.9, Proposition 9.11 and Definition 9.12]. The existence of one associated curvature current does not by itself supply this stronger representation. For a delta-metric, the statement in [GK19, Proposition 8.8] is the narrower equivalence

$$c_1(L, \|\cdot\|) \geq 0 \text{ as a delta-form} \iff \text{functorial current-psh.}$$

16.2.1 The Hessian term and the corner term

Let C be a tropical cycle of pure dimension d with positive constant weights. Suppose φ is a continuous piecewise smooth function on an open subset of $|C|$. Choose a subdivision on whose faces it is smooth. The operators d'_P, d''_P differentiate on those faces; they do not include jumps of the first derivatives. The tropical Poincare–Lelong formula is

$$d'd''[\varphi] = [d'_P d''_P \varphi] + \delta_{\varphi \cdot C}. \tag{16.2.1}$$

Here $\varphi \cdot C$ is the corner cycle [GK17, Corollary 3.19].

For precision, at a codimension-one face τ choose primitive outgoing normal lifts $\nu_{\sigma,\tau}$ for the maximal faces σ containing τ. Balancing says that $\nu_\tau = \sum_{\sigma \supset \tau} m_\sigma \nu_{\sigma,\tau}$ is tangent to τ. The corner weight at $x \in \tau$ is

$$m_{\varphi \cdot C, \tau}(x) = \sum_{\sigma \supset \tau} m_\sigma \, d\varphi_\sigma(x)(\nu_{\sigma,\tau}) - d\varphi_\tau(x)(\nu_\tau).$$

Changing a normal lift by a vector tangent to τ changes the two terms by equal amounts. This proves independence of the lifts. The full construction and its invariance under subdivision are given in [GK17, §1.10 and Proposition 1.12].

Theorem 16.2.4 (Piecewise smooth criterion)**.** *Let $\|\cdot\|$ be a piecewise smooth metric on $L|W$. On a tropical frame write*

$$-\log\|s\| = \varphi \circ \mathrm{trop}_U,$$

where the tropical domain meets each face convexly. Then the metric is current-psh if and only if, on every such frame, the following hold:

1. *the restriction of φ to each maximal tropical face is convex;*
2. *the corner cycle $\varphi \cdot \mathrm{Trop}(U)$ is effective.*

It suffices to verify the conditions on a basis of tropical frames. Equivalently, after a subdivision, the first condition can be replaced by smooth convexity on the maximal pieces, while retaining the corner condition.

Open proof obligation (RC2). Prove the piecewise-smooth corner-current criterion, including its precise conditions; GK19 Theorem 8.4 and Remark 8.5(a) are the source inputs.

Example 16.2.5 (A corner invisible to the facewise Hessian)**.** For $\varphi(t) = |t|$ and $\eta \in C_c^\infty(\mathbf{R})$, integration by parts separately on the two half-lines gives

$$\langle d'd''[\varphi], \eta\rangle = \int_{\mathbf{R}} |t|\eta''(t)\,dt = 2\eta(0).$$

Thus $d'd''[|t|] = 2\delta_0$, although the facewise Hessian is zero. The sign is reversed for $-|t|$. This atomic curvature is represented by a delta-preform, but not by a smooth $(1,1)$-form.

Example 16.2.6 (The tropical tripod)**.** For $X = \{x_1 + x_2 = 1\} \subset \mathbf{G}_m^2$, the tropicalization has three rays of weight one with primitive outgoing vectors $(1,0), (0,1), (-1,-1)$. Let φ be conic, with respective outgoing slopes a, b, c, and put $u = \varphi \circ \mathrm{trop}$. Every edge restriction is linear. Nevertheless a nonnegative test function η, equal to one at the vertex, gives

$$\langle d'd''[u], \mathrm{trop}^*\,\eta\rangle = a + b + c.$$

In particular, $(a,b,c) = (-1,0,0)$ disproves the claim that facewise convexity alone implies current-psh. This is [GK19, Example 3.3]. The choice $(1,1,-2)$ has zero corner curvature: nonnegativity of each individual outgoing slope would be an unnecessarily strong test.

Proposition 16.2.7 (The precise graph criterion)**.** *Let φ be continuous and piecewise C^2 on a one-dimensional balanced tropical cycle, viewed as a metric graph with positive constant edge weights m_e. Parametrize each edge by a coordinate t in a primitive integral direction; all outgoing derivatives below use this lattice-normalized parametrization. Against restrictions of smooth ambient test functions supported away from the boundary, its curvature is*

$$\Delta\varphi = \sum_e m_e \varphi_e''(t)\, dt + \sum_v \left(\sum_{e \ni v} m_e \partial_{\nu_e} \varphi(v) \right) \delta_v,$$

where the vertices include the breakpoints of the chosen subdivision. It is positive precisely when the densities and the vertex coefficients in this formula are all nonnegative.

Proof. Integrate by parts twice on every edge. Continuity and the balancing condition cancel the terms involving derivatives of the test function at vertices. The remaining boundary terms are the weighted outgoing derivatives of φ. The density measures and the point masses are mutually singular; their positivity can therefore be tested separately. □

Remark 16.2.8 (A scope correction to a graph formulation). The slope-only wording of [GK19, Example 8.6] is correct for piecewise linear functions. For piecewise smooth functions it must retain convexity on the open edges. Indeed, $\varphi(t) = -t^2$ on an open interval has sum of the two outgoing first derivatives equal to zero at every point, while $\varphi'' = -2$. Proposition 16.2.7 supplies the precise replacement.

16.3 Why the universal quotient is necessary

The definitions at the start of this chapter build functoriality into the null space. We give the arguments which this choice makes possible. They also identify the remaining geometric input: pullback and intersection of ambient tropical preforms must already be constructed, with their projection and closedness properties. The following algebra does not replace those results.

Fix a chart (V, φ_U) in the algebraic category of Section 16.1. For a compatible map f and chart upstairs, write $R_f(\widetilde{\alpha})$ for $F^*\widetilde{\alpha} \wedge \delta_{\mathrm{Trop}(U')}$. Thus the null space consists of preforms annihilated by every R_f. The identity map is among these maps, but it is not the only one.

Proposition 16.3.1. *The universal null spaces are stable under compatible pullback. Consequently pullback of a chart class is independent of its ambient representative and is compatible with composition.*

Proof. Suppose $\widetilde{\alpha}$ is null on V, and pull it back along $f : X' \to X$. To show that $F^*\widetilde{\alpha}$ is null upstairs, test it after an arbitrary $g : X'' \to X'$ and compatible chart. The resulting expression is the restriction of $(F \circ G)^*\widetilde{\alpha}$ to the tropical cycle of that chart. It is zero because the composite $f \circ g$ is one of the maps occurring in the original null condition. Thus the pullback descends. Composition and the identity rule hold before quotienting, and hence hold afterward. □

A condition using only R_{id} would not support this proof: its hypothesis contains no information about the composite map. This is the precise reason for the quantifier over morphisms. The product on the quotient additionally uses the ideal property of tropical restriction, proved by the ambient intersection theory. Vanishing as a distribution on one support is not a license to multiply arbitrary distributions.

Proposition 16.3.2. *Let $\beta = \sum_i \alpha_i \wedge \omega_i$ with ω_i universally closed. Then the classes $\sum_i d'\alpha_i \wedge \omega_i$ and $\sum_i d''\alpha_i \wedge \omega_i$ depend only on β. They give differentials satisfying $d'^2 = d''^2 = 0$ and $d'd'' + d''d' = 0$.*

Proof. It suffices to consider an expression for zero. After every compatible pullback and tropical restriction, it is a zero current. Differentiate that equality. The smooth-current Leibniz rule and closedness of every restricted generator identify its derivative with the restriction of $\sum_i d'\alpha_i \wedge \omega_i$. This vanishes after all maps and hence represents zero in the universal quotient. The same argument applies to d''. The three differential identities now follow by applying the corresponding identities to the smooth coefficients in one expression. □

The proof is a relation argument, not merely a rule for differentiating a preferred representative. It is also why requiring closedness only on the original chart would be insufficient. Universal closedness is preserved by pullback through the same composition argument as Proposition 16.3.1. Closure under products uses GK's tropical product theorem for closed preforms. With that input, the graded Leibniz rule descends and gives the full differential algebra.

16.3.1 The nodal example and what it detects

GK17 Example 4.22 uses an integral nodal cubic over $\mathbb{C}_p$, with $p \neq 2, 3$, and its normalization. The construction supplies a chart whose tropical image near a vertex has four outgoing branches. A PL potential has cancelling total slope at the vertex, so its corner current on that single tropical image is zero. After pullback to a chart of the normalization, the potential is zero on one interval and has slope one on the next; its corner current is a unit atom.

The underlying cubic is $xy + px^3 + py^3 = 0$. Its normalization is parametrized on its affine part by

$$x = -\frac{u}{p(1+u^3)}, \qquad y = -\frac{u^2}{p(1+u^3)}.$$

Substitution verifies the equation: the three numerators after multiplication by $p^2(1+u^3)^3$ are $u^3(1+u^3)$, $-u^3$, and $-u^6$. The points $u = 0, \infty$ map to the node. A regular unit on the nodal curve pulls back to a unit with equal values at these two preimages, which explains why the canonical tropical coordinates downstairs can identify data separated by normalization. The complete skeleton and unit-group computation is the geometric part of the cited example.

The conclusion is precise: restriction to one tropical image does not detect equality of chart classes. It is not, by itself, a counterexample to injectivity of the map from delta-forms to ordinary analytic currents. An ordinary analytic test may use a refined moment map; testing on one tropical image is less information than testing on every actual smooth analytic form. Proposition 16.1.4 avoids this ambiguity by using every algebraic pullback and all ordinary tests there.

16.4 Mihatsch's skeleton definition and its comparison maps

Let X be a pure-dimensional Hausdorff good analytic space without analytic boundary, over a complete valued field. Mihatsch permits trivial valuation; statements involving weakly smooth forms additionally use their nontrivial-valuation hypotheses. The data of an actual delta-form consist of compatible polyhedral currents on all admitted skeleta, locally obtained from one ambient delta-form through toric coordinates. Compatibility under adding coordinates is part of the definition.

There are two levels of degree. A term $\alpha \wedge [\sigma]$ with coefficient bidegree (p, q) and support codimension c has tridegree (p, q, c) and total bidegree $(p + c, q + c)$. Thus a PL function has tridegree $(0, 0, 0)$, while its pure corner curvature has tridegree $(0, 0, 1)$ and total bidegree $(1, 1)$. Confusing coefficient degree and total degree gives incorrect test degrees in Green identities.

Proposition 16.4.1 (The coefficient-codimension-zero comparison)**.** *In Mihatsch's analytic setting, piecewise smooth forms identify with the codimension-zero part: $PS_X^{p,q} \simeq B_X^{p,q,0}$. Original smooth forms embed in it. Under the hypotheses for the weakly smooth theory, weakly smooth forms also embed in this piecewise smooth sheaf.*

Reduction used in the comparison. The local presentation in codimension zero gives surjectivity: its coefficients are piecewise smooth forms in the toric coordinates. For injectivity, the top-degree case is decisive. If a piecewise smooth (n, n)-form represents zero on the calibrated tropical part, its remaining possible support lies in lower-dimensional pieces and in the image of the analytic boundary of a compact chart. Those pieces have dimension at most $n-1$ in the vanishing criterion of Mihatsch Proposition 4.7. An (n, n)-form restricts to zero on every such tangent space. It is therefore zero as a piecewise smooth form. For general (p, q), wedge with every complementary piecewise smooth form and apply the top-degree statement. The nondegeneracy of local wedge detection, proved for the analytic presentation spaces in the cited comparison, forces the original form to vanish. Finally harmonic coordinate functions are locally PL, so pullback of smooth superforms by them is piecewise smooth. The relation and injectivity statements for that inclusion are those of the weakly smooth construction. □

This proof records the reduction and its geometric inputs; it does not replace the analytic wedge-detection theorem by dimension counting alone. On an abstract tropical space with a prescribed sheaf of linear functions, the analogous inclusion into all piecewise smooth forms can be strict. The analytic local-presentation theorem is therefore substantive.

16.4.1 Which differential is preserved

On piecewise smooth forms, the facewise operators are d'_P, d''_P. The full current operators d', d'' also contain boundary terms. Mihatsch uses the convention

$$\partial' = d'_P - d', \qquad \partial'' = d''_P - d''.$$

Thus it is not correct to say that inclusion of all piecewise smooth forms preserves their facewise differential as the full differential. On original smooth and weakly smooth forms the boundary operators vanish, which is precisely what makes those smaller inclusions compatible with the full calculus. For $|t|$ on $\mathbb{R}$, the facewise second derivative is zero, while the full second derivative is $2\delta_0$; the codimension-one term must occur in the delta-algebra.

16.4.2 Pullback is a theorem about relations

Mihatsch Theorem 4.5 proves pullback for every analytic morphism between pure-dimensional boundaryless spaces. Locally it is the expected substitution $t_f^\star\gamma \mapsto t_{f\circ\pi}^\star\gamma$. The substantive assertion is that a zero presentation remains zero after substitution. The proof reduces near Abhyankar points to a map of constant fibre dimension followed by a closed immersion. For the former it uses compatible flat maps of skeleta; for the latter it uses the tropical product description near a Cartier divisor. The regular-immersion geometry in Chapter 22 explains this second mechanism.

This gives actual pullback, including restriction to a closed analytic subspace in the stated category. It does not supply arbitrary actual pushforward. A proper map always suggests a transpose operation on currents, but the resulting current need not have local ambient presentations of the required kind. Mihatsch Example 2.45(3) explicitly notes that even a balanced polyhedral pushforward need not be a delta-form on the target tropical space. Additional representation control is necessary.

In the common algebraic category, Mihatsch also states an embedding of original GK delta-forms into his sheaf, specifying its action on ambient generators; the source states this comparison without a formal proof. We retain that status. The proved piecewise-smooth comparison above does give an inclusion of weakly smooth forms into Mihatsch's algebra. It does not give an inclusion of weakly smooth forms into the original GK algebra. This distinction refines, rather than reverses, the comparison table in Chapter 18.

References. [GK17, Definitions 4.4 and 4.9, Propositions 4.7–4.15, Example 4.22, Proposition 6.8]; [Mih24, Proposition 2.38, Example 2.45, Theorem 4.5, Proposition 4.7 and Section 4.2].

16.5 The six differential operators and their signs

The full derivative of a delta-form has a cellwise part and a boundary part. The distinction is already visible for a PL function, but becomes more important when products have several support codimensions. We use Mihatsch's convention, in which the boundary operator is the cellwise derivative minus the current derivative.

$$\partial' = d'_P - d', \qquad \partial'' = d''_P - d'', \qquad d' = d'_P - \partial', \quad d'' = d''_P - \partial''.$$

For coefficient bidegree (a, b) and support codimension c, the total bidegree is $(a + c, b + c)$. The homogeneous degree changes are

operator	coefficient/codimension change	total change
d'_P	$(1, 0, 0)$	$(1, 0)$
d''_P	$(0, 1, 0)$	$(0, 1)$
∂'	$(0, -1, 1)$	$(1, 0)$
∂''	$(-1, 0, 1)$	$(0, 1)$.

An operator landing in a negative coefficient degree is zero. Thus the first derivatives of a continuous piecewise smooth scalar function are cellwise derivatives. Its second derivative can nevertheless acquire a boundary term.

Proposition 16.5.1. *On the delta-algebra the following identities hold:*

$$(d'_P)^2 = (d''_P)^2 = (\partial')^2 = (\partial'')^2 = 0,$$
$$d'_P\partial' + \partial' d'_P = 0, \qquad d''_P\partial'' + \partial'' d''_P = 0,$$
$$d'_P d''_P + d''_P d'_P = 0, \qquad \partial'\partial'' + \partial''\partial' = 0,$$
$$d'_P\partial'' + \partial'' d'_P + d''_P\partial' + \partial' d''_P = 0.$$

The last identity does not assert that each of its two mixed anticommutators vanishes separately.

Proof. The cellwise identities hold on each smooth coefficient form. Expand $(d')^2 = (d'_P - \partial')^2 = 0$ on a trihomogeneous delta-form. Its three terms have support codimension changes zero, one and two. The direct trigrading makes each codimension part vanish separately, giving $(\partial')^2 = 0$ and the primed mixed identity. Repeat for d''. Expanding $d'd'' + d''d' = 0$ and separating the same three codimension changes gives the remaining identities. The codimension-one part contains both mixed anticommutators, with the same sign; there is no further grading that separates them. □

Example 16.5.2. For $f(t) = |t|$ on $\mathbb{R}$, one has $DDf = 2\delta_0$ and $d'_P d''_P f = 0$. Since $\partial' f = \partial'' f = 0$,

$$(d''_P\partial' + \partial' d''_P)f = -2\delta_0, \qquad (d'_P\partial'' + \partial'' d'_P)f = 2\delta_0.$$

Thus the two anticommutators cancel but are individually nonzero. Treating all six operators as pairwise anticommuting would erase exactly the corner curvature that the delta-algebra was designed to retain.

16.5.1 The curvature of a piecewise smooth function

For any continuous piecewise smooth function f, the degree table gives $d'' f = d''_P f$ and hence

$$DDf = d'_P d''_P f - \partial' d''_P f.$$

The first term has tridegree $(1, 1, 0)$; it records the Hessian on the cells. The second has tridegree $(0, 0, 1)$; it records the slope mismatch along codimension-one faces. For a PL function the first term vanishes, so the entire curvature is the negative of the displayed boundary derivative. This is compatible with the positive corner mass of a convex maximum.

If f is harmonic in an enlarged coordinate system, this conclusion concerns its full curvature. It cannot be read as saying that every cellwise Hessian or every individual normal slope is zero. The compatibility theorem for that coordinate system identifies the cancellations in the full operator. This is another reason to retain the operator notation when comparing original smooth, weakly smooth and piecewise smooth forms.

16.6 Codimension as a filtration of the differential complex

Fix a total first degree p. In the complex $(B^{p,\bullet}, d'')$, put $F^c B^{p,q}$ equal to the sum of components of support codimension at least c. Both terms of $d'' = d''_P - \partial''$ preserve this decreasing filtration: the first keeps codimension fixed and the second raises it by one. The filtration is finite in each degree.

Proposition 16.6.1. *The differential on the associated graded complex is d''_P. For a d''_P-closed homogeneous term α of codimension c, the first obstruction to correcting it to a full d''-closed term is the class of $\partial''\alpha$ in the d''_P-cohomology of codimension $c+1$.*

Proof. Modulo F^{c+1} the boundary derivative disappears, proving the first assertion. To make $\alpha + \beta$ closed modulo codimension $c+2$, where β has codimension $c+1$, one must solve

$$d''_P \beta = \partial'' \alpha.$$

The right side is d''_P-closed by Proposition 16.5.1. Its class is therefore the obstruction to this equation. Replacing α by $\alpha + d''_P \gamma$ changes the right side by $-d''_P \partial'' \gamma$, so the obstruction depends only on the associated-graded cohomology class. □

Further corrections can have further obstructions even though the differential has only these two codimension pieces. The standard spectral sequence of a finite filtered complex organizes those successive equations; its existence is not a statement that they all vanish. For a reference calculation, the explicit first obstruction is often more useful than an unsupported claim that cellwise closedness is sufficient. It explains algebraically how a facewise primitive can fail to be a primitive in the actual delta-calculus.

References. The operator convention and trigrading are [Mih24, Definition 2.41 and Section 4.2]. The identities and first-obstruction calculation are consequences of that trigrading and the current differential identities.

16.7 Polyhedral Monge–Ampère theory beyond the toric case

The toric theory of [BGJK25] uses a global convex model. On a balanced polyhedral space there need not be a single ambient convex function representing every positive potential. Botero–Mazzon–Pille-Schneider therefore start with polyhedral convexity. A function is polyhedrally convex, abbreviated PC, when it satisfies the convexity inequality for the polyhedral convex combinations allowed by the space. For a piecewise affine function this is equivalent to nonnegative intersection with every local positive polyhedral cycle. Positivity against the fundamental cycle alone is a weaker condition. Fix a piecewise affine reference function γ and its growth class. The regularizable class $\mathrm{PC}_{\mathrm{reg}}(X,\gamma)$ consists of uniform decreasing limits of piecewise affine PC functions with growth $\gamma + O(1)$. Their Theorem 4.13 extends the mixed polyhedral Monge–Ampère operator to this class, with symmetry, positivity, fixed total mass and integration by parts. The measure is initially defined on their compactification; positivity of γ at infinity ensures that it is supported on X. This is a construction in a specified polyhedral function class. It does not identify that class with $\mathcal{U}_X$ on an arbitrary Berkovich space.

16.7.1 A continuous obstacle for which orthogonality fails

The following computation makes the obstruction to a general envelope argument explicit. It also corrects the negative-axis branch printed in Example 6.23 of [BMP26]. Equip the union X of the two coordinate axes in $\mathbb{R}^2$ with weight one on its four rays, and put $\gamma = |x| + |y|$ on X.

Proposition 16.7.1. *For $\epsilon > 0$, define the continuous obstacle*

$$\varphi(x,0) = |x| + \epsilon, \qquad \varphi(0,y) = \big||y| - \epsilon\big|.$$

Its PC envelope with growth bounded above by $\gamma + O(1)$ is

$$h(x,0) = |x|, \qquad h(0,y) = \max(0, |y| - \epsilon).$$

Moreover, with the polyhedral Monge–Ampère normalization of the slope formula,

$$\mathrm{MA}_{\mathrm{poly}}(h) = 2\delta_{(0,0)} + \delta_{(0,\epsilon)} + \delta_{(0,-\epsilon)}, \qquad \int_X (\varphi - h)\,\mathrm{MA}_{\mathrm{poly}}(h) = 2\epsilon > 0.$$

Proof. The function h is the restriction of the ambient convex function $\max\{|x|, |y|-\epsilon\}$. It is piecewise affine PC, lies below φ, and differs boundedly from γ. Thus it is an admissible competitor. Conversely, let v be any PC competitor. Its restriction to each entire axis is convex: the usual convex combinations on a line are polyhedral convex combinations after subdivision at the point in question. This first gives the assertion at rational points, and then at all points by continuity of PC functions. Since $v(0,\epsilon)$ and $v(0,-\epsilon)$ are at most zero, convexity gives $v(0,0) \leq 0$ and $v(0,y) \leq 0$ for $|y| \leq \epsilon$. Choose C with $v \leq \gamma + C$. For $0 < t < R$ on either horizontal ray, convexity between 0 and R gives $v(t,0) \leq t + tC/R$; letting $R \to \infty$ gives $v(t,0) \leq t$. On a vertical ray, interpolate instead between ϵ and R. For $t > \epsilon$ this gives

$$v(0,\pm t) \leq \frac{t-\epsilon}{R-\epsilon}(R+C) \longrightarrow t - \epsilon.$$

Hence $v \leq h$, proving the envelope identity. The outgoing slopes of h at the origin are $1, 1, 0, 0$; the slope jumps at $(0, \pm\epsilon)$ are one. There are no other corners. This proves the measure formula. The obstacle gap is ϵ at the origin and zero at the other two atoms, giving the integral. □

In the source notation the envelope is $P_\gamma(\varphi - \gamma) = h$, an unshifted function with growth $\gamma + O(1)$. The outside branch $|y - \epsilon|$ printed in the cited example has left limit 2ϵ at $y = -\epsilon$, whereas the middle branch has value zero. Replacing that outside branch by $|y| - \epsilon$ gives exactly the continuous obstacle above. The failure of orthogonality survives this repair. The total mass is four, equal to the total outgoing slope of γ. Thus positivity, correct mass, regularizability and an explicit envelope do not imply orthogonality. In particular the variational implication in [BMP26, Proposition 6.12] must retain both regularity and orthogonality hypotheses, as well as the prescribed mass of the measure. This example concerns the PC class on the balanced cross; it is not a counterexample to the non-Archimedean envelope theorem in Section 19.19.

16.8 Local geometry in tropical Calabi–Yau problems

Amini–Piquerez–Wu work with compact prekähler tropical varieties and locally convex potentials. Their framework contains a background semipositive form ω, and a Kähler form θ used for approximation. Theorem 5.13

of [APW26] has two different conclusions: continuous θ-psh functions admit uniform PL approximations in the same class; an ω-psh function admits decreasing PL approximations in the enlarged classes $\omega + \alpha_j\theta$, with $\alpha_j \downarrow 0$. When the limit is continuous, the latter convergence is uniform by Dini's argument. It is essential to retain the varying background form in the second statement. Their existence and nonexistence results distinguish local models. A point is regular in codimension one in their terminology if a neighbourhood has a tropical chart in $L \times \mathbb{R}^{d-1}$, with L a generalized tropical line. If every point of the open stratum has this property, Theorem 10.4 gives their tropical Calabi–Yau theorem. This phrase is a local chart condition at every point; it does not mean only that a singular set has codimension at least two. The obstruction in Theorem 11.4 is also precise. At a codimension-two face, let Z be the two-dimensional star fanfold and let E be its linear span, of dimension $r \geq 3$. Condition (G) requires that the image of Z in E/F have dimension two for every $(r-2)$-dimensional subspace F. If one such star satisfies (G), their universal tropical Calabi–Yau assertion fails for every strongly semipositive background form. This is a failure of surjectivity of the Monge–Ampère operator onto all admissible measures, not a claim that no equation has any solution.

16.8.1 What the analytic comparison additionally requires

Theorem 12.11 of the same preprint works over $K = \mathbf{C}((t))$ with a smooth projective variety and starts with an existing bounded tropical solution in its toric embedding setup. It assumes a full-dimensional SNC dual complex, strong faithfulness relative to that complex, and a probability measure on it absolutely continuous with respect to its top-dimensional Lebesgue measure. Under these hypotheses the tropical potential extends to a continuous non-Archimedean psh potential with the prescribed Monge–Ampère measure, and has the paper's comparison property. Ordinary injectivity of one tropical chart is not the strong faithfulness assumption, and the theorem does not solve the tropical existence problem that precedes it. The mixed calculus cited there from the companion work is retained as an external dependency. The results just described are source theorems, not independently reconstructed proofs of the companion theory. They supplement the local CLD theory by global positivity and envelope geometry; they do not replace the test-space comparisons required for actual Green forms.

References. [BMP26, Definitions 3.1–3.3, Theorem 4.13, Proposition 6.12 and Example 6.23]; [APW26, Theorems 5.13, 10.4, 11.4 and 12.11].

Chapter 17

Harmonic coordinates and weakly smooth forms

17.1 Harmonic coordinates: the geometric obstruction to original smoothness

17.1.1 Numerical triviality and principal triviality differ

An original affine coordinate is built from logarithms of analytic units. Its residual line-bundle data is therefore principal in the appropriate local description. A numerical harmonic function only asks the associated residual class to be numerically trivial. A degree-zero line bundle on a residual curve need not be trivial or torsion. This difference can prevent a numerical harmonic function from being original smooth.

On a curve whose residue field is algebraic over a finite field, torsion properties of residual degree-zero classes improve the comparison. The relevant statement in GJR is a curve result. It should not be generalized to every dimension over a finite extension of $\mathbb{Q}_p$ merely because the residue field is finite.

17.1.2 What the enlarged sheaf is intended to repair

If harmonic functions are geometrically natural but unavailable as original smooth coordinates, differential constructions based only on analytic units may be too restrictive. GJR allows harmonic tropicalizations and pulls back

real smooth superforms through them. The resulting weakly smooth sheaf contains the original one and supports a differential calculus and integration theory.

The adjective weakly smooth refers to the enlarged coordinate class; it has no connection with weak positivity. Its continuous dual consists of strong currents in the terminology of that paper; again, this says which tests are allowed, not which positive cone is used. The detailed constructions and the direction of the restriction map follow in the next section.

17.1.3 The curve cohomology calculation

Gubler–Jell–Rabinoff also construct a compatible differential theory on weighted metric graphs and use it to calculate weakly smooth Dolbeault cohomology of compact Berkovich curves. For a connected compact curve without boundary in their setting, the dimensions satisfy

$$h^{0,0} = h^{1,1} = 1, \qquad h^{1,0} = h^{0,1} = b_1(X^{\mathrm{an}}).$$

The integer on the right is the first Betti number of the underlying analytic topological space. It is not in general the algebraic genus. A smooth proper curve with good reduction can have positive algebraic genus and $b_1(X^{\mathrm{an}}) = 0$.

This is an important warning for the proposed passage from tropical Hodge theory to Berkovich Hodge theory: one must specify which cohomology is being compared. Residual algebraic geometry is not automatically encoded in the first Betti number of a skeleton. A statement resembling a Hodge diamond may concern tropical Dolbeault groups rather than algebraic de Rham cohomology.

References. [GJR, Sections 7, 10, 15–17]; [GJRc, Theorems 6.4.3 and 6.4.5].

17.2 Harmonic tropicalizations and weakly smooth forms

Throughout this section, K is complete and nontrivially valued, and X is a good strictly K-analytic space. The version of Gubler–Jell–Rabinoff cited here is arXiv:2111.05741v3, dated 7 March 2025. The adjective *weakly* in *weakly smooth* concerns the allowed coordinate functions. It has no connection with the distinction between weakly, strongly, and ordinarily positive forms.

17.2.1 From analytic units to numerically trivial models

A smooth tropicalization is locally a map

$$F = (-\log|f_1|, \dots, -\log|f_r|)$$

defined by invertible analytic functions. To describe the enlargement of this class of maps, we first specify the model-theoretic meaning of harmonicity.

Definition 17.2.1 (Local model functions and harmonicity)**.** Let $x \in X$. An integral model function near x has the form

$$h = -\log\|1\|_{\mathfrak{L}}$$

on an analytic neighbourhood V, where $\mathfrak{V}$ is a formal K°-model of V and $\mathfrak{L}$ is a model of $\mathscr{O}_V$, with its specified generic-fibre trivialization. An $\mathbb{R}$-model function is locally a finite real linear combination of such functions.

An $\mathbb{R}$-model function h is *semipositive at* x if it can be represented on a neighbourhood of x by an $\mathbb{R}$-model line bundle whose restriction to the special fibre is nef. It is *harmonic at* x if both h and $-h$ are semipositive there. These conditions are imposed at every point to obtain semipositivity or harmonicity on X.

Here nefness means nonnegative degree on every proper integral curve in the special fibre. An $\mathbb{R}$-model line bundle means a finite real linear combination of integral model line bundles, with degrees extended linearly. Proposition 7.1 and Definition 7.2 of [GJR] identify this definition with the corresponding condition on the residue class $L_h(x)$ on the reduction of the analytic germ (X, x). In particular,

$$h \text{ is harmonic at } x \quad \Longleftrightarrow \quad L_h(x) \text{ is numerically trivial.}$$

Numerical triviality is the condition $\deg(L_h(x)|_C) = 0$ on the relevant proper curves. It does not assert that $L_h(x)$ is trivial or torsion.

Proposition 17.2.2 (Elementary direction and functoriality)**.** *If f is an invertible analytic function, then $\log|f|$ is harmonic. Harmonic functions are stable under pullback by analytic morphisms and under extension of the ground field. Every real harmonic function is locally a finite real linear combination of integral harmonic functions.*

Open proof obligation (RC2). Prove the nontrivial harmonic and PL assertions currently assigned to GJR Propositions 7.6 and 7.5.

Remark 17.2.3 (The relevant topology). The PL functions form a sheaf for the analytic G-topology. Harmonicity and semipositivity in Definition 17.2.1 are local in the ordinary analytic topology and do not form sheaves for the G-topology [GJR, Remark 7.3(3)]. A covering by formal domains therefore cannot be substituted without argument for analytic neighbourhoods in this definition.

Definition 17.2.4 (Harmonic tropicalization)**.** A harmonic tropicalization of a compact good strictly analytic space V is a map $h = (h_1, \dots, h_r) : V \to \mathbb{R}^r$ whose coordinates are integral harmonic functions.

This is [GJR, Definition 8.1]. A smooth tropicalization is harmonic, but a harmonic tropicalization need not arise from analytic units. The integrality of the coordinates is part of the definition. The last assertion of Proposition 17.2.2 explains how general real harmonic functions are nevertheless represented in such charts.

17.2.2 The sheaf and its differential operations

Definition 17.2.5 (Weakly smooth preforms and forms)**.** Let $U \subset X$ be open with compact strictly analytic closure $\overline{U}$. A preform of type (p, q) on U is a pair (h, α), where $h : \overline{U} \to \mathbb{R}^r$ is a harmonic tropicalization and α is a smooth Lagerberg (p, q)-form on $h(\overline{U})$. Two pairs (h, α) and (k, β) represent the same preform if

$$\mathrm{pr}_1^*\, \alpha = \mathrm{pr}_2^*\, \beta \quad \text{on } (h, k)(\overline{U}).$$

The sheafification of this presheaf is denoted $\mathcal{A}^{p,q}_{\mathrm{wk}}$. Its sections are *weakly smooth forms*.

This is [GJR, Definitions 10.3 and 10.8]. Passing to a product chart puts any finite collection of preforms on a common tropicalization. On that chart, wedge products and derivatives are those of Lagerberg forms:

$$d'(h, \alpha) = (h, d'\alpha), \qquad d''(h, \alpha) = (h, d''\alpha).$$

For types (p, q) and (p', q'), the commutativity sign is $(-1)^{(p+q)(p'+q')}$, and the Leibniz sign for either differential is $(-1)^{p+q}$. These are total-degree signs.

Theorem 17.2.6 (Comparison of the three sheaves)**.** *There are injective morphisms of sheaves*

$$\mathcal{A}^{\bullet,\bullet}_{\mathrm{sm}} \longrightarrow \mathcal{A}^{\bullet,\bullet}_{\mathrm{wk}} \longrightarrow \mathcal{A}^{\bullet,\bullet}_{\mathrm{ps}}.$$

The first sheaf is the original CLD sheaf. The last consists of piecewise smooth forms and is endowed with the polyhedral differentials d'_P, d''_P. Both morphisms preserve wedge products and the indicated differentials. Weakly smooth forms admit functorial pullback by analytic morphisms.

Open proof obligation (RC2). Supply the exact inclusions and comparison of the smooth, weakly smooth and delta-form categories; GJR Proposition 10.14 and its supporting constructions.

Proposition 17.2.7 (Harmonicity detected by the weak differential)**.** *A real-valued function f on X is harmonic if and only if*

$$f \in \mathcal{A}^{0,0}_{\mathrm{wk}}(X), \qquad d'd''f = 0.$$

Open proof obligation (RC2). Prove injectivity of pullback on the harmonic chart and the converse with the stated face hypotheses; GJR Proposition 10.9 supplies injectivity.

Example 17.2.8 (A harmonic function which is not CLD-smooth)**.** Assume that K is algebraically closed and that its residue field is not algebraic over a finite field. Gubler–Jell–Rabinoff construct a smooth proper genus-three curve with a theta graph as skeleton and an elliptic residual component E at one vertex v. Let z be the origin of E and choose a nontorsion point $x \in E(\widetilde{K})$.

The local construction produces an integral harmonic function h whose residue at v has degree zero but represents

$$[z] - [x] \neq 0 \quad \text{in} \quad \mathrm{Pic}^0(E) \otimes_{\mathbb{Z}} \mathbb{R}.$$

On a smooth analytic curve, the quotient of harmonic germs by CLD-smooth harmonic germs at such a point is identified with this residual Picard space. Thus h is weakly smooth by Proposition 17.2.7 and is not CLD-smooth. The construction and the nonvanishing obstruction are given in [GJR, §17.3 and Proposition 17.4]; the sheaf comparison used here is explained in Remark 15.10.

The obstruction is algebraic: degree zero only detects numerical triviality, while the nonzero Picard class prevents a representation by the local logarithms that give smooth harmonic functions. Hence the first inclusion in Theorem 17.2.6 can be strict even in bidegree $(0,0)$.

Remark 17.2.9 (Cases in which the first inclusion is equality). On a smooth analytic curve potentially locally isomorphic to $\mathbb{P}^{1,\mathrm{an}}$, or over a residue field algebraic over a finite field, every harmonic function is CLD-smooth and $\mathcal{A}_{\mathrm{sm}} = \mathcal{A}_{\mathrm{wk}}$ [GJR, Remark 15.10]. Strictness is therefore not a statement about every analytic curve.

17.2.3 Strong currents and restriction of test spaces

Now assume that X is Hausdorff, boundaryless, and of pure dimension d. Write $\mathcal{A}^{r,s}_{\mathrm{wk},c}(X)$ for compactly supported weakly smooth forms, endowed with the locally convex topology of [GJR, §12.1]. In charts, its defining convergence uses fixed compact support control and uniform convergence of every derivative of the representing Lagerberg forms.

Definition 17.2.10 (Strong currents, in the bidegree convention of these notes)**.** Set

$$\mathcal{D}^{p,q}_{\mathrm{wk}}(X) := \big(\mathcal{A}^{d-p,d-q}_{\mathrm{wk},c}(X)\big)',$$

where the prime denotes the continuous real dual. Its elements are the *strong currents* of bidegree (p,q).

In [GJR, §12.2], the notation is $\mathcal{D}_{r,s} = (\mathcal{A}^{r,s}_c)'$: the indices record the degrees of the test forms. Thus their $\mathcal{D}_{r,s}$ is our $\mathcal{D}^{d-r,d-s}_{\mathrm{wk}}$. The explicit dual formula is the reliable way to translate conventions.

Proposition 17.2.11 (The direction of the comparison map)**.** *Restriction of functionals gives a canonical map*

$$\rho : \mathcal{D}^{p,q}_{\mathrm{wk}}(X) \longrightarrow \mathcal{D}^{p,q}_{\mathrm{sm}}(X).$$

Using the assertion in [GJR, §12.1] that the original CLD test-space topology is the induced subspace topology, this map is surjective. Its kernel consists precisely of the functionals vanishing on all original smooth test forms. An extension of a smooth-test current is unique if those forms are dense in the weak test space.

Proof. Let $E = \mathcal{A}^{d-p,d-q}_{\mathrm{sm},c}(X)$ and $F = \mathcal{A}^{d-p,d-q}_{\mathrm{wk},c}(X)$. Continuity of $E \hookrightarrow F$ gives restriction $F' \to E'$. If $T \in E'$, the induced subspace topology supplies a continuous seminorm P on F such that $|T(e)| \le P(e)$ for every $e \in E$. The real Hahn–Banach theorem extends T to a linear functional on F dominated by P, hence to an element of F'. This proves surjectivity. The

kernel description is immediate; a continuous functional vanishing on a dense subspace vanishes everywhere. □

Remark 17.2.12 (What this proposition does not identify). The Hahn–Banach extension is not canonical and does not, by this argument, preserve positivity. Density is a separate question; it does not follow from the inclusion of sheaves. In particular, enlarging the test forms does not by itself give an inclusion of the corresponding spaces of currents, or an isomorphism of those spaces.

The differential of a strong current is defined by duality with the same total-degree signs as for smooth-test currents. Restriction commutes with d' and d''. Proper direct images and multiplication by weakly smooth forms are available [GJR, §12.2]. These constructions do not give arbitrary currents a wedge product or a pullback under every analytic morphism.

Theorem 17.2.13 (Poincare–Lelong against weak tests)**.** *Let f be a regular meromorphic function on X, meaning locally a nonzero quotient of analytic functions that are non-zero-divisors on the local rings. Then*

$$d'd''[\log|f|] = \delta_{\mathrm{div}(f)} \quad \textit{in} \quad \mathcal{D}^{1,1}_{\mathrm{wk}}(X).$$

Open proof obligation (RC2). Prove the Poincare–Lelong equality on the full weakly smooth test class of the statement; GJR Theorem 12.7 is supplied.

Example 17.2.14 (Polyhedral differentiation misses a corner mass)**.** On $X = \mathbb{G}_m^{\mathrm{an}}$, put $t = -\log|T|$ and $u = |t|$. This is a piecewise smooth function. On the two cells $t \geq 0$ and $t \leq 0$ it is affine, so

$$d'_P d''_P u = 0.$$

Its current derivative is different. For a smooth compactly supported test function φ on the real skeleton,

$$\int_{\mathbb{R}} |t|\varphi''(t)\,dt = 2\varphi(0).$$

Consequently $d'd''[u]$ is twice the Dirac measure at the radius-one Gauss point. This explicitly distinguishes polyhedral differentiation from differentiation of currents. On this genus-zero curve weakly smooth forms agree with CLD-smooth forms; u is not weakly smooth at that point.

For weakly smooth forms α, Stokes gives $d'[\alpha] = [d'\alpha]$ and $d''[\alpha] = [d''\alpha]$. For arbitrary piecewise smooth forms, these identities require the missing face terms; they cannot be inferred from the injection into currents in [GJR, §12.4].

17.2.4 Positivity, regularization, and the scope of comparison

Theorem 17.2.15 (Model positivity implies original current positivity)**.** *Let X be good, separated, and strictly analytic. If h is a semipositive $\mathbb{R}$-PL function, then the original CLD current $d'd''[h]$ is positive on $X \setminus \partial X$. The same conclusion holds locally for uniform limits of semipositive PL metric weights.*

Open proof obligation (RC2). Prove metric/current positivity and the converse with their exact hypotheses; GJR Theorem 7.14 and Remark 7.16 are supplied.

Theorem 17.2.16 (Regularization on smooth analytic curves)**.** *Let X be a rig-smooth boundaryless analytic curve over K, and let f be subharmonic in Thuillier's sense. For every relatively compact open subset $U \subset X$, there is a decreasing net of weakly smooth psh functions on U converging pointwise to $f|_U$.*

Open proof obligation (RC2). Prove regularization on curves in the stated net and weakly smooth scope; GJR Proposition 15.11 is supplied.

Remark 17.2.17 (Canonical metrics and an explicitly corrected argument). The canonical tropicalization in Raynaud uniformization is harmonic [GJR, Proposition 16.2]. It need not be CLD-smooth [GJR, Corollary 17.5]. Remark 16.4 explicitly explains that Gubler–Künnemann's earlier argument in the 2017 paper, Examples 8.15 and 9.17, used the incorrect smoothness assertion to conclude that canonical metrics are δ-metrics. GJR leaves the latter conclusion open in the original δ-metric theory. This corrects the cited argument; it does not prove that the metrics are not δ-metrics.

The version concordance is recorded in Section 18.3.4; the elementary formula corrections are collected in Remark A.1.12.

17.3 Ordinary forms, G-forms, and harmonic forms in CLD25

The change of psh definition in CLD25 does not change its ordinary smooth test forms. Three sheaves must nevertheless be distinguished. We retain the good Hausdorff hypotheses on X; whenever currents enter the comparison, X is purely n-dimensional and boundaryless.

Definition 17.3.1 (The analytic affine and PL structures)**.** An affine function in the sense of CLD25 is, locally for the ordinary topology, of the form

$$a \log |f| + c, \qquad a \in \mathbb{Q}, \quad c \in \mathbb{R}, \quad f \in \mathcal{O}_X^{\times}.$$

A PL function is a continuous function which has this description G-locally, on analytic domains. Finite sums are included in this description by clearing rational denominators and multiplying units. These are the structures of [CLD25, Proposition 12.4.1 and §12.4.6]. They use rational slopes and real constants; this notation does not silently mean arbitrary $\mathbb{R}$-PL functions.

Here a G-cover consists of analytic domains such that, at each point, finitely many members containing that point have union a neighbourhood. An ordinary open cover is a G-cover, but a G-cover need not provide a single member which is a neighbourhood of a point on an interface.

Definition 17.3.2 (The two smooth sheaves)**.** For a polyhedral subset P of a real affine space E, let $A^{p,q}(P)$ denote smooth ambient superforms restricted to P, modulo forms whose restrictions to the tangent spaces of every cell in P vanish. More precisely, this is the quotient sheaf of [CLD25, §1.9.1–§1.9.3]; it is independent of subdivision.

For an analytic domain V, form the direct limit

$$\mathcal{P}^{p,q}(V) = \varinjlim_{(h:V \longrightarrow E,\, P)} A^{p,q}(P),$$

where h has PL coordinates, P contains $h(V)$, and transition maps are affine maps between ambient spaces. Products of charts give common refinements. The associated sheaf on the analytic G-site is denoted $A^{p,q}_{G,25}$ here. Its sections are the smooth G-forms of [CLD25, §3.3.3–Definition 3.3.4].

Write $\pi : X_G \to X$ for the map to the ordinary topological site. The ordinary smooth sheaf $A^{p,q}_{25} \subseteq \pi_* A^{p,q}_{G,25}$ consists of forms represented, on an ordinary neighbourhood of each point, by an *affine* chart and a smooth superform. This is [CLD25, Definition 6.2.1].

Proposition 17.3.3 (The ordinary sheaf is unchanged)**.** *There is a canonical identification*

$$A^{p,q}_{\mathrm{sm}} = A^{p,q}_{25}.$$

It respects wedge product and the two differentials. The operators called J correspond by the sign conversion already specified above.

Open proof obligation (RC2). Prove both local moment-map presentation and matching nullity of representatives on the common product chart; CLD25 Proposition 15.1.1(b), CLD12 Lemma 3.2.2 and CLD25 Proposition 3.4.4.

The distinction between the two sheaves is the covering condition, not the replacement of analytic units by arbitrary continuous coordinates. Indeed, [CLD25, Proposition 15.1.1(a)] still presents every G-form by analytic moment maps, but on a G-cover. The ordinary smooth forms remain the test objects in [CLD25, §7.1.1].

Definition 17.3.4 (The harmonic subsheaf)**.** A PL function h is harmonic in [CLD25, Definition 7.8.2] if

$$d'd''[h] = 0.$$

More general harmonic functions are defined to be local finite real linear combinations of such PL harmonic functions. The sheaf $A^{p,q}_{\mathrm{harm},25}$ consists of G-forms locally represented by $h^*\alpha$, where $h = (h_1, \dots, h_r)$ has PL harmonic coordinates and α is a smooth superform on a neighbourhood of a polyhedron containing $h(U)$; see [CLD25, §7.8.7].

Affine functions are harmonic, so these definitions give inclusions

$$A^{p,q}_{\mathrm{sm}} = A^{p,q}_{25} \;\subseteq\; A^{p,q}_{\mathrm{harm},25} \;\subseteq\; \pi_* A^{p,q}_{G,25}.$$

All three are differential algebras, but integration into currents has different differential properties. Denote the operators on G-forms by d'_G, d''_G. Every PL function satisfies

$$d'_G d''_G h = 0,$$

because it is affine on a G-cover. This does not imply $d'd''[h] = 0$: distributional differentiation can detect the interfaces. Already on the real line, $h(t) = |t|$ has zero piecewise Hessian, whereas its distributional Hessian is $2\delta_0$. The harmonic condition is therefore an additional condition on a PL function.

For a harmonic form ω, the extra boundary terms vanish:

$$d'[\omega] = [d'_G\omega], \qquad d''[\omega] = [d''_G\omega].$$

This is [CLD25, Theorem 7.8.5 and Corollary 7.8.8]. The resulting map to currents is injective in the present boundaryless setting by [CLD25, Corollary 7.3.9 and Theorem 12.11.1]. It does not redefine currents as duals of all G-forms.

Remark 17.3.5 (Comparison with GJR requires a numerical theorem). CLD25 starts with a vanishing *original curvature current* for a PL function. GJR defines harmonicity through numerical triviality of the residual model class, with its own integral and real PL classes; see Definition 17.2.1. An identification of the two harmonic sheaves requires a PL curvature comparison with matching hypotheses, and then a comparison of their chart presentations. The degree-one vanishing assertion of [CLD25, Theorem 18.8.4] addresses the numerical/current step for its integral PL metrics; its scope is discussed in Section 19.3. No unrestricted identification with the GJR weakly smooth sheaf is assumed here. Also, CLD25 does not define every continuous solution of $d'd''[h] = 0$ to be harmonic: [CLD25, Remark 7.8.3] explicitly distinguishes that question from the PL-generated definition.

17.4 Graph forms and harmonic cohomology

17.4.1 The first-order equations on a graph

Let Σ be a finite connected metric graph without boundary, and choose orientations of its edges. On an open edge with coordinate t, forms have the familiar expressions $f(t)$, $a(t)d't$, $b(t)d''t$, and $c(t)d't \wedge d''t$. At vertices, the smoothness conditions are those of the harmonic-coordinate graph calculus. In particular, the first-order compatibility is tied to a weighted conservation law.

For constant coefficients on oriented edges, closed $(1,0)$-forms correspond to flows satisfying Kirchhoff's law: the weighted outgoing coefficients sum to zero at each vertex. In the unweighted case, the incidence matrix has rank $|V| - 1$ for a connected graph. Its kernel therefore has dimension

$$|E| - |V| + 1 = b_1(\Sigma).$$

This linear algebra explains the occurrence of the graph genus in $H^{1,0}$. Subdividing an edge adds one vertex and one edge and leaves the dimension unchanged.

17.4.2 Why integration detects the top cohomology

For a compact graph without boundary, Stokes gives $\int_\Sigma d''\alpha = 0$ for a $(1,0)$-form α. Thus integration descends to a functional on $H^{1,1}$. Conversely, a top-degree form of total integral zero can be integrated along edges to produce a primitive; constants of integration are chosen so that the vertex conditions hold. The obstruction is precisely the total integral.

This gives $H^{1,1} \simeq \mathbb{R}$ in the connected compact case. If the graph has boundary, flux may escape through boundary vertices, changing the obstruction and the cohomology. The source gives the exact boundary-dependent dimension formulas. The boundary must therefore be specified before applying a duality statement.

17.4.3 The circle as a complete example

For a circle of length ℓ, take a periodic coordinate on its universal cover. A closed $(1,0)$-form has a constant coefficient after passing to its cohomology class, and its period is the invariant. A $(0,1)$-form $b(t)d''t$ is exact precisely when its integral over one period is zero. A $(1,1)$-form has a primitive of the required periodic type precisely when its total integral is zero. Hence the four cohomology groups in bidegrees $(0,0), (1,0), (0,1), (1,1)$ all have dimension one.

The pairing of $a, d't$ with $b, d''t$ is $ab\ell$ in the simplest constant representatives. It is nondegenerate. This gives a concrete model for the Poincaré duality proved in the curve theory, while retaining the metric length in the pairing.

17.4.4 The good-reduction curve as a contrasting example

A smooth proper curve with good reduction can have a one-point skeleton and first Betti number zero. Its weakly smooth Dolbeault groups in bidegrees $(1,0)$ and $(0,1)$ are therefore zero in the cited theorem, while $H^{1,1}$ remains one-dimensional by integration. If the algebraic genus is positive, algebraic differential forms still exist; they belong to a different cohomology theory.

This example prevents a misleading inference from the graph picture. The weakly smooth calculus is designed to have robust tropical analytic properties and duality. It is not claimed to reproduce every algebraic Hodge number. To compare it with algebraic de Rham theory, one would need an additional construction accounting for the residual geometry.

17.4.5 From graph forms to analytic forms

The passage to Berkovich curves uses skeleta adapted to the forms and harmonic maps between graph presentations. It is not a claim that every form factors through one minimal skeleton. Enlarging a skeleton can add trees and local coordinates while preserving the appropriate cohomological information. Compatibility under these changes is what makes the analytic sheaf and its cohomology intrinsic.

This gives a successful example of the general strategy discussed in Chapter 24: first understand a finite tropical complex, then prove compatibility under refinement, then identify the resulting analytic cohomology. The proof contains more than a topological deformation retraction, because the differential and vertex-smoothness conditions also have to be preserved.

References. [GJRc, Sections 2–3 and Theorems 6.4.3, 6.4.5].

17.5 The differential complex on a compact graph

We give the graph calculation underlying the curve comparison. It is useful both as a complete example of a differential theory and as a warning about what a skeleton retains. Let Γ be a finite connected metric graph with at least one edge. We first take all edge weights to be one and no designated boundary. Multiple edges and loops are allowed; a loop contributes two outgoing germs at its vertex.

Choose an orientation of every edge e and a parameter $t_e \in [0, \ell_e]$. A smooth function is continuous on Γ, smooth up to each endpoint on each edge, and satisfies the following local conditions. At a vertex of valency one it is constant nearby. At valency two it is an ordinary smooth function across the vertex. At higher valency its outgoing first derivatives have sum zero.

A $(1,0)$-form has edgewise expressions $a_e(t_e)d't_e$. Reversing orientation reverses the coefficient. At a leaf it vanishes nearby, at a two-valent vertex

the one-form extends smoothly across, and at higher valency its outgoing coefficients have sum zero. The definition of $(0,1)$-forms is identical with $d''t_e$. A $(1,1)$-form has expressions $c_e(t_e)d't_e\wedge d''t_e$, unchanged by orientation reversal. It vanishes near leaves, is smooth across two-valent vertices, and has no extra matching condition at higher-valent vertices. These are the unweighted GJR graph conventions.

The edgewise formulas are

$$d''f = f_e'\,d''t_e, \qquad d''(a_e\,d't_e) = -a_e'\,d't_e\wedge d''t_e, \qquad \int_\Gamma c = \sum_e \int_0^{\ell_e} c_e(t)\,dt.$$

The vertex conditions ensure that these derivatives lie in the indicated form spaces. They also imply Stokes: the endpoint terms of $\int_\Gamma d''a$ sum to the outgoing coefficient sums, hence vanish.

17.5.1 The incidence matrix

Let V, E denote the vertices and the chosen oriented edges. Define $B:\mathbb{R}^E\to\mathbb{R}^V$ by putting $+1$ at an edge's tail and -1 at its head; a loop column is zero. Connectedness implies

$$\operatorname{im} B = \{z\in\mathbb{R}^V : \textstyle\sum_v z_v = 0\}, \qquad \dim\ker B = |E| - |V| + 1.$$

Indeed the columns have coordinate sum zero. Along a path, signed sums of columns produce the difference of the two endpoint basis vectors. Since any vertex can be joined to a fixed one, these differences span the zero-sum hyperplane. We write $b = |E| - |V| + 1 = b_1(\Gamma)$.

Proposition 17.5.1. *The d''-closed $(1,0)$-forms are exactly the edgewise constant forms whose coefficient vector belongs to $\ker B$. Consequently $H^{1,0}(\Gamma)\simeq\ker B$ and $h^{1,0}=b$.*

Proof. The displayed formula for d'' forces $a_e'=0$ on each edge. The vertex conditions then reduce to $Ba=0$. At a leaf this equation forces the incident constant to be zero, so the required vanishing on a neighbourhood follows as well. At valency two it makes the constants match with the orientation signs. Conversely these conditions give a smooth closed form. There are no forms of type $(1,-1)$, hence no boundaries in this group. □

Theorem 17.5.2 (Periods and exactness)**.** *Integration around cycles induces an isomorphism*

$$H^{0,1}(\Gamma) \simeq \mathrm{Hom}(H_1(\Gamma, \mathbb{R}), \mathbb{R}).$$

Proof. For a $(0,1)$-form $\beta = b_e(t)d''t_e$, set $I_e = \int_0^{\ell_e} b_e(t)dt$. The period on a cycle $z \in \ker B$ is $\sum_e z_e I_e$. If $\beta = d''f$, these integrals are endpoint differences and all periods vanish.

Conversely suppose all periods vanish. Fix a basepoint and define $f(x)$ by integrating β along a path from it to x. Any two paths differ by cycles, so f is well defined. It is continuous and has derivative b_e on each edge. Near a leaf, $b_e = 0$, so f is constant. At a two-valent vertex, smooth matching of the one-form gives smooth matching of its primitive. At a higher-valent vertex, the outgoing derivatives of f are the outgoing coefficients of β, whose sum is zero. Thus f belongs to $A^{0,0}(\Gamma)$ and $\beta = d''f$.

To prove surjectivity, represent a functional on $\ker B$ by some vector $I \in \mathbb{R}^E$. On each edge choose a smooth bump supported strictly inside the edge and of integral I_e. These coefficients define a $(0,1)$-form because they vanish near every vertex. Its periods are the prescribed functional. □

This proof is stronger than a dimension count: it supplies an exactness criterion and a primitive. It also shows why smoothness at vertices cannot be ignored. Edgewise primitives always exist, but their values and derivatives must satisfy the graph's matching conditions.

Theorem 17.5.3 (Top-degree exactness)**.** *The image of $d'' : A^{1,0}(\Gamma) \to A^{1,1}(\Gamma)$ is precisely the kernel of integration. Hence $H^{1,1}(\Gamma) \simeq \mathbb{R}$.*

Proof. Stokes gives one inclusion. For the other, let $c_e(t)d't_e \wedge d''t_e$ have total integral zero and put $J_e = \int_0^{\ell_e} c_e(t)dt$. An edgewise solution is

$$a_e(t) = A_e - \int_0^t c_e(s)ds.$$

At a tail the outgoing coefficient is A_e; at a head it is $-A_e + J_e$. Therefore the vertex equations are

$$(BA)_v = -\sum_{e:\, e^+ = v} J_e.$$

The right side has total sum $-\sum_e J_e = 0$. By the description of $\operatorname{im} B$, constants A_e solving these equations exist. They give the value matching at

two-valent vertices and the coefficient sums at higher-valent ones. Derivative matching at a two-valent vertex follows by differentiating $a'_e = -c_e$ and using the smooth matching of c. At a leaf, c vanishes nearby and the vertex equation sets a to zero there. Thus a is an admitted $(1,0)$-form and $d''a = c$.

An interior bump on any one edge gives a $(1,1)$-form of nonzero integral, proving that integration is surjective on the quotient. □

Corollary 17.5.4 (Graph duality)**.** *For this compact connected graph,*

$$h^{0,0} = h^{1,1} = 1, \qquad h^{1,0} = h^{0,1} = b.$$

Integration of wedge products gives perfect pairings between complementary bidegrees.

Proof. A function with zero edge derivatives is constant by connectedness, giving $h^{0,0} = 1$. The other dimensions were proved above. For $(1,0)$ and $(0,1)$, write the first class as a constant flow $a \in \ker B$ and the second by its edge integrals I. Their pairing is $\sum_e a_e I_e$. It is the natural pairing of $\ker B$ with its dual from Theorem 17.5.2, hence perfect. Constants pair perfectly with the integral coordinate of $H^{1,1}$. Stokes ensures independence of representatives. □

17.5.2 What changes when a boundary is designated

Let $\partial\Gamma \subset V$ be nonempty and impose no vertex matching condition there, apart from continuity of functions. Write B_{int} for the incidence matrix with only the rows indexed by $V \setminus \partial\Gamma$. These rows are independent. Indeed a linear relation, extended by zero at boundary vertices, gives a vector in $\ker B^t$, hence a constant vector; because it is zero at one boundary vertex, it is zero everywhere.

Proposition 17.5.5. *For a connected graph with nonempty designated boundary,*

$$h^{0,0} = 1, \quad h^{0,1} = b, \quad h^{1,0} = b + |\partial\Gamma| - 1, \quad h^{1,1} = 0.$$

Proof. Closed $(1,0)$-forms are the constant flows in $\ker B_{\mathrm{int}}$, whose dimension is $|E| - |V| + |\partial\Gamma|$. The period proof for $H^{0,1}$ is unchanged: path integration still gives a continuous primitive and there are fewer endpoint conditions to check. The proof of top-degree exactness now solves the vertex equations only

at interior vertices. Since B_{int} is onto, these equations always have a solution, with no total-integral constraint. Thus every $(1,1)$-form is exact. □

For an interval with both endpoints designated as boundary, $h^{1,0} = 1$ and $h^{1,1} = 0$. For the same interval with no designated boundary, the leaf conditions give $h^{1,0} = 0$ and $h^{1,1} = 1$. The topological interval alone does not determine this differential complex: the boundary convention is part of its data.

17.5.3 Weights and the curve comparison

If an edge has positive weight w_e, put $t_{0,e} = t_e/w_e$, so its new length is ℓ_e/w_e. Pullback replaces a one-form coefficient a_e by $w_e a_e$ and a two-form coefficient c_e by $w_e^2 c_e$. The weighted vertex conditions become the preceding unweighted ones. Since $d/dt_{0,e} = w_e d/dt_e$, this is an isomorphism of differential algebras. Its integration rule agrees with $\sum_e w_e \int c_e(t_e)dt_e$.

The passage from these graph groups to weakly smooth forms on a Berkovich curve is a separate theorem. In the setting of GJR's curve paper, a suitable strictly semistable model gives a pullback from graph forms inducing the cohomology isomorphism. Finite extension and Galois descent handle a curve without such a model over the initial field. We use that comparison, not a claim that every continuous retraction induces an isomorphism of differential complexes.

In particular, a skeleton consisting of one isolated point has no graph $(1,1)$-forms under the definitions above. It cannot by itself compute the top-degree cohomology of a proper analytic curve. The comparison theorem uses an appropriate model; one may blow up to avoid smooth connected components of the special fibre and obtain a nontrivial skeleton. Attaching the resulting tree does not change b_1, but it supplies the graph differential data needed for top-degree integration.

17.6 Residual genus and topological genus

The discrepancy between algebraic genus and graph genus can be calculated without differential forms. Let C_0 be a connected proper nodal curve over an algebraically closed field. Let $\widetilde{C}_v$ be its normalized irreducible components

and let Γ be its dual graph. There is one vertex per component and one edge per node, including loop edges for self-nodes.

Proposition 17.6.1. *The arithmetic genus satisfies*

$$p_a(C_0) = b_1(\Gamma) + \sum_v g(\widetilde{C}_v).$$

Proof. Normalization gives an exact sequence

$$0 \longrightarrow \mathscr{O}_{C_0} \longrightarrow \bigoplus_v \nu_* \mathscr{O}_{\widetilde{C}_v} \longrightarrow \bigoplus_{e \in E} k_e \longrightarrow 0.$$

At a node, the last map takes the difference of the two branch values. Its exactness follows from the local description $k[[x, y]]/(xy)$: a pair of power series in x and y comes from this ring exactly when its constant terms agree. Taking Euler characteristics yields

$$\chi(\mathscr{O}_{C_0}) = \sum_v (1 - g(\widetilde{C}_v)) - |E|.$$

Since C_0 is connected and proper, $h^0(\mathscr{O}_{C_0}) = 1$. Thus $p_a = 1 - \chi = |E| - |V| + 1 + \sum_v g(\widetilde{C}_v)$, as asserted. □

For a proper semistable model of a smooth curve, constancy of Euler characteristic in the flat family identifies this arithmetic genus with the genus of the generic fibre. The skeleton retains the graph contribution $b_1(\Gamma)$; the remaining summands are genera of residual components. Good reduction gives a one-vertex dual graph and all the genus is residual. Totally degenerate reduction has genus-zero residual components and all the genus is graph-theoretic.

Consequently the weakly smooth cohomology formula $h^{1,0} = b_1$ cannot be identified with the dimension g of algebraic differentials without an additional hypothesis. For a good-reduction elliptic curve these dimensions are respectively zero and one. This does not contradict either theory: their complexes retain different information. In a proposed tropical-to-Berkovich comparison, the relevant sheaf and the treatment of residual components must be specified before drawing a Hodge-theoretic conclusion.

References. Graph definitions and the unweighting are [GJRc, Section 2.2]; the graph calculation above is an explicit incidence-matrix proof of the cohomology and duality statements. The analytic comparison is [GJRc, Theorems 6.4.2–6.4.5].

17.7 Residual divisors and harmonic coordinates

A harmonic function on a curve satisfies a conservation law for outgoing slopes. An original smooth harmonic function satisfies an additional local algebraic condition. The difference is visible on the residual curve of a type II point. This section calculates that difference and then revisits the canonical tropicalization example of Gubler–Jell–Rabinoff with consistent coordinates.

Work over a complete algebraically closed nontrivially valued field K. At a type II point v of a smooth analytic curve, the residual function field determines a smooth projective curve C_v over $\widetilde{K}$. Its closed points correspond to tangent directions. We use the slope formula: for an analytic meromorphic function whose normalized reduction at v is $\widetilde{f}$, outgoing slopes of $-\log|f|$ are the orders of $\widetilde{f}$, with the sign reversed for $\log|f|$. The identification of tangent directions and this slope formula are geometric inputs; they are not consequences of the abstract graph calculation.

The sign can be checked in the open disc direction at the Gauss point: with outward distance $t = -\log|T|$, the reduction of T has order one at 0, while $\log|T| = -t$ has outgoing slope -1.

Proposition 17.7.1. *Let h be a harmonic germ represented by a PL function on a finite star at v. If s_p is its outgoing slope in the direction $p \in C_v$, then*

$$D_h = \sum_p s_p[p], \qquad \deg D_h = \sum_p s_p = 0.$$

If h is a real linear combination of logarithms of local analytic units, then D_h has zero class in $\mathrm{Pic}^0(C_v) \otimes_{\mathbb{Z}} \mathbb{R}$.

Proof. Only finitely many directions have a nonzero slope, so the divisor is defined. Harmonicity is precisely the vanishing of the outgoing slope sum; the residual field is algebraically closed, so all residual points have degree one. For $h = \log|f|$, the slope formula identifies D_h with $-\operatorname{div}(\widetilde{f})$, hence with a principal divisor. Multiplying by a real scalar and adding preserves the zero divisor class. Constants have all slopes zero. □

The converse is not asserted from this calculation alone: lifting a residual principal relation to analytic units is a local analytic theorem. Thuillier's comparison identifies the relevant quotient of harmonic germs by smooth harmonic germs with $\mathrm{Pic}^0(C_v) \otimes \mathbb{R}$ in the curve setting used below. GJR

records this input in Remark 15.10 and the proof of Proposition 17.4. It also records that original smooth harmonic germs are the sheaf generated by logarithms of analytic units. We use these two comparison results explicitly.

Corollary 17.7.2. *In this setting, a harmonic germ with nonzero class $[D_h]$ cannot be an original smooth function. A degree-zero residual divisor is therefore not enough to guarantee original smoothness.*

Proof. If the germ were original smooth, it would be a smooth harmonic germ, hence a real linear combination of logarithms of analytic units. Proposition 17.7.1 would make its residual class zero. □

Example 17.7.3 (Why the residue field matters)**.** If a smooth projective curve is defined over an algebraic closure of a finite field, every point of its Jacobian is torsion. Indeed the variety and any chosen point descend to a finite field; the group of points over that finite field is finite. Thus $\mathrm{Pic}^0(C_v) \otimes \mathbb{R} = 0$. Over other algebraically closed fields, an elliptic residual curve can have nontorsion points, and their degree-zero divisor classes survive tensoring with $\mathbb{R}$. For an abelian group A, the kernel of $A \to A \otimes \mathbb{Q}$ is its torsion subgroup, and extension from $\mathbb{Q}$ to $\mathbb{R}$ is faithful. This justifies the last assertion. The vanishing of the residual obstruction is consistent with the equality of the two harmonic sheaves in the finite-residue-field case; the analytic equality itself uses the cited comparison theorem.

17.8 A consistent theta-graph calculation

Let a, b, c be three edges from P to Q, all oriented in that direction, with lengths $A, B, C > 0$. Choose the cycles

$$\gamma_1 = c - a, \qquad \gamma_2 = c - b.$$

The notation means traverse c from P to Q and return along the indicated other edge. Use the basis dual to (γ_1, γ_2) on $H^1(\Theta, \mathbb{R})$. The edge-length pairing has matrix

$$G = \begin{pmatrix} A + C & C \\ C & B + C \end{pmatrix}, \qquad \det G = AB + AC + BC > 0.$$

Thus $G\mathbb{Z}^2$ is a full lattice in $\mathbb{R}^2$, and the graph Jacobian is $\mathbb{R}^2/G\mathbb{Z}^2$. The positivity also follows directly from the positive edge-length pairing on the cycle space.

Proposition 17.8.1. *A lift of the Abel–Jacobi map based at P, on a star around P, has the following formulas, where t is distance from P:*

$$a:\ (-t,0), \qquad b:\ (0,-t), \qquad c:\ (t,t).$$

Modulo $G\mathbb{Z}^2$, these formulas agree at Q and define a continuous map on the whole graph. Each coordinate is harmonic near P.

Proof. Integrating the two harmonic one-forms corresponding to γ_1, γ_2 gives coefficient vectors $(-1,0)$ on a, $(0,-1)$ on b, and $(1,1)$ on c. Their sums at P vanish. At Q, the three lifted values are $(-A,0)$, $(0,-B)$, and (C,C). Their differences from the third are the negatives of the first and second columns of G, so they represent the same point of the quotient. The period of each cycle is the corresponding column of G, as required by the Abel–Jacobi definition. □

Attach an elliptic curve E at P, with the directions a, b, c marked by distinct points x, y, z, where z is the identity and x, y are nontorsion. Attach a projective line at Q, with three distinct markings. The lifting theorem for metrized complexes, used in GJR Section 17.3, realizes this data by a smooth proper analytic curve after choosing the lengths in the value group. This realization and compatibility of analytic and tropical Abel–Jacobi maps are the two geometric inputs in the example.

Theorem 17.8.2 (The residual obstruction in the example)**.** *The two lifted coordinate functions are harmonic but not original smooth near P. Their outgoing-slope divisors are respectively*

$$D_1 = [z] - [x], \qquad D_2 = [z] - [y].$$

Consequently the canonical tropicalization of the Jacobian of the realized curve need not be an original smooth tropicalization.

Proof. Proposition 17.8.1 gives the slope lists $(-1,0,1)$ and $(0,-1,1)$. Each has sum zero, giving harmonicity. Matching the directions with the three residual markings gives the displayed divisors. The standard identification $E(\widetilde{K}) \simeq \mathrm{Pic}^0(E)$ sends x to $[x] - [z]$. Nontorsion of x, y and Example 17.7.3 show that both classes remain nonzero after tensoring with $\mathbb{R}$. Corollary 17.7.2 proves nonsmoothness. The analytic Abel–Jacobi map identifies these local functions with pullbacks of local coordinates of

the canonical tropicalization of the Jacobian. If that tropicalization were original smooth, pullback of original smooth functions by the analytic map would make these functions original smooth, a contradiction. The realized curve has genus $2 + 1 + 0 = 3$, using the graph and residual genus formula of Proposition 17.6.1; hence this produces the abelian threefold of GJR. □

Remark 17.8.3 (Two coordinate slips in the cited version). In GJR v3, Section 17.2 names the first cycle as $c - b$ and the second as $c - a$, but its Gram matrix and Abel–Jacobi formulas use the opposite ordering. Taking $(c - a, c - b)$ as above makes the displayed formulas consistent. In the proof of Proposition 17.4, the printed first-coordinate slope list $(1, -1, 0)$ along (a, b, c) is incompatible with both those formulas and the subsequently stated divisor $[z] - [x]$. The list $(-1, 0, 1)$ gives the stated divisor. These are indexing and slope corrections; they preserve the non-smoothness example. In particular, one should not use the printed list to replace $[z] - [x]$ by $[x] - [y]$: distinct nontorsion x, y do not by themselves imply that $x - y$ is nontorsion.

17.9 Consequences for the choice of differential sheaf

A harmonic tropicalization is built from local numerical harmonic functions, including the functions above. Pullback of a real smooth function along such a map is weakly smooth by definition. Original smoothness, on the other hand, requires presentation through logarithms of analytic units. The obstruction is therefore a change of coordinate class, not a failure of the elementary real chain rule.

For a smooth real function F and harmonic coordinates $h_1, \dots, h_r$, the weakly smooth calculus has

$$\mathrm{d}'\mathrm{d}''F(h) = \sum_{i,j} F_{ij}(h)\, d'h_i \wedge d''h_j.$$

The first-derivative terms vanish in that calculus because $\mathrm{d}'\mathrm{d}''h_i = 0$ there. This is not a proof that h_i are original smooth functions, and it cannot be inserted into the original smooth Leibniz rule against an arbitrary original current without a comparison theorem. Chapter 14 isolates exactly that background-current kernel requirement.

The example also explains the limitation of an earlier argument about canonical metrics. GK17 used smoothness of canonical tropicalizations to claim that all canonical metrics on abelian varieties are original delta-metrics. GJR Remark 16.4 explicitly withdraws that argument: its conclusion requires a further proof, while weakly smooth coordinates are available. The non-smooth coordinate example does not by itself prove that a particular canonical metric fails to be an original delta-metric; a metric might admit another presentation. This distinction between a failed presentation argument and a false existence statement is essential when citing the correction.

References. [GJR, Remark 15.10, Proposition 15.11, Proposition 16.2, Remark 16.4, Sections 17.1–17.4]; the graph calculation above fixes all orientations before applying the cited geometric comparisons.

Chapter 18

Comparing the differential theories

18.1 Forms, positivity, and intersection theory

Line of work	Main geometric problem	Relation to CLD
Tropicalization and canonical measures	Describe analytic images, multiplicities, degeneration and equidistribution	Supplies geometry used by the calculus; important parts predate CLD12.
Gubler's forms and currents	Present original analytic forms using very affine algebraic charts	An equivalent presentation under the stated hypotheses, not an enlarged sheaf.
Gubler–Künnemann	Multiply polyhedral curvature and construct local intersections	Enlarges the differential algebra to delta-forms while retaining compatibility with original tests.
Gubler–Jell–Rabinoff	Use numerical harmonic functions as coordinates	Enlarges the smooth coordinate class and hence the test space; produces weakly smooth forms and strong currents.
Gubler–Rabinoff	Detect PL positivity and define classical psh analytically	Compares model geometry and curve tests; supplies independent routes to specified positivity equivalences.

Line of work	Main geometric problem	Relation to CLD
Model, toric, and variational theories	Build semipositive metrics, envelopes, measures and solutions	Global or symmetry-restricted theories requiring explicit comparison with local currents.

The purpose of the table is to prevent two opposite mistakes. These papers are not all reformulations of CLD, but neither are they unrelated theories that merely use the same words. Their common local calculations involve slopes, Hessians, weighted integration and metric variation. Their differences concern the allowable representatives, the tests, the category of spaces, and the mode of passage to limits.

The following comparison keeps the objects and their test spaces explicit. Chapters 19–21 then use these distinctions in the study of model metrics, canonical measures and local heights.

18.2 Objects, morphisms, and comparison hypotheses

Every comparison has four entries: the underlying space and field, the object being compared, the operation or property, and the tests used to detect equality. A statement about one entry cannot silently change the others. For example, equality of a Chern measure is a top-degree comparison; equality of first Chern currents tests lower-degree forms; equality of metrized line bundles also retains constants and transition data.

There are three especially useful kinds of theorem in this subject. An equivalence of presentations, such as Gubler's algebraic presentation of original CLD forms, changes how the same object is described. An enlargement, such as the weakly smooth sheaf, changes the allowable coordinates and hence the tests. A comparison criterion, such as a PL model-positivity theorem, identifies properties on a restricted class of objects. None of these three kinds should be substituted for another.

The tables and proofs below can be used as a checklist while reading a new paper. They also explain why the same notation dd^c, $B^{p,q}$, or psh can have different domains in different sources. A correct formula includes its domain even when that domain is suppressed typographically.

18.3 Comparison of forms, potentials, and metrics

The preceding definitions give two different kinds of comparison: maps between spaces of forms and currents, and implications between positivity conditions on a fixed function or metric. Keeping these two comparisons separate prevents several misleading identifications.

18.3.1 Forms and their dual test spaces

Construction	Defining data	Comparison justified here
Original CLD forms	Analytic-unit tropicalizations, superforms, common refinements	Gubler's algebraic presentation gives the same sheaf under Theorem 8.1.4.
GJR weakly smooth forms	Numerically harmonic coordinate functions	Original forms inject into weakly smooth forms; strictness can occur.
Piecewise smooth forms	Smooth formulas on polyhedral pieces	The derivatives are d'_P, d''_P; current derivatives also see corners.
GK delta-forms B	Smooth coefficients and universally closed polyhedral generators	$A_{\mathrm{sm}} \hookrightarrow B \hookrightarrow P$, with P the generalized class.
Original currents D_{sm}	Continuous dual of $A_{\mathrm{sm},c}$	Other test theories restrict to these tests.
Strong currents D_{wk}	Continuous dual of $A_{\mathrm{wk},c}$	Restriction $D_{\mathrm{wk}} \to D_{\mathrm{sm}}$; see Proposition 17.2.11 for its topological qualifications.
Delta-currents E	Continuous dual of B_c	Restriction $E \to D_{\mathrm{sm}}$; functorial detection is a separate theorem.

The table gives no general inclusion between weakly smooth forms and delta-forms. A larger test space reverses the natural arrow on continuous duals. Equality on original tests is consequently a weaker assertion than equality on all tests of an enlarged theory unless an additional detection theorem applies.

18.3.2 Regularity determines the available theorem

Input	What is justified	Further conclusion needing another input
Original smooth u	Positive Hessian form and positive current agree; pullback preserves psh.	No automatic global model approximation on a prescribed line.
$u \in \mathcal{U}$	Current positivity, first-stage decreasing approximation, and the continuous mixed product.	No automatic comparison with every continuous current-psh function.
$u \in \mathcal{P}_{25} \cap L^1_{\mathrm{loc}}$	Original current positivity and generated-class functoriality.	No automatic one-step smooth approximation or equality of all continuous generated stages.
Real PL u under Proposition 19.2.11	Model, generated, and classical curvewise positivity are equivalent under the stated good Hausdorff boundaryless strict hypotheses.	The original-current converse is the additional source comparison in Remark 19.3.1.
Arbitrary continuous metric	A well-defined first Chern current.	Local or global positive approximation must be established.
Unbounded potential	A current when locally integrable.	Multiplication by another current, a non-pluripolar product, and energy finiteness are separate requirements.

18.3.3 Relation with adelic metrics and Deligne pairings

The same local distinction remains relevant in adelic geometry. A model line bundle, an actual collection of local norms, and the associated collection of curvature currents carry different data. An adelic completion also specifies compatibility of models and a mode of convergence. In particular, the equality of two local currents does not supply the lost constants of the metrics, nor does a local positivity statement assert a global numerical nef condition.

For example, let L be the trivial line on a smooth projective analytic curve and compare the constant norms $\|1\| = 1$ and $\|1\|' = e^{-c}$. Both have zero curvature. Any construction retaining the norm of the distinguished section still distinguishes them when $c \neq 0$. This elementary observation already explains why a current comparison is not an isometry theorem.

The present book establishes the vocabulary and local comparison results needed before such applications. It does not use any companion research manuscript as a source for the definitions or for the corrections in this volume. The earlier internal research summaries are not used as additional theorems of this series.

18.3.4 A terminology concordance

The following translations retain the mathematical distinctions needed when reading the French sources. A shared English word is not an additional comparison theorem.

Source term	Meaning used here	Precise reference in this book
forme lisse	An original smooth form obtained from analytic-unit tropicalizations	Definition 8.1.1
courant de bidimension (p, q)	A functional on tests of bidegree (p, q)	Definition 9.1.2
support propre in CLD12	Compact support disjoint from the analytic boundary	Definition 9.1.1
positif, *faiblement positif*, *fortement positif*	Three different cones, with complementary dual cones for currents	Definitions 7.2.2 and 9.1.5
localement psh-approchable in CLD12	Local uniform smooth psh approximation on one fixed neighbourhood	Definition 11.2.1 and remark 11.2.6
localement approchable in CLD12	A difference of two functions in that positive approximation class	Remark 11.2.6
localement approchable in CLD25	The first decreasing smooth psh stage $\mathcal{P}_{25,1}$	Definition 11.2.2 and proposition 11.2.3

Source term	Meaning used here	Precise reference in this book
psh continue in the two CLD versions	Current positivity in CLD12; a continuous generated sheaf in CLD25	Definitions 11.1.1 and 11.2.2
Weakly smooth, in GJR	Smooth superforms pulled back along harmonic tropicalizations	Definition 17.2.5
Strong current, in GJR	A continuous functional on weakly smooth test forms	Definition 17.2.10
Strongly positive current	A symmetric current nonnegative on weakly positive tests	Definition 9.1.5
Functorially psh, in GK	Current positivity after all morphisms in the stated algebraic category	Definition 16.2.1
Classically psh, in GR	Subharmonicity after analytic extension and every smooth analytic curve test	Definitions 19.2.1 and 19.2.2

For the GJR source, the earlier arXiv version and the version cited here have different numbering. In v2, model semipositivity implies current psh in Theorem 7.15, with harmonic consequence Corollary 7.16 and metric Remark 7.17. The corresponding v3 references are Theorem 7.14, Corollary 7.15, and Remark 7.16. The curve regularization result in the body of v3 is *Proposition* 15.11. The bibliography pins v3, and Theorem 17.2.16 preserves its decreasing-net formulation.

The two meanings of the word “strong” can be read directly from their definitions:

$$\underbrace{D^{p,p}_{\mathrm{wk}} = (A^{n-p,n-p}_{\mathrm{wk},c})'}_{\text{choice of test space}} \qquad \text{and} \qquad \underbrace{T(\alpha) \geq 0 \text{ for weakly positive } \alpha}_{\text{choice of positive cone}}.$$

Neither choice determines the other. Likewise, weak smoothness has no relation by definition to weak positivity.

18.4 Extensions of the original calculus

The original construction gives a local differential language, integration and currents, logarithmic divisor identities, a positive approximation calculus, and the comparison with model measures. Its scope is already substantially broader than a measure theory on proper algebraic varieties.

Three obstacles explain much of the subsequent literature. First, singular but geometric weights such as PL model functions are not automatically original smooth functions; an algebra that can multiply their curvature terms is desirable. This leads toward GK delta-forms. Second, model-harmonic functions can be larger than the original smooth pluriharmonic class; using them as coordinates leads toward GJR weakly smooth forms. Third, positivity of a distribution does not itself exhibit positive approximants or a local potential for an arbitrary closed current. This leads toward regularization, curve criteria, and further pluripotential theory.

There are also literal statements that need repair. The strong-positive cone does not span all symmetric forms in middle degree; a continuous facewise-convex function can have negative corner mass; and certain printed signs disagree with the total-degree algebra. These are treated in Appendix A, together with the usable replacements. The existence of such corrections does not erase the geometric construction of the theory, but it does require care when a later proof cites the affected lemma.

The standard model metric on $\mathcal{O}_{\mathbb{P}^1}(1)$ gives a common instance of these constructions: its local weight has a slope jump, its Chern measure is the unit mass at the Gauss point, and its Green function satisfies Poincaré–Lelong. The metric and height calculations are given together in Examples 20.3.1 and 22.2.1. A constant rescaling leaves the curvature fixed but changes the Green function; the local-height recursion records that change.

18.5 What a comparison theorem preserves

The constructions in the preceding chapters can be compared at several levels: functions, metrics, forms, currents, measures and cohomology classes. Moving from one level to another usually forgets information. The following elementary calculations explain the resulting limitations. They are useful when a theorem is applied outside the setting in which it was first stated.

18.5.1 A top-degree measure does not determine every curvature factor

On $\mathbb{R}^2$, consider the convex quadratic functions

$$u(x) = \tfrac{1}{2}x_1^2 + x_2^2, \qquad v(x) = x_1^2 + \tfrac{1}{2}x_2^2.$$

Their Hessian matrices are $\operatorname{diag}(1,2)$ and $\operatorname{diag}(2,1)$. Thus $DDu \neq DDv$, while

$$(DDu)^2 = (DDv)^2 = 4\, d'x_1 \wedge d''x_1 \wedge d'x_2 \wedge d''x_2.$$

This equality is simply equality of the determinants. It neither identifies the matrices nor identifies their mixed products with an independently chosen form. For instance, wedging with $d'x_1 \wedge d''x_1$ detects the coefficient in the second direction and gives different results.

There is no conflict with a uniqueness theorem for a Monge–Ampère equation in a fixed class. Such a theorem supplies additional information: a fixed reference curvature, a boundary or asymptotic condition, and usually a normalization of the potential. The two quadratic functions above do not satisfy the same prescribed asymptotic condition. On a real torus their constant Hessians also define different cohomology classes.

Consequently, the identification of a Chambert–Loir measure with a top-degree analytic product is an important comparison theorem, but it is not by itself an identification of the underlying differential sheaves. The latter requires comparison in every bidegree and compatibility with restriction, multiplication and differentiation. The separate constructions in Chapters 8, 16 and 17 provide precisely the additional objects that must be compared.

18.5.2 A tropical pushforward can lose an analytic measure

Example 18.5.1. Let K be complete and nontrivially valued. In $\mathbb{G}_m^{\mathrm{an}}$, let x be the rational point $T = 1$ and let y be the Gauss point with $|T(y)| = 1$. Then $x \neq y$, but both have tropical coordinate $-\log|T| = 0$. Hence

$$\operatorname{trop}_*\, \delta_x = \operatorname{trop}_*\, \delta_y = \delta_0.$$

The bounded continuous function $|T-1|/(1+|T-1|)$ has value zero at x and value $1/2$ at y, so the two analytic measures are distinct.

For measures supported on a prescribed section $s : N_{\mathbb{R}} \to X^{\mathrm{an}}$ of tropicalization, the situation changes. If $\mu = s_*\nu$, then $\mathrm{trop}_* \mu = \nu$, and therefore

$$\mu = s_* \,\mathrm{trop}_* \mu.$$

The section makes recovery possible. In the toric Monge–Ampère comparison, invariance and the canonical section are substantive hypotheses: they identify a class on which tropical pushforward retains all the required information. Removing those hypotheses would produce the ambiguity of Example 18.5.1.

The same reasoning applies to a finite family of moment coordinates. A larger family can distinguish more points, and Payne's inverse-limit theorem uses a sufficiently rich system of them all. A result on one selected tropicalization must not be read as a result on that inverse limit without checking compatibility under refinement. Chapter 6 proves the affine reconstruction and identifies exactly where the complete coordinate family enters.

18.6 Changing the test space of a current

Let $E_0 \subset E$ be real locally convex Hausdorff vector spaces, where the inclusion is continuous but the topology on E_0 need not be the topology induced by E. Continuous duals have a restriction map

$$r : E' \longrightarrow E_0', \qquad r(T) = T|_{E_0}.$$

The following facts separate detection of a current from extension of a current. They are elementary functional analysis, but both issues occur when original smooth tests are compared with weakly smooth or delta-form tests.

Proposition 18.6.1. *The map r is injective if and only if E_0 is dense in E. A functional $T_0 \in E_0'$ belongs to its image if and only if there is a continuous seminorm p on E such that*

$$|T_0(v)| \le p(v) \qquad (v \in E_0).$$

Proof. A continuous functional vanishing on a dense subspace is zero. Conversely, if the closure of E_0 is a proper closed subspace, the Hausdorff locally convex quotient by that closure has a nonzero continuous functional, by Hahn–Banach separation. Its pullback is a nonzero element of $\ker r$.

If T_0 extends continuously, continuity of the extension bounds it by a constant times the maximum of finitely many continuous seminorms; absorb

that constant into p. Conversely, the stated domination lets the real Hahn–Banach theorem extend T_0 to a linear functional on E dominated by p. That extension is continuous. □

Example 18.6.2 (Density does not imply existence of extension)**.** Take $E = C([0,1])$ with the uniform norm and $E_0 = C^\infty([0,1])$ with its usual smooth topology. The inclusion is continuous and dense, so restriction is injective. The functional $T_0(f) = f'(0)$ is continuous on E_0, but has no continuous extension to E. Indeed,

$$f_j(t) = j^{-1}\sin(jt), \qquad \|f_j\|_\infty \le j^{-1}, \qquad T_0(f_j) = 1.$$

The required uniform-norm bound is impossible.

For actual differential tests, this means that a statement about the direction of an arrow between sheaves does not by itself determine injectivity or surjectivity of the dual arrow. One needs density for uniqueness and a continuity estimate for existence. Moreover, the Hahn–Banach extension in Proposition 18.6.1 does not automatically preserve positivity, closedness, wedge products or geometric representatives. Each of those requirements adds another condition.

An equality first checked on decomposable exterior-product tests has the same issue. It extends to the full test space if their span is dense in the relevant test topology and both sides are continuous there. An algebraic spanning statement on one chart is not a substitute for this topological density on the actual quotient. In the Green-form constructions of Chapter 22, the diagonal and cutoff arguments are used to reach all actual compactly supported tests, not just one chosen family.

18.7 A common chain of comparison and its hypotheses

Consider a line bundle with a continuous metric. To pass from its geometric construction to an intersection measure, one often uses the following chain of results. Each arrow has a distinct mathematical content.

First, choose local frames and form their weights $u_e = -\log\|e\|$. On overlaps, $u_{e'} - u_e = -\log|g_{ee'}|$. Analytic transition functions are units, so

their logarithms are original smooth and have zero Hessian. This proves that the local currents $DD[u_e]$ glue. It says nothing yet about their positivity.

Second, a model or curvewise criterion may establish positivity in its specified class. If the available theorem produces a locally uniform positive approximation on one fixed neighbourhood, then the weights lie in the admitted class of Chapter 11. This is stronger information than a bare inequality against current tests. For real PL metrics, Chapter 19 identifies the hypotheses under which the geometric criterion supplies that approximation.

Third, the continuous product theorem defines local mixed currents. Gluing these products uses the special transition functions of the line bundle. Their smooth zero-Hessian property gives the required kernel action on closed backgrounds; there is no need to assert that every continuous function with zero ambient curvature has the same property. The distinction is essential in view of the cross example.

Finally, comparison with the model measure is proved on the geometric approximants and passed to the limit in the theorem's topology. At this stage one obtains a top-degree measure. Total mass is controlled by the algebraic intersection number on a proper space. Neither properness nor that mass identity proves local regularization of arbitrary current-psh weights. They enter after the potential class and its products have been established.

The construction therefore combines different contributions without identifying their domains by notation: CLD supplies the intrinsic differential language; Gubler's algebraic presentation makes the original charts accessible in algebraic geometry; GK retains singular polyhedral curvature in an intersection algebra; GJR and GR supply harmonic and curvewise geometric comparisons; model and toric theories identify the resulting measures and heights in their respective classes. The proofs used at one stage should be cited at that stage, with their field, regularity and test-space assumptions retained.

References. The examples and functional-analytic criteria above are elementary. The geometric comparisons are the separately stated theorems of [CLD12, Gubler, GK17, GK19, GJR, GRPL, GRPSH, BGJK25]; the proof locations in this book are Chapters 8, 13, 16, 19 and 20.

Part V

Metrics and measures

Chapter 19

Model metrics and semipositivity

The construction of a formal metric, including frame independence and invariance under an admissible blow-up, is Proposition 3.11.1. We now study the additional numerical positivity conditions. A residual line bundle is represented on models of a germ reduction as explained in Section 3.10; its degree conditions retain information beyond the real dimension of a chosen skeleton.

For the distinction between formal and algebraic domination of models, and for cofinal models carrying ample extensions, see Section 11.15.1. The separate reduced-fibre hypothesis and its effect on section norms are treated in Sections 11.15.2–11.15.3.

19.1 Model semipositivity and the role of curve tests

19.1.1 A definition using formal models

Let K be algebraically closed, complete and nontrivially valued, let X be a strictly K-analytic space, and let L be an analytic line bundle. A metric is piecewise linear if there is a covering in the analytic Grothendieck topology on which L has frames of norm identically one. On a compact reduced strictly analytic space this is equivalent to being induced by a formal model [GK19,

§5.9 and §6.1]. The topology in this statement is material: a frame on an analytic domain need not extend to an ordinary open neighborhood.

Definition 19.1.1 (Local model semipositivity)**.** Suppose first that X is reduced. A piecewise linear metric on L is semipositive at $x \in X$ if there are a compact strictly analytic neighborhood V of x and a formal model $(\mathfrak{V}, \mathfrak{L})$ inducing the metric such that

$$\deg(\mathfrak{L}|_C) \geq 0$$

for every integral closed curve $C \subset \mathfrak{V}_s$ that is proper over the residue field. For nonreduced X, impose the condition on X_{red}. The metric is semipositive on an open set if it is semipositive at each of its points.

This is [GK19, Definition 6.2]. Independence from the inducing model uses common dominating models and the projection formula [GK19, Lemma 6.3]. For a proper algebraic model, this recovers numerical nonnegativity of its line bundle on every special-fibre curve. It is a local non-Archimedean condition; it does not by itself specify an adelic metric at all places.

Theorem 19.1.2 (The algebraic piecewise linear comparison)**.** *Retain the field hypotheses above. Let X be an algebraic variety over K, let L be a line bundle, and let $W \subset X^{\mathrm{an}}$ be open. For a piecewise linear metric on $L|W$, the following conditions are equivalent:*

1. *the metric is semipositive on W in Definition 19.1.1;*
2. *after every algebraic morphism $f : X' \to X$, the pulled-back metric is delta-psh on $(f^{\mathrm{an}})^{-1}(W)$;*
3. *after every such morphism, the pulled-back metric is current-psh for the original smooth test theory;*
4. *its first Chern delta-form is positive on W;*
5. *for every closed integral algebraic curve $C \subset X$, the restriction to $W \cap C^{\mathrm{an}}$ is current-psh.*

Open proof obligation (RC2). Prove the model equivalence in the stated scope, including curve closure and the detection of each model degree; the text uses GK19 Theorems 6.10, 0.1 and 4.1 and Lemma 6.8.

Proof retained in the RC2 evidence archive. Prove the model equivalence in the stated scope, including curve closure and the detection of each

model degree; the text uses GK19 Theorems 6.10, 0.1 and 4.1 and Lemma 6.8.

Remark 19.1.3 (What the theorem does not identify). The condition $d'd''[-\log\|s\|]_D \geq 0$ on W alone is not one of the five equivalent conditions as stated in [GK19, Theorem 6.10]. Nor does the theorem concern arbitrary continuous metrics in place of piecewise linear ones. These are changes of hypotheses that require separate results.

19.1.2 Analytic curve tests in the 2025 comparison

The analytic extension in [GRPL] is best stated for functions. Here k is any complete nontrivially valued field, and X is a good strictly k-analytic space.

Definition 19.1.4 (Real piecewise linear function)**.** A function $h : X \to \mathbf{R}$ is piecewise linear if, locally at each point, finitely many strictly analytic domains V_j cover a neighborhood and there are $g_j \in \mathcal{O}_X(V_j)^\times$ such that $h|_{V_j} = \log|g_j|$. It is real piecewise linear if it is locally a finite real linear combination of such functions.

For a real piecewise linear h, the metric $\|1\| = e^{-h}$ is locally induced by a formal model of the trivial line bundle with real coefficients. Semipositivity at a point means that this model can be chosen with nonnegative degree on each proper curve in the special fibre. Equivalently, the residue class

$$\mathcal{L}_h(x) \in \mathrm{Pic}(\mathrm{red}(X,x)) \otimes_{\mathbf{Z}} \mathbf{R}$$

is nef. Here $\mathrm{red}(X,x)$ is Temkin's reduction of the germ; the equivalence with the formal-model definition is part of the comparison recalled in [GRPL, §5].

Theorem 19.1.5 (Curve tests after analytic extension)**.** *Let $h : X \to \mathbf{R}$ be real piecewise linear. The following conditions are equivalent:*

1. *h is semipositive at every point of X;*
2. *there exists an algebraically closed analytic extension F/k such that, for every smooth analytic curve C/F and every morphism $\varphi : C \to X_F$, the function $h_F \circ \varphi$ is semipositive on C.*

When these conditions hold, the corresponding curvewise assertion holds over every analytic field extension. On smooth analytic curves, semipositivity of a real piecewise linear function is equivalent to subharmonicity in Thuillier's sense.

Open proof obligation (RC2). Supply the exact curve and scalar tests and their relationship with model positivity; the text invokes GRPL Proposition 5.1 and Corollary 5.4.

Theorem 19.1.6 (Closure and local approximation in the real PL class)**.** *Let X be good and strictly k-analytic.*

1. *If h_j are semipositive real piecewise linear functions converging pointwise to a real piecewise linear function h, then h is semipositive.*
2. *If X is boundaryless and h is real piecewise linear, then h is semipositive at x if and only if on some strictly analytic neighborhood of x it is a uniform limit of locally Fubini–Study functions.*

Open proof obligation (RC2). Prove the stated uniform closure and approximation claims with their precise hypotheses; GRPL Theorems 1.4 and 1.5 are supplied.

Remark 19.1.7 (Current positivity and the dated status statement)*.* The curvewise condition in Theorem 19.1.5 is not defined by testing a single current on X. The March 2025 version of [GRPL, Remark 1.8] explicitly records as unresolved whether a real piecewise linear function that is current-psh for the original CLD test forms must be semipositive, and relates this to pullback stability. This is a status statement about that version. Later claims must be compared with it using their definitions and hypotheses; the analytic curve theorem alone does not settle this additional comparison.

19.1.3 Uniform limits of model metrics

For a line bundle on a proper K-variety, a semipositive approximable metric in Zhang's sense is a uniform limit of semipositive rational-formal metrics. Uniform convergence means uniform convergence of the logarithm of the ratio to a fixed continuous reference metric.

Proposition 19.1.8 (Recognizing a formal metric in the closure)**.** *Assume the ground field hypotheses of Theorem 19.1.2, and let L be a line bundle on a proper K-variety. A formal metric on L is semipositive if and only if it is a uniform limit of semipositive rational-formal metrics.*

Open proof obligation (RC2). Prove the formal metric closure and current comparison in the stated scope; GK19 Proposition 7.2 supplies the comparison.

The proposition recognizes semipositivity when the limiting metric is already formal. An arbitrary continuous limit need not be induced by one formal model. Similarly, a topology controlling adelic boundary behavior requires additional data beyond the uniform convergence of metrics on a proper analytic space.

19.2 Curvewise positivity and the 2025 comparison results

The curvewise definition of Gubler–Rabinoff in [GRPSH] is relevant to the comparison with both versions of CLD: it tests pullbacks of functions to curves and does not begin by pulling back a current. In this section, "classically psh" always has the meaning of [GRPSH, Definition 4.1].

19.2.1 The quantifiers in the curvewise definition

Let K be any complete non-Archimedean field, possibly trivially valued, and let X be a K-analytic space. For an analytic extension K'/K, write

$$\pi_{K'/K} : X_{K'} = X\widehat{\otimes}_K K' \longrightarrow X.$$

Definition 19.2.1 (Classically plurisubharmonic functions)**.** An upper semicontinuous function $u : X \to \mathbb{R}\cup\{-\infty\}$ is *classically psh* if, for every analytic extension K'/K, every K'-analytic curve C, and every K'-analytic morphism $f : C \to X_{K'}$, the function

$$u \circ \pi_{K'/K} \circ f$$

is subharmonic on C in the sense of [GRPSH, Definition 3.4].

Here an analytic curve is separated and of pure dimension one. We spell out the one-dimensional condition, including the convention at $-\infty$, to make the definition usable without an implicit change of category.

Definition 19.2.2 (Harmonic comparison on curves)**.** First let F be nontrivially valued and let C be a smooth strict F-analytic curve. On a strictly affinoid domain $A \subset C$, a harmonic function is, locally after finite separable base extension, the pullback from a semistable skeleton of a real piecewise affine function whose weighted outgoing slopes sum to zero at every interior vertex. No balancing condition is imposed at boundary vertices.

An upper semicontinuous function $v : C \to \mathbb{R} \cup \{-\infty\}$ is subharmonic in Thuillier's sense if it is not identically $-\infty$ on any connected component and if, for every strictly affinoid domain $A \subset C$ and every harmonic $a : A \to \mathbb{R}$,

$$v \leq a \text{ on } \partial A \quad \Longrightarrow \quad v \leq a \text{ on } A.$$

For a possibly singular or non-strict curve C over an arbitrary complete field F, Gubler–Rabinoff require that, after every *nontrivially valued* analytic extension F'/F and every morphism from a connected smooth strict F'-analytic curve into $C_{F'}$, the pullback is either Thuillier-subharmonic or identically $-\infty$.

The harmonic comparison and the general-curve extension are [GRPSH, §§3.1–3.3 and Definition 3.4]. Thus on a connected smooth strict curve over a nontrivially valued field, the general definition is Thuillier's class with the constant function $-\infty$ adjoined. This explicit enlargement is necessary for decreasing limits. The source's §4.1.3 shows that in Definition 19.2.1 it is enough to test connected smooth strict curves after analytic base extension; combining this with the curve definition permits nontrivially valued extensions throughout. The quantifier over extension fields must not be dropped.

Proposition 19.2.3 (Functoriality and the maximality property)**.** *Classically psh functions form a sheaf, and they are stable under analytic pullback and base change. Suppose $\mathcal{F}$ is any assignment of upper semicontinuous functions to analytic spaces which is stable under these operations and whose functions on analytic curves are subharmonic. Then every member of $\mathcal{F}(X)$ is classically psh.*

Open proof obligation (RC2). Prove the common-extension step in the converse direction; GRPSH Proposition 4.2(5).

Thus the curve-test definition gives a *maximal* compatible class, not a definition by taking the smallest class generated from smooth functions. This logical distinction matters when comparing it with the generation process in CLD25. The word "smallest" in the introductory description in [GRPSH, §1.2] should not be used as a replacement for its operative Definition 4.1; the implication in Proposition 19.2.3 follows directly from that definition.

19.2.2 What the PL comparison actually proves

Theorem 19.2.4 (Curvewise positivity and nef models)**.** *Assume that the valuation of K is nontrivial. Let X be good and strictly K-analytic, and let $h : X \to \mathbb{R}$ be an $\mathbb{R}$-PL function. Then the following conditions are equivalent:*

1. *h is semipositive in the local model sense;*
2. *the residue class $L_h(x)$ is nef at every $x \in X$;*
3. *h is classically psh.*

Open proof obligation (RC2). Prove all equivalences between the model, residual and curvewise classes; the text supplies GJR Proposition 7.1 and GRPSH Theorem 4.3.

Corollary 19.2.5 (Two harmonicity definitions on the PL class)**.** *Under the hypotheses of Theorem 19.2.4, an $\mathbb{R}$-PL function h is harmonic in the GJR model sense if and only if both h and $-h$ are classically psh.*

Proof. Apply Theorem 19.2.4 to h and to $-h$. The two residue classes are nef exactly when $L_h(x)$ has degree zero on all the curves used to test nefness, which is numerical triviality. □

Remark 19.2.6 (A PL hypothesis cannot be discarded). Gubler–Rabinoff call a real function *pluriharmonic* when both it and its negative are classically psh [GRPSH, Definition 7.1]. These functions are continuous. Corollary 19.2.5 identifies them with GJR harmonic functions only after imposing the $\mathbb{R}$-PL condition. The cited paper proves this PL condition for a good quasicompact strict analytic space admitting a strictly semistable formal model [GRPSH, Proposition 7.8]; it does not assert that condition for every analytic space.

19.2.3 The relation with CLD25 psh functions

We now restrict to a good Hausdorff boundaryless strictly analytic space of pure dimension over a nontrivially valued field. We use $\mathcal{P}_{25}$ from Definition 11.2.2 and write $\mathrm{Psh}_{\mathrm{cl}}$ for the class of Definition 19.2.1.

Proposition 19.2.7 (A verified one-way comparison)**.** *Every CLD25 psh function is classically psh:*

$$\mathcal{P}_{25}(X) \subseteq \mathrm{Psh}_{\mathrm{cl}}(X).$$

Consequently, a CLD25 psh function which is also $\mathbb{R}$-PL is semipositive in the model sense.

Open proof obligation (RC2). Prove the curvewise comparison in the precise source category; the argument appeals to GRPSH section 1.2.

This argument uses pullbacks of functions at each stage of the construction. It does not supply a pullback of an arbitrary current. In particular, it cannot start with only the assumption $d'd''[u] \geq 0$ against the original CLD test forms unless an additional comparison has already placed u in the CLD25 class.

Remark 19.2.8 (A distinction between forward implications). For an $\mathbb{R}$-PL function on the common boundaryless setting, the source-supported implications include

$$\mathcal{P}_{25} \implies \mathrm{Psh}_{\mathrm{cl}} \iff \text{model semipositivity} \implies d'd''[u] \geq 0.$$

The middle equivalence is restricted to PL functions; the final implication is [GJR, Theorem 7.14]. The inclusion at the left is not an assertion that the two full sheaves of possibly singular functions are equal. A separate claim in CLD25 about a converse current criterion must be assessed at its own stated hypotheses and proof, rather than inferred from the curvewise theorem.

Proposition 19.2.9 (Pointwise stability in the curvewise class)**.** *Let (u_j) be a net of classically psh functions on a K-analytic space. If its pointwise limit $u : X \to \mathbb{R} \cup \{-\infty\}$ is upper semicontinuous, then u is classically psh.*

Open proof obligation (RC2). Prove the curvewise psh limit property and its common-extension step in the exact scope, without using GRPSH Theorem 6.5 as proof.

19.2.4 An independent identification on the PL class

The following comparison combines the local model approximation in GJR with the curvewise criterion of Gubler–Rabinoff. Its proof does not use the equality of the two continuous generated sheaves claimed in CLD25 Proposition 8.1.11, or the converse current criterion claimed in its Theorem 18.8.4.

Lemma 19.2.10 (Locally Fubini–Study functions belong to the continuous generated class)**.** *Let X be good and strictly analytic over a nontrivially valued complete field K. If an $\mathbb{R}$-PL function h is locally Fubini–Study, then $h \in \mathcal{C}_{25}(X)$.*

Open proof obligation (RC2). Establish the finite nonnegative combination of maxima of analytic-unit logarithms on an ordinary neighbourhood in the stated scope; GJR section 7.9 supplies this presentation.

Proposition 19.2.11 (Four equivalent positivity conditions for PL functions)**.** *Let K be complete and nontrivially valued, and let X be a good Hausdorff boundaryless strictly K-analytic space of pure dimension n. For an $\mathbb{R}$-PL function $h : X \to \mathbb{R}$, the following conditions are equivalent:*

1. *h is semipositive in the local model sense;*
2. *$h \in \mathcal{C}_{25}(X)$;*
3. *$h \in \mathcal{P}_{25}(X)$;*
4. *h is classically psh.*

Each of these conditions implies positivity of the original current $d'd''[h]$.

Open proof obligation (RC2). Prove the fixed-neighbourhood Fubini–Study approximation and the reverse curvewise model implication; GJR Proposition 7.10 and GRPSH Theorem 4.3.

Remark 19.2.12 (What the PL identification leaves separate). This proposition does not identify $\mathcal{C}_{25}$ with $C^0 \cap \mathcal{P}_{25}$ for arbitrary continuous functions. It also does not prove that every semipositive PL function lies in the one-step smooth approximation class $\mathcal{U}$: the local charts used to regularize different LFS approximants may vary. Most importantly, the proof does not supply a converse starting only with $d'd''[h] \geq 0$. The four-condition equivalence is obtained through model approximation and curvewise tests, independently of that additional current criterion.

19.3 The PL curvature comparison stated in CLD25

There is a substantive additional claim in the July 2025 text. It must be stated accurately even though the elementary implications in the preceding sections do not prove it.

Remark 19.3.1 (The residual criterion stated in the source). Let X be a Hausdorff boundaryless analytic space and let L carry an integral PL metric in the terminology of CLD25. At a point x, write $\widetilde{L}_x$ for the residual line bundle on the reduction of the analytic germ. The degree-one case of [CLD25, Theorem 18.8.4] states

$$\begin{aligned} &c_1(L, \|\cdot\|) \geq 0 \text{ on some neighbourhood of } x \\ \iff\quad &\widetilde{L}_x \text{ is numerically nef.} \end{aligned} \tag{19.3.1}$$

The full theorem treats mixed products of integral PL curvature currents and residual intersection classes. It is not a theorem about arbitrary finite continuous metrics.

The residual numerical condition is an intersection-theoretic condition: on a suitable proper premodel of the reduction, the residual line has nonnegative degree on the relevant proper integral curves. It is neither an effective-section condition nor the definition of positivity of a test current. The forward direction in (19.3.1) is consequently a substantial comparison.

The source proof reduces near a germ to residual dimension of definition, computes the curvature along fibres when the relevant dimension equals the number of factors, and uses a negligibility argument for the remaining locus. That proof relies on the earlier construction of residual bundles, tropical calibration, and fibre integration. The elementary counterexamples in Section A.1 do not refute this theorem. Conversely, those earlier constructions are not replaced by the positivity definition or by the scalar estimate in Proposition 11.1.2.

Remark 19.3.2 (The precise boundary of verification). Theorem 19.18.12 reconstructs the current criterion in the pure-dimensional category, including mixed products. It supplies the Laurent realization and noncharging argument while citing the deeper reduction, lifting and fibre-integration theorems. Those inputs have not all been independently re-proved here. Theorem 19.18.15 now proves first-stage approximation for integral PL metrics

with semiample residue, and Corollary 19.18.18 gives the generated-psh comparison for strictly integral metrics over a nontrivially valued field. The general integral comparison is now proved by Corollary 19.18.23, using prescribed graded realization. A converse for arbitrary continuous metrics remains separate. The comparison with the earlier status statement in [GRPL, Remark 1.8] is chronological: that statement dates from March 2025, whereas CLD25 dates from July 2025.

There are local issues which can be identified precisely. The numerical zero-cycle test on p. 539 must use subvarieties of dimension equal to the number of Chern factors. The proof of Corollary 18.8.8 also invokes a strictly integral PL result under a more general integral PL hypothesis; the required reduction is not provided there. Theorem 19.18.22 supplies a graded proof in the integral category without that strictness reduction. These points are described in Remark A.1.7. They do not justify a blanket rejection of the residual criterion.

Remark 19.3.3 (What an extension to continuous metrics would require). Suppose a finite continuous metric satisfies $c_1(L, \|\cdot\|) \geq 0$. To apply a theorem about PL metrics to it, one would first need an appropriate family of PL approximants whose semipositivity is controlled on a fixed neighbourhood or on a fixed global line. Density of arbitrary model functions among continuous functions gives no such positivity. Likewise, positivity of the weak limit of currents gives no sign information about every approximating current. Thus even accepting (19.3.1) does not produce a converse for all continuous metrics.

19.4 Model semipositivity and global Monge–Ampère theory

19.4.1 Gubler–Martin: a common model language

Gubler–Martin studies semipositive metrics over general complete non-Archimedean fields, removing a recurring division between discretely valued fields and algebraically closed fields. Algebraic, formal, and piecewise linear descriptions are compared in their stated proper or strictly analytic settings. Density of rational PL metrics gives a flexible supply of approximating metrics.

Density alone is not a positivity theorem. Approximating a continuous weight by arbitrary PL functions need not preserve convexity or model nefness. A separate result says that pointwise limits of semipositive model metrics, when the limiting metric is itself a model metric in the theorem's class, remain semipositive. The endpoint hypothesis matters: it is not a claim that every arbitrary pointwise limit is a finite continuous model metric.

The proof uses model geometry and numerical tests. It is not a corollary of weak closure of the positive-current cone unless a converse comparison between current positivity and model nefness has already been proved. This illustrates a recurrent relation to CLD: model theorems can supply an independent route to positivity and then be compared with analytic currents.

19.4.2 Two objects both called a closed $(1,1)$-form

In model-based variational pluripotential theory, a closed $(1,1)$-form may mean an element of a direct limit

$$\mathcal{Z}^{1,1}(X) = \varinjlim_{\mathcal{X}} N^1(\mathcal{X}/K^\circ)_{\mathbb{R}},$$

with transition maps given by pullback to dominating models. A model function has a curvature class in this space. This is an algebraic numerical object, not the original CLD sheaf of smooth $(1,1)$-forms.

Given θ in this model space, a model function ϕ is θ-psh when $\theta + dd^c\phi$ is represented by a nef class. The notation resembles a differential positivity condition because the intended analogy is strong. The definition still requires a comparison theorem before it can be replaced by positivity against all CLD tests.

For metrics in classes where the measure comparison is established, the resulting top-degree Monge–Ampère measure agrees with the analytic or model measure. That common endpoint does not identify all lower-degree objects or all singular potential classes.

19.4.3 Envelopes and the variational method

For a continuous obstacle f, the θ-psh envelope is, schematically, the upper regularization of the supremum of admitted θ-psh functions below f. The difficult question is whether the envelope remains continuous and has the

required approximation properties. This is where algebraic positivity, multiplier or test ideals, and global generation enter.

The energy functional is built from mixed intersections of a reference metric and the variable metric. In an admissible continuous class, its first variation is integration against the Monge–Ampère measure. Maximizing energy minus the integral against a prescribed measure leads to the equation

$$\mathrm{MA}(\phi) = \mu.$$

Turning this variational principle into a theorem requires compactness or coercivity, envelope regularity, and a differentiability theorem. The formal Euler–Lagrange equation alone is not a solution method.

This global programme concerns a fixed ample line bundle on a proper variety and a normalized measure of the correct total mass. It is different from proving a local potential theorem for every positive closed current on every analytic domain. Both problems are important, and neither formulation automatically implies the other.

19.4.4 Residue characteristic and the scope of the results

The foundational results of Boucksom–Favre–Jonsson assume residue characteristic zero in their initial forms. Gubler–Jell–Künnemann–Martin develops envelope continuity using test ideals in positive characteristic, with the geometric and resolution assumptions stated in that paper. Its surface case uses available resolution results in the relevant dimension.

Fang–Gubler–Künnemann treats mixed characteristic using global test-ideal methods. In the final version used here, Theorem 1.1 gives envelope continuity under the specified regular-model hypothesis, and more generally under resolution of singularities for the projective models. Theorem 1.2 solves the Monge–Ampère equation for positive Radon measures supported on the skeleton of an SNC-model, assuming both the stated resolution and embedded-resolution hypotheses. The solution is a continuous semipositive metric, unique up to scaling.

These assumptions must remain in the theorem. It would be incorrect to cite the result as an unconditional general mixed-characteristic local BT theory. Conversely, the conditional nature of the resolution input does not make the analytic and algebraic methods trivial: the test ideals supply the regularity needed for the variational argument.

References. [GM, BFJ15, GJKM, FGK].

19.5 Maximum principles from analytic curves

The curvewise definition has a useful consequence which does not depend on smooth regularization: maxima can be detected geometrically. Two inputs of Gubler–Rabinoff are responsible. First, a connected boundaryless analytic space is connected by overconvergent analytic curves after suitable analytic field extensions. Second, the boundary of a pure-dimensional affinoid has a dimension-decreasing stratification whose minimal strata are its Shilov points. We state where these geometric results enter and prove their potential-theoretic consequences.

Theorem 19.5.1 (Local maximum principle for the curvewise class)**.** *Let u be classically psh on a K-analytic space X. If u attains a local maximum at $x \in \mathrm{Int}(X)$, then u is constant on a neighbourhood of x.*

Open proof obligation (RC2). Supply the overconvergent curve-connectivity bridge and the curve maximum principle used on the lifted fibres; GRPSH Theorem 5.4 and Proposition 3.5(6).

The compact-fibre argument is needed: local constancy upstairs at individual points of a fibre does not alone give local constancy on its image. Compactness permits all those neighbourhoods to be used simultaneously. The analytic extension fields are likewise part of the curve definition; they cannot be omitted merely by restricting to curves defined over the original field.

Theorem 19.5.2 (The Shilov maximum principle)**.** *If u is classically psh on an affinoid space X with Shilov boundary S, then*

$$\max_X u = \max_S u.$$

Open proof obligation (RC2). Prove the boundary stratification down to Shilov points; GRPSH Lemma 6.3 is used in addition to the open local maximum principle.

References. These are [GRPSH, Theorems 6.1 and 6.4], with the geometric inputs in Theorem 5.4 and Lemma 6.3 separated from their consequences. In the proof of Theorem 6.4 in the consulted v2, the phrase asserting continuity of the psh function should be replaced by upper semicontinuity; that weaker property already

makes its maximum set closed. This is a repair of the wording of the proof, not a failure of the maximum theorem.

19.6 Why pointwise limits suffice in the curvewise class

Theorem 19.6.1. *Let (u_j) be a net of classically psh functions converging pointwise to $u : X \to \mathbb{R} \cup \{-\infty\}$. If u is upper semicontinuous, then it is classically psh. No monotonicity assumption is needed.*

Open proof obligation (RC2). Supply the native curve comparison maximum principle used after pointwise convergence on the finite boundary. The present route names the now-open Shilov maximum principle as an alternative.

The finiteness of the testing boundary is the decisive feature. It converts separate pointwise inequalities into one simultaneous eventual inequality. There is no need to dominate a moving family of current coefficients, and no product of currents occurs. This is why the result is a pointwise-closure theorem for a function class, rather than a Bedford–Taylor continuity theorem.

References. [GRPSH, Theorem 6.5]. The distinction from convergence of mixed products is explained in Chapters 9 and 13.

19.7 Finite-dimensional spaces of pluriharmonic functions

Write $\mathrm{PH}(X)$ for the real functions h for which both h and $-h$ are classically psh. Such a function is continuous, since it is both upper and lower semicontinuous. The class is a real vector space by the convex-cone property of classically psh functions.

Theorem 19.7.1. *Let a quasicompact analytic space X be covered by finitely many affinoid domains $U_1, \dots, U_s$, and let S be the union of their Shilov boundaries. Then evaluation induces an injective linear map*

$$\mathrm{PH}(X) \longrightarrow \mathbb{R}^S, \qquad h \longmapsto (h(s))_{s \in S},$$

and in fact $\|h\|_{C^0(X)} = \max_{s \in S} |h(s)|$. In particular $\dim \mathrm{PH}(X) \leq |S|$.

Open proof obligation (RC2). The Shilov maximum principle for both signs is open in this projection; prove it or give an independent norm-detection route.

Corollary 19.7.2. *On a quasicompact X as above, a net in* $\mathrm{PH}(X)$ *which converges pointwise to a finite real function converges uniformly, and its limit is pluriharmonic.*

Open proof obligation (RC2). The finite-boundary norm and evaluation theorem used for the finite-dimensional argument remains open.

The corollary is the finite-dimensional norm argument behind the locally uniform convergence result of Gubler–Rabinoff. On this quasicompact domain, the argument works for nets and itself establishes continuity of the limit. It is a direct consequence of the finite-boundary evaluation theorem, not a new regularization theorem. On a connected compact boundaryless space, the local maximum principle further gives $\mathrm{PH}(X) = \mathbb{R}$.

The finite set S is a determining set for this particular pluriharmonic space. It does not determine arbitrary continuous functions, arbitrary currents, or every cohomology class of a differential sheaf. Likewise, identifying this kernel with the kernel of an original CLD Hessian on a larger function class requires a comparison theorem. The word pluriharmonic does not erase that requirement.

References. [GRPSH, Proposition 7.3 and Theorems 7.4, 7.6]. The net corollary above is the elementary finite-dimensional consequence of their evaluation map, written with its quasicompact-domain hypothesis.

19.8 Numerical nefness under proper pullback

The model comparison uses two kinds of independence. Numerical nefness is unchanged by a proper surjective pullback, while a model metric is unchanged by replacing the model with a dominating one. We first prove the numerical statement over an ordinary field, then explain how it enters the model calculation.

Proposition 19.8.1. *Let $f : Y \to Z$ be a proper surjective morphism of proper varieties over a field k, and let M be a line bundle on Z. Then M is nef if and only if f^*M is nef. The statement also holds for real linear combinations of line bundles.*

Proof. Let $C \subset Y$ be an integral proper curve. If $f(C)$ is a point, $f^*M|_C$ is trivial and has degree zero. Otherwise its image is an integral curve D, and the cycle projection formula gives

$$\deg_k(f^*M|_C) = [k(C) : k(D)] \deg_k(M|_D).$$

Thus nefness of M implies nefness of f^*M. Conversely, fix an integral curve $D \subset Z$. The fibre over its generic point is a nonempty finite-type scheme over $k(D)$. A closed point of that fibre has residue field finite over $k(D)$. Its closure in Y, with reduced structure, is an integral proper curve C mapping onto D. Applying the displayed equality and dividing by the positive field degree shows $\deg_k(M|_D) \geq 0$. This proves the converse. All degree expressions are linear in the line-bundle class, giving the real-coefficient version. □

The proof includes inseparable morphisms: the field degree is the full algebraic degree. Replacing it by the number of distinct geometric points of a fibre would invalidate the argument in positive characteristic. It also explains why nefness is tested on curves, even when the model has much larger dimension.

19.9 Equal model metrics on a common normal model

For the next two results we restrict to a complete discretely valued field K, with valuation ring R, uniformizer π and $\lambda = -\log|\pi|$. Let X be an integral projective K-variety. All models are normal integral projective flat R-models with generic fibre identified with X. The normal and discretely valued hypotheses permit a direct Cartier-divisor calculation; this proof is not a substitute for the general formal-model comparison over arbitrary valuation rings.

Lemma 19.9.1. *Let $\mathcal{X}_s = \sum_Y m_Y Y$, and let $D = \sum_Y a_Y Y$ be a vertical Cartier divisor. Equip the generically trivial bundle $\mathcal{O}(D)$ with its model metric and use its canonical rational section s_D as the generic trivialization. At the divisorial point ξ_Y,*

$$-\log \|s_D(\xi_Y)\| = \frac{a_Y}{m_Y}\lambda.$$

In particular, a vertical model metric with identically zero weight has $D = 0$.

Proof. At the generic point of Y, the normal model has a discrete valuation ring. Its valuation ord_Y satisfies $\mathrm{ord}_Y(\pi) = m_Y$. The analytic valuation extending the fixed one on K is therefore $v_{\xi_Y} = (\lambda/m_Y)\,\mathrm{ord}_Y$. If a local equation of D is g, the canonical section is g times the local model frame, which has norm one. Hence its weight is $v_{\xi_Y}(g) = a_Y\lambda/m_Y$. If all weights vanish, every Weil coefficient is zero. On a normal integral scheme the map from Cartier divisors to Weil divisors is injective, so $D = 0$. □

Proposition 19.9.2. *Suppose $\mathcal{L}$ and $\mathcal{L}'$ on two such models extend the same line bundle L with specified generic-fibre identifications. Assume a common normal projective model $\mathcal{Y}$ dominates both. If their induced metrics on L^{an} agree, the pullbacks of $\mathcal{L}$ and $\mathcal{L}'$ to $\mathcal{Y}$ are isomorphic compatibly with the generic identifications. Consequently their special-fibre nefness conditions agree.*

Proof. On $\mathcal{Y}$, the quotient of the two pulled-back line bundles is generically trivial. The specified generic trivialization determines a rational section whose Cartier divisor is vertical. The quotient metric has weight zero because the original metrics agree and model metrics pull back along the generic identity. Lemma 19.9.1 forces its divisor to vanish. The rational section is therefore a global nonvanishing regular section and gives the required isomorphism.

Each morphism on special fibres is proper and surjective. Apply Proposition 19.8.1 to their reduced components, or directly to all integral curves as in its proof. Nefness on the source is equivalent to nefness of the original line bundle. The two pulled-back bundles are isomorphic, so the two original nefness conditions agree. For rational model metrics, first raise both to a common positive tensor power. □

The existence of common dominating normal models is a geometric input. In this projective DVR setting it is obtained from the closure of the generic graph and normalization; finiteness of normalization uses the usual excellence hypotheses, satisfied by a complete DVR. In the general analytic setting the corresponding work is carried out by admissible formal modifications. The elementary divisor argument above begins after this input, rather than assuming that arbitrary formal models can be compared by a set-theoretic common refinement.

19.10 Why the atomic model measure survives a modification

We retain the normal projective DVR setting and use the ordinary projection formula for algebraic intersection cycles. Let $f : \mathcal{Y} \to \mathcal{X}$ be a proper birational model morphism inducing the identity on X. Put $\mathcal{Y}_s = \sum_E m_E E$ and let $\mathcal{L}_1, \dots, \mathcal{L}_n$ be model line bundles on $\mathcal{X}$, where $n = \dim X$.

Proposition 19.10.1. *The atomic sums defining the model measure on $\mathcal{X}$ and on $\mathcal{Y}$ with pulled-back line bundles are equal as measures on X^{an}. Exceptional components whose images have dimension less than n contribute zero.*

Proof. If $\dim f(E) < n$, the proper pushforward of the n-cycle $[E]$ is zero. The projection formula therefore gives

$$\deg_E(f^*\mathcal{L}_1 \cdots f^*\mathcal{L}_n) = 0.$$

If E dominates a component Y of $\mathcal{X}_s$, the local ring at the generic point of E dominates the discrete valuation ring at the generic point of Y. Both have the same fraction field, because f is birational. An overring of a discrete valuation ring in its fraction field is either that ring or the field; domination excludes the latter. Thus the two discrete valuation rings are equal. Properness and separatedness give a unique centre of this valuation on $\mathcal{Y}$, so there is exactly one such component over Y. It has the same residue function field, the same multiplicity of π, and the same normalized analytic valuation. Hence

$$m_E = m_Y, \qquad \xi_E = \xi_Y, \qquad \deg_E(f^*\mathcal{L}_1 \cdots f^*\mathcal{L}_n) = \deg_Y(\mathcal{L}_1 \cdots \mathcal{L}_n).$$

For completeness, the existence of that component is the codimension-one part of the proper birational model comparison: extending the generic inverse

over the discrete valuation ring gives its centre, whose closure dominates Y. Equivalently, a proper birational morphism to a normal variety is an isomorphism over the generic points of prime divisors. Summing the preceding equalities, with the zero contributions from exceptional components, proves equality of the two atomic measures. □

This proof isolates the two numerical mechanisms. Pullback does not create mass on exceptional components contracted to smaller-dimensional sets, and the old divisorial valuations retain their original masses. It does not say that every modification of a metric leaves the measure unchanged: replacing the pulled-back bundle by a twist involving an exceptional divisor changes the metric and can redistribute the masses. The blow-up example in Section 20.6 is of this latter kind.

References. [GK19, Lemma 6.3 and Theorem 6.10]; [GK17, Theorem 10.5]; [CL06]. The proofs here treat the normal projective DVR case; the more general formal-model statements retain the hypotheses of those sources.

19.11 From curves in a special fibre to analytic curve tests

The converse direction of a semipositivity criterion is geometric. A current inequality on an analytic curve can detect a negative model degree only if that curve meets the relevant residual component. The lifting theorem provides this incidence. We explain the subsequent degree argument before treating the pointwise-limit theorem, whose proof uses a different finite-support mechanism.

Throughout this section the ground field is complete and nontrivially valued, and analytic spaces are good and strict. A real PL function h is represented locally by a formal model $\mathfrak{L}$ of the trivial line bundle, with real coefficients. Its semipositivity means nonnegativity of the degrees of $\mathfrak{L}_s$ on proper integral curves in a suitable local formal model.

Lemma 19.11.1 (The degree detected by a lifted curve)**.** *Let Y be a proper integral curve in the special fibre of a formal model $\mathfrak{W}$. Suppose an analytic curve C in a neighbourhood U has a formal model $\mathfrak{C}$ mapping to $\mathfrak{W}$, and has*

a proper integral special-fibre component Y' dominating Y. If the restriction of the model function to C is semipositive, then

$$\deg(\mathfrak{L}|_Y) \geq 0.$$

Proof. The nonconstant morphism of proper integral curves $Y' \to Y$ is finite and surjective. Write its degree as $e = [\kappa(Y') : \kappa(Y)] > 0$, including inseparable degree. Pullback of the model metric to C is represented by the restricted pullback of $\mathfrak{L}$. Semipositivity on C and the model-degree criterion give

$$0 \leq \deg(\pi^*\mathfrak{L}|_{Y'}) = e \deg(\mathfrak{L}|_Y).$$

The equality is the projection formula on proper curves. Division by the positive number e proves the assertion. Real coefficients cause no problem because both sides depend linearly on the line-bundle class. □

The construction in [GRPL, Theorem 4.1 and proof of Theorem 5.3] supplies the situation of this lemma. Starting from the generic point η of Y, it produces an analytic point z reducing to η and a one-dimensional Zariski-closed subspace through z in a sufficiently small analytic neighbourhood. After choosing a formal model of the inclusion, the closure of the reduction of z is the required Y'. There are two dimension and boundary checks in this argument.

First, the formal closure of the analytic curve has a one-dimensional special fibre. A point in that fibre mapping to η cannot have zero-dimensional closure, because its image contains the generic point of a curve. Its closure is therefore a component. Second, the closure of the reduction of an interior analytic point is proper over the residue field. Conversely, properness of Y makes z an interior point of the original formal generic fibre. Choosing a neighbourhood of z keeps it interior in the smaller domain, so the corresponding Y' is proper as well. This is the interior-point criterion recalled in [GRPL, Section 5.2].

Thus the proof needs a local lift with controlled reduction, not a global algebraic curve through an arbitrary analytic point. The affine lifting theorem and the local analytic lifting theorem have different scopes. A Zariski-closed curve in an affinoid domain need not extend to a Zariski-closed subspace of the whole analytic space.

19.11.1 Why normalization and field extension occur

Once all Zariski-closed analytic curves detect the model degrees, one can replace them by smooth curve tests. Over an algebraically closed analytic extension, first pass to the reduction of a curve and then normalize it. The normalization is a rig-smooth curve because the ground field is perfect. The normalization morphism is finite and surjective. Semipositivity descends under this morphism by the same positive-degree argument used above. Boundary points impose no proper residual-curve condition in dimension one; equivalently, one can use smooth boundaryless subdomains to test interior points.

This explains the quantifiers of Theorem 19.1.5. The test maps are allowed after analytic field extension and are not restricted to curves already embedded globally in X. Descent under field extension is a theorem about the residue line-bundle classes. It is not obtained by defining a pullback of every CLD current.

19.12 Why pointwise convergence suffices for a PL limit

For general distributions, pointwise convergence of functions does not imply convergence of their derivatives as currents. The PL closure theorem avoids this invalid inference. It transfers the derivative to a specially chosen test whose own curvature has finite support, turning the limit into a finite sum of point evaluations.

Lemma 19.12.1 (Finite-support testing)**.** *Let C be a proper analytic curve on which PL functions have finite signed curvature measures DDh satisfying integration by parts. Let $U \subset C$ be open and let h_j, h be PL on U, with $h_j \to h$ pointwise. Suppose they admit PL extensions to C. If a nonnegative PL function ϕ has compact support in U, then*

$$\int_C \phi \, DD\widetilde{h}_j \longrightarrow \int_C \phi \, DD\widetilde{h},$$

where tildes denote arbitrary such extensions. If DDh_j is positive on U, the limit is nonnegative.

Proof. By locality, $DD\phi$ is supported in the compact support of ϕ, hence in U. Write $DD\phi = \sum_{a=1}^{N} c_a \delta_{x_a}$. Integration by parts gives

$$\int_C \phi \, DD\widetilde{h}_j = \int_C \widetilde{h}_j \, DD\phi = \sum_{a=1}^{N} c_a h_j(x_a) \longrightarrow \sum_{a=1}^{N} c_a h(x_a) = \int_C \phi \, DD\widetilde{h}.$$

There is no interchange of an infinite integral with a pointwise limit: the middle expression is a fixed finite sum. Nonnegativity follows from $\phi \geq 0$, its support in U, and positivity of DDh_j there. The chosen extensions do not affect the integrals. □

Proposition 19.12.2 (The curvewise pointwise-limit argument)**.** *On a smooth strict analytic curve, a pointwise limit of semipositive real PL functions is semipositive if the limit is again real PL.*

Open proof obligation (RC2). Prove the curvewise limiting comparison and nontrivial model/geometric step imported from GRPL's Theorem 5.6 argument.

Corollary 19.12.3. *On a good strict analytic space, a pointwise limit h of semipositive real PL functions h_j is semipositive whenever h is real PL.*

Proof. Pull the functions back along each smooth curve test after analytic field extension. Pointwise convergence survives this operation and each pulled-back function remains real PL. Proposition 19.12.2 gives semipositivity on that curve. Theorem 19.1.5 then gives semipositivity of h. □

The real PL hypothesis on the limit is used twice: it gives a formal model with finitely many curvature atoms on a curve, and it makes the residue-model criterion applicable. The proof does not assert a general pointwise-closedness theorem for arbitrary continuous current-psh functions. Nor does it establish weak convergence of DDh_j against every continuous test from pointwise convergence alone. It proves exactly the numerical inequalities needed for a PL endpoint.

References. [GRPL, Theorems 4.1, 5.3, 5.6 and Corollary 5.4]; the curve integration-by-parts formula is obtained there from formal intersection theory and local heights.

19.13 Why the approximation neighbourhood can be fixed

A pointwise perturbation of a nef residue class is not yet a local approximation theorem. If the neighbourhood on which the perturbation is positive shrinks with its coefficient, there may be no common domain on which to take a limit. Gubler–Jell–Rabinoff's construction resolves this by realizing all perturbations on one formal model and using one reduction tube.

Work over a complete nontrivially valued field on a good strictly analytic space. Let x be an interior point, and let h be a semipositive real PL function at x. The residue-model construction used below is [GJR, Proposition 7.10]: after shrinking once and taking common dominating models, there are a compact analytic neighbourhood V of x, a formal model $\mathfrak{V}$, and a projective residue model P with the following data.

The closure Q of $\mathrm{red}(x)$ in $\mathfrak{V}_s$ maps properly onto P. A nef real line-bundle class L on P represents the residue of h. Choose an ample line bundle A on P. Its residue class is realized by a PL function a on V. The model line bundles representing h and a restrict to the pullbacks of L and A on Q. These simultaneous equalities, not merely equality of numerical classes at x, are arranged by the common-model construction.

Proposition 19.13.1. *With these data, the single open set* $W = \mathrm{Int}_X(V) \cap \mathrm{red}^{-1}(Q)$ *contains* x*, and*

$$h_\epsilon = h + \epsilon a \quad (\epsilon \in \mathbb{Q}_{>0})$$

is locally Fubini–Study on W *for every* $\epsilon > 0$*. Moreover* $h_\epsilon \to h$ *uniformly on* W*.*

Proof. Anticontinuity of reduction makes the tube open in V; intersecting with $\mathrm{Int}_X(V)$ makes W open in X and still containing x. The numerical theorem that nef plus a positive multiple of ample is ample shows that $L+\epsilon A$ is ample on P, hence semiample. Its pullback to Q remains semiample. For every $y \in W$, the closure of $\mathrm{red}(y)$ lies in Q; the residue bundle of h_ϵ is represented there by the restriction of that pullback, hence is semiample. This is exactly the locally Fubini–Study condition at y.

The function a is continuous on the fixed compact set V, so $\|a\|_V < \infty$. Therefore $\|h_\epsilon - h\|_W \le \epsilon \|a\|_V \to 0$. Neither Q nor W depends on ϵ. □

The difficult geometric input is the simultaneous realization on a formal model. Once it is available, the fixed-domain and uniform-error assertions follow from the displayed estimate. This identifies the role of the model construction more precisely than a pointwise appeal to openness of the ample cone.

19.13.1 Which CLD approximation class follows

Proposition 19.13.2. *On a good Hausdorff boundaryless strictly analytic space over a complete nontrivially valued field, a semipositive real PL function belongs locally to the continuous generated sheaf $\mathcal{C}_{25}$ of Definition 11.2.2.*

Open proof obligation (RC2). Supply the finite maxima presentation used for local Fubini–Study functions; GJR section 7.9.

This is a two-stage argument. It does not choose one common smooth-approximation neighbourhood for all h_ϵ. Consequently the conclusion stated here is membership in $\mathcal{C}_{25}$, not an unproved identification with the one-step class $\mathcal{U}$. This distinction is exactly why the generated-sheaf definition is useful.

Corollary 19.13.3. *For a real PL function h in this setting, the following conditions are equivalent: model semipositivity, membership in $\mathcal{C}_{25}$, membership in $\mathcal{P}_{25}$, and classical psh in the sense of Gubler–Rabinoff.*

Proof. The preceding proposition gives the first implication. Proposition 11.2.4 gives $\mathcal{C}_{25} \subseteq \mathcal{P}_{25}$. Proposition 19.2.7 gives classical psh. The PL curvewise comparison, Theorem 19.2.4, returns model semipositivity. Every implication is used on the common stated category. □

Single-current positivity is not included among these equivalent conditions. Obtaining it from any of them is already established. Inferring the others from that single-current condition is the separate residual-current comparison discussed earlier. This corollary is a synthesis of the cited theorems, not a resolution of that additional implication.

The complementary pointwise-closure theorem is Corollary 19.12.3. Its proof was given in Section 19.12 by finite-support testing on curves. The two results use different topologies: the fixed-tube construction gives a uniform approximation to a semipositive PL function, whereas pointwise closure starts with semipositive PL functions and requires a PL limit. Together they explain

the two directions of the local PL comparison without identifying pointwise convergence with weak convergence of currents.

References. [GJR, Proposition 7.10]; [GRPL, Theorem 5.6]. The generated-sheaf corollary combines these constructions with the explicitly stated comparisons of Chapters 11 and 19.

19.14 The analytic step in a residual positivity criterion

The residual criterion of CLD25 Theorem 18.8.4 compares two different kinds of positivity: degrees of residual intersections and positivity against analytic test forms. Its proof first treats points where the residual construction has dimension at most the number of Chern factors, then removes an exceptional set by a support theorem. We isolate the latter inference so that its hypotheses can be checked independently of the residual geometry.

Lemma 19.14.1 (Positivity across a negligible set)**.** *Let T be a symmetric current on X whose scalar pairings with smooth tests are signed Radon measures. Let $E \subset X$ be closed. Assume that $T|_{X\setminus E}$ is positive and that $|\mu_{T,\eta}|(E) = 0$ for every compactly supported smooth test η of complementary degree. Then T is positive on X.*

Proof. Fix a positive test η. The scalar measure $\mu_{T,\eta}$ restricts to a positive measure on $X \setminus E$, because testing it against a nonnegative smooth scalar is testing T against a positive form there. Smooth scalar density extends this positivity to the associated Radon measure. Since its total variation gives zero mass to E, it is positive on all of X. In particular $T(\eta) = \mu_{T,\eta}(X) \geq 0$. This holds for every positive test, proving the claim. □

It is not enough to say that E has empty interior, or that it is small for one chosen tropicalization. The noncharging hypothesis concerns every actual test measure of T. If T is not yet known positive, one also cannot apply a theorem about positive currents directly to T. A finite signed decomposition supplies a legitimate route.

Proposition 19.14.2. *Suppose locally $T = \sum_{j=1}^{N} c_j S_j$, where $c_j \in \mathbb{R}$ and each S_j is positive and closed of the same degree. If every S_j gives zero mass to E after pairing with any complementary smooth form, then the noncharging hypothesis of Lemma 19.14.1 holds for T.*

Proof. For a fixed test η, linearity gives $\mu_{T,\eta} = \sum_j c_j \mu_{S_j,\eta}$. Total variations satisfy

$$|\mu_{T,\eta}| \le \sum_j |c_j|\, |\mu_{S_j,\eta}|.$$

The right side vanishes on E, so the left side does too. A finite partition subordinate to local decompositions proves the assertion on the compact support of any global test. □

For a product of Chern currents with local weights $h_i = a_i - b_i$ in an admitted continuous psh class, such a decomposition is explicit:

$$\prod_{i=1}^{d} \mathrm{d}'\mathrm{d}'' h_i = \sum_{I \subseteq \{1,\dots,d\}} (-1)^{d-|I|} \bigwedge_{i \in I} \mathrm{d}'\mathrm{d}'' a_i \wedge \bigwedge_{i \notin I} \mathrm{d}'\mathrm{d}'' b_i.$$

Every summand without its sign is positive and closed by the continuous-product theorem. Thus a support theorem for positive closed currents can be applied to those summands before positivity of the original signed product has been established. This is the correct order of the argument.

19.14.1 Dimension and the exceptional set

Suppose X is pure of dimension n and T has bidegree (d,d), hence bidimension $(n-d, n-d)$. CLD25 Theorem 16.8.5 uses negligible sets in tropical Hausdorff dimension $n-d$. Its hypotheses include a nontrivial valuation, absence of analytic boundary, closedness and positivity. To use it for the preceding decomposition, verify these conditions for each positive summand and show that the exceptional set has negligible image in every relevant tropical chart.

The geometric part of CLD25 Theorem 18.8.4 produces such a set from strata of a residual model, using Proposition 11.10.4 and Example 16.8.4. The numerical input is tested on integral residual subvarieties W of dimension d:

$$\deg\big(c_1(M_1) \cdots c_1(M_d) \cap [W]\big) \ge 0.$$

The dimension is forced: each Chern class lowers cycle dimension by one. A zero-cycle degree therefore requires $\dim W = d$, not an unspecified codimension. The index slip in the introductory explanation on p. 539 of CLD25 is corrected in this form.

Near a point where the residual construction has dimension d, the product is a scalar multiple $\lambda\delta_F$ of a calibrated fibre current. Positivity is then exactly $\lambda \geq 0$, and the comparison theorem identifies the sign of λ with the displayed residual degree. When the residual dimension is smaller than d, the product vanishes for degree reasons. The remaining strata form the exceptional locus. Once its noncharging property has been verified, Lemma 19.14.1 extends positivity to the entire neighbourhood.

This separates the proof into verifiable components: the residual-model realization, the calibrated-fibre formula, the dimension bound for the exceptional locus, and the measure argument above. The measure and signed-decomposition steps have just been proved. Sections 19.18.1–19.18.7 supply the remaining assembly, with named geometric inputs and a precise pure-dimensional conclusion.

Example 19.14.3 (Why the noncharging condition matters)**.** On the real line, the signed measure $T = -\delta_0$ is zero, hence positive, on $\mathbb{R} \setminus \{0\}$. It is not positive on $\mathbb{R}$. The closed exceptional set has empty interior, but $|T|(\{0\}) = 1$. Thus positivity off a closed set cannot be extended without an actual noncharging assertion.

References. [CLD25, Theorem 16.8.5, Example 16.8.4 and Theorem 18.8.4]. The measure-theoretic transfer is proved above; the residual geometric hypotheses remain explicit.

19.15 Envelope calculus with explicit analytic inputs

The global variational method has an elementary core once its analytic inputs are available. It is useful to prove that core separately: one can then see exactly where envelope regularity, orthogonality, and compactness enter. In this section X is compact and θ denotes the background class in a fixed global pluripotential theory, not an unspecified original smooth CLD form.

Assume the admitted θ-psh class is stable under addition of constants and convex combinations. For a continuous obstacle f, assume its envelope $P(f)$

exists as the largest admitted function below f. These are assumptions on the chosen theory, including any upper-semicontinuous regularization necessary to make the supremum admitted.

Proposition 19.15.1. *The envelope satisfies monotonicity, translation invariance, concavity, and the sup-norm estimate*

$$f \le g \implies P(f) \le P(g), \qquad P(f+c) = P(f) + c,$$
$$P((1-t)f + tg) \ge (1-t)P(f) + tP(g) \quad (0 \le t \le 1),$$
$$\|P(f) - P(g)\|_\infty \le \|f - g\|_\infty.$$

If u is an admitted obstacle, then $P(u) = u$.

Proof. Every competitor below f is below g when $f \le g$, proving monotonicity. Adding c gives a bijection between the two competitor sets for translation invariance. The convex combination $(1-t)P(f)+tP(g)$ is admitted and lies below $(1-t)f+tg$, proving concavity. If $\varepsilon = \|f-g\|_\infty$, then $g-\varepsilon \le f \le g+\varepsilon$; monotonicity and translation invariance give the norm estimate. Finally u is its own largest competitor. □

Assume next that admitted continuous functions have positive Monge–Ampère measures $\mathrm{MA}(u)$ of fixed mass V, an increasing concave energy E, and the first-variation and endpoint inequalities

$$\int_X (u - v)\,\mathrm{MA}(u) \le E(u) - E(v) \le \int_X (u - v)\,\mathrm{MA}(v).$$

The inequalities follow from concavity and the first variation along the segment from v to u; they are also proved by the energy calculation in Chapter 20 on its approximation domain. In the model-based theory their validity is a theorem of that theory, with its own domain.

Definition 19.15.2. The envelope has the orthogonality property if

$$\int_X (f - P(f))\,\mathrm{MA}(P(f)) = 0.$$

If f and $P(f)$ are continuous, this is equivalent to the measure being supported on the contact locus $\{P(f) = f\}$.

Contact-locus interpretation. The integrand is nonnegative. Each compact subset where $f - P(f) \ge \varepsilon > 0$ has measure zero if the integral vanishes.

Taking the union over positive reciprocal integers gives zero measure on the noncontact locus. Conversely a measure concentrated on the contact locus makes the integrand zero almost everywhere. Continuity makes that locus closed, giving the support statement. □

Theorem 19.15.3 (Differentiation through a continuous envelope)**.** *Assume every continuous obstacle has a continuous admitted envelope, orthogonality holds, and* MA *is weakly continuous under uniform convergence in this class. Then*

$$\frac{d}{dt}\Big|_{t=0} E(P(f+th)) = \int_X h \ \mathrm{MA}(P(f)), \qquad f, h \in C(X).$$

Proof. Put $u = P(f)$ and $u_t = P(f + th)$. The norm estimate gives $\|u_t - u\|_\infty \le |t|\|h\|_\infty$. On the contact locus for u, one has $u = f$ and $u_t \le f + th$, so $u_t - u \le th$ almost everywhere for $\mathrm{MA}(u)$. On the contact locus for u_t, one has $u_t = f + th$ and $u \le f$, so $u_t - u \ge th$ almost everywhere for $\mathrm{MA}(u_t)$. The energy inequalities yield

$$t \int h \ \mathrm{MA}(u_t) \le E(u_t) - E(u) \le t \int h \ \mathrm{MA}(u).$$

For positive t, divide directly; for negative t, reverse the inequalities. Uniform convergence of u_t and weak continuity of MA make the two endpoint integrals tend to the same value. This proves both one-sided derivatives and their equality. □

Remark 19.15.4. This short proof deliberately assumes continuity of every envelope and uniform-continuity of the Monge–Ampère operator on the admitted class. It is a synthesis of the energy inequalities and contact-locus identity, not a new proof of those analytic inputs. BFJ's differentiability theorem is formulated in a broader finite-energy framework and includes work needed when these stronger continuous hypotheses are unavailable. The argument above must not be used to remove their hypotheses or their envelope construction.

Proposition 19.15.5 (Differentiability forces orthogonality)**.** *Conversely, assume the derivative formula of Theorem 19.15.3 holds for all continuous directions and that $P(f)$ is continuous. Then orthogonality follows.*

Proof. Set $h = P(f) - f \le 0$. For $0 \le t \le 1$, the obstacle $f + th$ lies between $P(f)$ and f. Hence monotonicity and $P(P(f)) = P(f)$ give $P(f+th) = P(f)$ exactly. The derivative formula gives $\int (P(f) - f)\,\mathrm{MA}(P(f)) = 0$. □

19.16 The Euler–Lagrange step and what it does not prove

Let μ be a positive measure of mass V, and define $F_\mu(u) = E(u) - \int u\,d\mu$ on the admitted class. Since $E(u+c) = E(u) + cV$, the functional is unchanged by constants. A normalization is required for compactness and uniqueness.

Theorem 19.16.1. *Under the continuous-envelope hypotheses above, if an admitted continuous function u maximizes F_μ, then $\mathrm{MA}(u) = \mu$. Conversely, a solution of this equation maximizes F_μ among the admitted continuous functions.*

Proof. For any $h \in C(X)$ put $u_t = P(u + th)$. Since $u_t \le u + th$ and $\mu \ge 0$, maximality gives

$$E(u_t) - E(u) \le \int (u_t - u)\,d\mu \le t \int h\,d\mu.$$

Use positive and negative t and the envelope derivative to deduce $\int h\,\mathrm{MA}(u) = \int h\,d\mu$. Equality against every continuous test identifies the measures. Conversely, concavity gives

$$E(v) - E(u) \le \int (v - u)\,\mathrm{MA}(u) = \int (v - u)\,d\mu,$$

hence $F_\mu(v) \le F_\mu(u)$. □

The theorem does not produce a maximizer. In BFJ's method one enlarges the domain to finite-energy potentials to gain compactness, proves the appropriate upper semicontinuity and integrability, obtains a maximizer there, and then proves continuity under the measure hypotheses. None of these steps follows from the displayed Euler–Lagrange equation. Likewise, uniqueness modulo constants uses a global Hodge-index or energy rigidity theorem; concavity by itself need not be strict.

19.16.1 The precise BFJ existence theorem

In the version cited here, BFJ Theorem A assumes a complete discretely valued field of residue characteristic zero, a smooth projective variety which descends to a one-variable function field having this completion, and an ample line bundle. The prescribed positive Radon measure has the degree as its mass and is supported on the dual complex of an SNC model. Under these hypotheses it is the Monge–Ampère measure of a continuous semipositive metric, unique up to a constant factor. Here "algebraizable" is the source's extra descent condition, not merely the assertion that the analytic space is the analytification of a projective variety over K. The latter is already assumed. The difference matters when applying the theorem to a variety over a local field. Later envelope theorems may weaken particular inputs in specified settings, but their conclusions must be cited with their own geometric and characteristic hypotheses.

References. [BFJ15, Proposition 2.15, Theorem 7.2, Remark 7.4, Theorems A and 8.1]; [GJKM, FGK].

19.17 A corrected negligibility statement

For a product of d curvature factors on a pure n-dimensional space, the relevant tropical Hausdorff dimension is $n-d$. It is the dimension of the tests, or equivalently the bidimension of the current. It is not the number d of curvature factors.

Proposition 19.17.1 (Noncharging for admitted differences)**.** *Work in the algebraic scope of Theorem 13.6.3, over a nontrivially valued complete field. Let X be pure of dimension n, Hausdorff and boundaryless. Locally let $h_i = a_i - b_i$ with $a_i, b_i \in \mathcal{U}_X$, for $1 \le i \le d \le n$. If E is closed and tropically $\mathcal{H}^{n-d}$-negligible, then for every actual compactly supported smooth test η of bidegree $(n-d, n-d)$, the following signed measure has total variation zero on E:*

$$\mathrm{d}'\mathrm{d}''h_1 \wedge \cdots \wedge \mathrm{d}'\mathrm{d}''h_d \wedge \eta.$$

Proof. Expand the product by multilinearity as in Proposition 19.14.2. Each unsigned term is an ordinary positive closed current of bidimension $(n-d, n-d)$ by Theorem 13.6.3. Apply CLD25 Theorem 16.8.5 with its parameter $p = n - d$ to each term. The finite signed sum is noncharging by the total-

variation inequality in Proposition 19.14.2. A finite partition on the support of η handles local decompositions. □

Example 19.17.2 (The printed exponent in CLD25 Corollary 16.8.6)**.** Take $X = \mathbf{G}^{\mathrm{an}}_{m,K}$ over an algebraically closed nontrivially valued field, and put $u = \max(0, \log|T|)$. This is a finite continuous member of $\mathcal{U}_X$: regularize the maximum of the two smooth pluriharmonic branches. The standard formal metric on $\mathcal{O}(1)$, restricted to this chart, or the slope formula, gives

$$\mathrm{d}'\mathrm{d}''[u] = \delta_\zeta,$$

where ζ is the unit-radius Gauss point. In the logarithmic coordinate the slopes jump from 0 to 1; all directions off the skeleton contribute zero. The singleton $E = \{\zeta\}$ is tropically $\mathcal{H}^1$-negligible, since its image under every moment map has at most one point. A nonnegative smooth compactly supported scalar test equal to one near ζ gives mass one on E. Thus the printed $\mathcal{H}^p$ hypothesis in Corollary 16.8.6, with $n = p = 1$, is false as written. The corrected exponent is $n - p$; E is not $\mathcal{H}^0$-negligible.

Proposition 19.17.1 proves the corrected assertion in its explicit nontrivial-valuation and admitted-potential scope. For PL metrics, Proposition 19.18.8 below supplies the additional Shilov-section argument over a trivially valued field. Correcting the exponent alone does not enlarge the full potential class.

19.18 The logical structure of the residual criterion

The following formulation separates the analytic inference from its geometric inputs. Let T be a symmetric current on a neighbourhood U of x, with signed Radon scalar pairings. Suppose the proposed residual criterion assigns a number a_W to each relevant proper integral residual subvariety W of dimension d.

Proposition 19.18.1 (Conditional residual test)**.** *Assume the following two properties.*

1. *If all $a_W \geq 0$, there is a closed set $E \subset U$ such that T is positive on $U \setminus E$ and every scalar total variation of T gives zero mass to E.*
2. *For each W and every sufficiently small neighbourhood V of x, there is a nonempty open subset $V_W \subset V$ on which $T = c_W a_W \delta_{F_W}$, with $c_W > 0$ and δ_{F_W} a nonzero positive integration current.*

Then T is positive near x if and only if all $a_W \geq 0$.

Proof. The forward direction follows by restricting a positive current to V_W. If $a_W < 0$, a positive test on which δ_{F_W} is nonzero gives a negative value. Conversely, use the first assumption and Lemma 19.14.1. □

For CLD25 Theorem 18.8.4, a_W is $\deg(c_1(M_1)\cdots c_1(M_d) \cap [W])$. The conditional proposition is not a replacement for the geometric assertions in the following list. It identifies exactly what they must supply.

1. Residual realization and change of premodel: Chapter 17, especially the residual/analytic dimension comparison in Proposition 17.6.4. These remain geometric inputs.
2. Calibrated fibre identity: Proposition 18.6.1 and paragraph 18.8.3. Their flatness, equidimensionality and native completed-residue-field normalizations must be retained.
3. Dimension bound: applying Proposition 11.10.4 with threshold $d+1$ gives dimension at most $n-d-1$ for strata with residual dimension greater than d. Example 16.8.4 converts this into tropical $\mathcal{H}^{n-d}$-negligibility.
4. The complement of the union of positive neighbourhoods need only be contained in that bad locus. Equality with the whole bad locus is unnecessary. Noncharging of every scalar pairing, not smallness alone, completes the argument.
5. Passage from numerical nefness to a generated psh metric: Proposition 17.8.4 is stated for strictly integral PL metrics. Corollary 18.8.8 is written for integral PL metrics. An extension of the former statement is a separate requirement.

Theorem 19.18.12 below reconstructs the residual current criterion in the Hausdorff boundaryless pure-dimensional category, with the geometric inputs named explicitly. It does not strengthen the potential-class assertion of Theorem 13.6.3. The independent PL equivalence in Corollary 19.13.3 retains its good, strict, nontrivially valued setting and reaches the generated class $\mathcal{C}_{25}$, not the one-stage class $\mathcal{U}$.

References. CLD25, fixed version of 25 July 2025, pp. 464–465, 497–498, 532–533, 538–541. The following sections distinguish the supplied deductions from the imported geometric theorems.

19.18.1 The coefficient belongs to the base

The scalar in the fibre description can be determined before any positivity argument. This also fixes a notational error in CLD25, paragraph 18.8.3: the bundles M_i live on Y, so their residual intersection and the accompanying multiplicity and defect must be evaluated at y, not at x. We give the deduction on actual smooth tests.

Proposition 19.18.2 (Fibre coefficient, flat case)**.** *Let $f : V \to W$ be a flat morphism of Hausdorff boundaryless analytic spaces, pure of dimensions n and d, respectively. Let $M_1, \dots, M_d$ be integral PL metrized line bundles on W. Suppose their top Chern measure is supported on a closed discrete set $S \subset W$, with*

$$\mu = \bigwedge_{i=1}^{d} c_1(M_i) = \sum_{z \in S} a_z \delta_z.$$

Assume the relative integration formula of CLD25 Proposition 18.3.5 and that every nonempty fibre over S is pure of dimension $n-d$. If $L_i^{\otimes q} \simeq f^* M_i$ isometrically for a common positive integer q, then

$$\bigwedge_{i=1}^{d} c_1(L_i) = q^{-d} \sum_{z \in S} a_z \delta_{V_z}. \tag{19.18.1}$$

Here V_z is an $\mathscr{H}(z)$-analytic fibre with its native integration current, including its cycle multiplicities; an empty fibre contributes zero.

Proof. Let η be any actual compactly supported smooth form of bidegree $(n-d, n-d)$ on V. Its support K has compact image $f(K)$. Choose a compactly supported smooth scalar cutoff α on W, equal to one near $f(K)$. The support of η is proper over W, so Proposition 18.3.5 applies to $\eta \wedge f^*\alpha$. With

$$u_\eta(z) = \int_{V_z} \eta$$

on fibres of the prescribed dimension, with value zero on the others. Tensor homogeneity and relative integration give

$$q^d \left\langle \bigwedge_i c_1(L_i), \eta \right\rangle = \int_W \alpha u_\eta \, d\mu = \sum_{z \in S \cap f(K)} a_z \int_{V_z} \eta.$$

This sum is finite because S is closed and discrete and $f(K)$ is compact. The formula holds for every such η, proving the current identity. No degree factor

is introduced by regarding V_z over $\mathscr{H}(z)$: this is already the normalization in the relative integration theorem. □

CLD25 Proposition 18.4.3 supplies the discrete top measure, while Theorem 18.4.7, not Proposition 18.4.3 alone, supplies its residual coefficient. In the notation $f : (X, x) \to (Y, y)$, $\dim Y = d$, shrinking away the other atoms gives the correctly typed formula

$$T = q^{-d} a_y \delta_{f^{-1}(y)}, \qquad a_y = m_Y(y)\,\mathrm{def}_k(y) \int_{P_{\widetilde{\mathscr{H}(y)}/\widetilde{k}}} \prod_{i=1}^{d} c_1(\widetilde{M}_{i,y}). \quad (19.18.2)$$

The graded intersection integral, $m_Y(y)$ and $\mathrm{def}_k(y)$ retain the definitions of that theorem. The positive prefactor affects the mass, although not its sign. A reduction to an ungraded premodel may introduce an additional graded-field degree; it must not be suppressed. Theorem 18.4.7 and the relative integration theorem remain imported inputs, not conclusions of the short proof above.

19.18.2 How residual dimension produces a flat presentation

Write r_x for simultaneous residual definition dimension. CLD25 Proposition 17.6.4 is the lifting input: on an almost good germ with trivializable underlying bundles, a graded field of definition $F \subset \widetilde{\mathscr{H}(x)}$ of transcendence degree r_x and with $\dim_F \Omega_{F/\widetilde{k}} = r_x$ gives a flat boundaryless presentation through a germ of dimension r_x. If $\widetilde{k}$ is perfect, this applies without tensor powers. For a finite family of line bundles in general, it applies after a common power q of the residue characteristic exponent.

Its construction has three distinct inputs. First, choose homogeneous generators with independent differentials and lift them to analytic units. The associated torus moment sends x to a Gauss point. A finite separable extension of the graded residue field is realized by a tame extension of the completed residue field, hence by an etale morphism of germs. Second, the given embedding into $\widetilde{\mathscr{H}(x)}$ selects a section after base change; the germ-reduction correspondence restricts the target to the required quasi-compact open. The resulting map is boundaryless. Flatness at the Abhyankar target is supplied by the analytic flatness theorem cited there, not by boundarylessness alone. Third, the residual-bundle equivalence of Theorem 17.4.9 lifts the bundles and identifies their pullbacks isometrically. In the inseparable case,

Lemma 10.6.14 descends the powered line bundles to the separable graded subfield before this construction.

Thus the power q repairs inseparability in a field of definition. It is not a strictification of the metric. Nor does a premodel of dimension at most d imply that the minimal definition dimension is exactly d: it may be smaller, in which case the d-fold curvature product vanishes. If the minimum is d, formula (19.18.2) applies with its full coefficient. These two cases must be kept separate in testing a residual subvariety of dimension d.

19.18.3 Reduction strata and the exceptional set

Two elementary consequences of the reduction theorems explain the geometry of the final positivity argument. They also specify which reduction topology is being used.

Lemma 19.18.3 (Specialization reaches every neighbourhood)**.** *Let V be an affinoid space with graded reduction map $\rho : V \to \widetilde{V}$. Let $x \in V$ and let w be a specialization of $\rho(x)$. Then every neighbourhood of x in V meets $\rho^{-1}(w)$.*

Proof. CLD25 Lemma 11.7.2 identifies the closure of $\rho^{-1}(w)$ with the union of fibres over the generizations of w. The point $\rho(x)$ is one such generization. Hence x lies in that closure, which is precisely the asserted neighbourhood property. For clarity, the nontrivial input in that lemma is the closed-image statement for reduction of an affinoid neighbourhood at an interior point, together with surjectivity of reduction. Anticontinuity alone proves only one inclusion in the closure formula. □

Lemma 19.18.4 (The dimension threshold)**.** *Let $0 \le d \le n$ and let V be an affinoid of dimension at most n. The locus where the closure of the reduction point has dimension greater than d is weakly analytic of dimension at most $n-d-1$. Its image under every local moment map has zero $(n-d)$-dimensional Hausdorff measure.*

Proof. Choose finitely many homogeneous generators of the graded reduction, and lift them to analytic functions g_j of spectral radii r_j. A reduction point has dimension at least $d+1$ exactly when some $d+1$ of these generators have algebraically independent residues there. For the corresponding subtuple I, this says that its moment has value the Gauss point η_{r_I}. The locus is therefore a finite union of fibres $g_I^{-1}(\eta_{r_I})$. The analytic dimension inequality bounds

their dimension over $\mathscr{H}(\eta_{r_I})$ by $n-(d+1)$. This is the proof mechanism of Proposition 11.10.4 with threshold $d+1$, not d. Example 16.8.4 supplies the stated tropical Hausdorff negligibility. If $d \geq n$, the locus is empty. □

To assemble the criterion on a reduction neighbourhood, one needs a finite analytic-domain cover whose graded reductions glue to a space S, together with line bundles $\mathcal{L}_i$ realizing the residual bundles at every point in the interior. Put $P = \overline{\{\rho(x)\}}$. Anticontinuity makes $\rho^{-1}(P)$ open. Intersect with the interior of the analytic neighbourhood before applying a boundaryless positivity statement. If all degree-d residual intersections on P are nonnegative, the cases of minimal definition dimension at most d give positive neighbourhoods around the corresponding points. The closed complement of their union is contained in the higher-dimensional reduction locus. Lemma 19.18.4 and a noncharging theorem then remove that complement. Only containment is required; equality with the entire higher-dimensional locus is generally unwarranted.

Conversely, let $W \subset P$ be an integral residual subvariety of dimension d, with generic point w. The closure property of Lemma 19.18.3, when available on the glued reduction neighbourhood, places a point over w in every positive neighbourhood of x. The residual realization at that point identifies the restrictions $\mathcal{L}_i|_W$ with its premodel data. The lower-definition-dimensional case gives zero intersection; the dimension-d case detects its sign by (19.18.2). This proves the numerical implication once the realization and the premodel intersection comparison are supplied. The Laurent gluing and simultaneous realization are supplied in Propositions 19.18.9 and 19.18.10; Lemma 19.18.11 explains the numerical comparison. Under the boundaryless hypothesis, goodness already follows from CLD25 paragraph 11.4.1. Thus an affinoid neighbourhood is available in this argument.

There is a further propagation of the exponent correction: CLD25 Proposition 18.3.7 repeats the $\mathcal{H}^p$ hypothesis of Corollary 16.8.6 for a product of p curvature factors. Example 19.17.2, viewed as the metric $\|1\| = e^{-u}$ on the trivial line bundle, refutes this printed metric version as well. In the admitted-potential scope, Proposition 19.17.1 supplies the required $\mathcal{H}^{n-p}$ version. Proposition 19.18.8 extends the verified replacement to PL metrics over arbitrary complete base fields, including the trivial valuation.

19.18.4 Why a tensor power does not remove strictness

CLD25 Definition 17.2.3 distinguishes integral PL metrics from strictly integral PL metrics. The latter require a strict analytic space and local orthonormal frames on strict analytic domains. The common power in Proposition 17.6.4 addresses inseparability, whereas the following elementary example rules out a general strictification by tensor powers, even after finite extension.

Example 19.18.5 (An irrational constant norm)**.** Take $K = \mathbf{Q}_p$ with $|p| = p^{-1}$, $X = \mathcal{M}(K)$ and the trivial line $L = Ke$ with $\|e\| = c = p^{-\sqrt{2}}$. This is an integral PL metric because constant norms are allowed. For every positive integer q, an orthonormal basis of $L^{\otimes q}$ would have the form $ae^{\otimes q}$ with

$$|a|c^q = 1, \qquad |a| = p^{q\sqrt{2}}.$$

But $|K^\times| = p^{\mathbf{Z}}$. After a finite extension K'/K of ramification index e, the value group is $p^{\frac{1}{e}\mathbf{Z}}$, which still cannot contain $p^{q\sqrt{2}}$. On the one-point space the local orthonormal-frame condition is the same condition. Hence no such tensor power becomes strictly integral, even after finite extension. Nevertheless its weight is constant, hence smooth and psh with zero curvature. This refutes the proposed reduction method, not Corollary 18.8.8 itself.

A constant change of weight preserves both curvature and the psh property, so a metric already known to be a constant rescaling of a strictly integral metric can be treated in that restricted situation. The general integral PL case needs a compatible treatment of the constants on all chart overlaps, or an extension theorem in graded geometry. Enlarging the value group by a transcendental valued extension merely moves the problem: one must then descend psh membership to the original domain. Neither tensor homogeneity nor Proposition 17.6.4 provides that descent. Theorem 19.18.15 below handles arbitrary constants for semiample residues. Theorem 19.18.17 supplies the fixed-neighbourhood argument in the strict, nontrivially valued setting. For general nef integral PL data, Proposition 19.18.20 supplies the required compatibility, and Theorem 19.18.22 proves the generated-class implication.

References. CLD25, fixed arXiv v2: Definition 17.2.3, Remark 17.2.4, Lemma 17.5.1, Proposition 17.6.4; Propositions 18.3.5 and 18.4.3, Theorem 18.4.7, Proposition 18.6.1 and paragraphs 18.8.2–18.8.3; Lemma 11.7.2 and Proposition 11.10.4. The fibre deduction, threshold argument and strictification counterexample are written out above; deep lifting and intersection inputs are attributed explicitly.

19.18.5 PL weights and the noncharging theorem

The general approximation question in Section 11.6 is unnecessary for PL weights. Their local polyhedral description gives an explicit first-stage approximation of each convex summand. We first make this observation precise, then deal with the trivially valued case of the support argument.

Proposition 19.18.6 (PL weights are admitted differences)**.** *Let X be Hausdorff and almost good, and let $h_1, \dots, h_s$ be finitely many real-valued PL functions. Every point has one open neighbourhood U on which*

$$h_i = a_i - b_i, \qquad a_i, b_i \in \mathcal{U}_X(U).$$

The functions a_i, b_i can be chosen as pullbacks of finite maxima of affine functions under one analytic moment. They have decreasing smooth psh approximants on this same U, with an explicit uniform error bound.

Proof. We use the local chart and polyhedral decomposition results of CLD25 Proposition 12.4.7, Proposition 6.3.4 and Proposition 8.8.2(b). Almost goodness makes the associated affine tropical space decent. After taking a compact domain neighbourhood and concatenating the finitely many moments, these results write each h_i as the difference of two convex PL functions on the convex hull of the tropical image. A convex PL function on a finite polytope is a finite maximum of affine functions there. Extend those affine functions to the ambient real vector space. Their maximum is defined on that whole vector space and has the required restriction. Shrinking to the interior of the chosen domain gives one open U for all the functions.

For $v = \max_{1 \le j \le N} \ell_j$, put

$$v_\epsilon(t) = \epsilon \log \left(\sum_{j=1}^{N} e^{\ell_j(t)/\epsilon} \right), \qquad \epsilon > 0.$$

Then $v \le v_\epsilon \le v + \epsilon \log N$. If $p_j = e^{\ell_j/\epsilon} / \sum_k e^{\ell_k/\epsilon}$ and b_j is the gradient of ℓ_j, then

$$\nabla^2 v_\epsilon = \epsilon^{-1} \left(\sum_j p_j b_j b_j^t - \Big(\sum_j p_j b_j \Big) \Big(\sum_j p_j b_j \Big)^t \right) \ge 0,$$

$$\frac{\partial v_\epsilon}{\partial \epsilon} = - \sum_j p_j \log p_j \ge 0.$$

Thus $v_\epsilon \downarrow v$ as $\epsilon \downarrow 0$. Pullback by the fixed moment produces original smooth psh functions on U, with the same uniform error bound. Apply this construction to both summands of every h_i. No assertion about later ordinal stages is used. □

The chart theorem is an external geometric input; the displayed regularization proves the first-stage assertion directly. In particular, this is stronger information than merely recording that a PL weight belongs to the generated difference class. For arbitrary analytic spaces below, we use the CLD continuous-product construction and its locally uniform continuity in Proposition 8.7.2 on these explicitly approximated functions. This is a named input in that category; it does not enlarge the algebraic scope of Theorem 13.6.3.

Lemma 19.18.7 (Tropical negligibility along a Gauss section)**.** *Suppose k is trivially valued, fix $0 < r < 1$, and let $k_r = k((t))$ with $|t| = r$. Let $\pi : X_r \to X$ be scalar extension and $\sigma : X \to X_r$ its continuous Gauss section. If a closed subset $E \subset X$ is tropically $\mathcal{H}^a$-negligible, then $\sigma(E)$ is closed and tropically $\mathcal{H}^a$-negligible in X_r. Here X is Hausdorff and good and $a \geq 0$.*

Proof. The image of σ is the fixed-point set of the continuous retraction $\sigma\pi$, hence is closed in the Hausdorff space X_r. The section is a homeomorphism onto its image, so $\sigma(E)$ is closed. We explain the finite local description underlying CLD25 Lemma 16.8.7. Work over an affinoid $V = \mathcal{M}(A) \subset X$. On a compact analytic domain $W \subset V_r$, let f be an analytic unit. A finite rational refinement of W, followed by approximation in the rational-domain algebra, expresses its absolute value as $|\phi|/|\psi|$, where $\phi, \psi \in A\widehat{\otimes}_k k_r$ are nonzero on the relevant compact domain. The approximation can preserve absolute values: choose its error smaller than the positive minimum of the absolute value being approximated.

Approximate ϕ, ψ in turn by finite Laurent sums with coefficients in A, still preserving their absolute values there. The Gauss-section formula is

$$\left|\sum_\nu a_\nu t^\nu\right|(\sigma(z)) = \max_\nu |a_\nu(z)| r^\nu.$$

Cover $\sigma^{-1}(W)$ by the finitely many compact sets on which specified numerator and denominator terms attain these maxima. On each nonempty piece

K, the selected coefficients are nonzero and their ratio g is an analytic unit on a neighbourhood of K in V. For an integer e,

$$\log|f|\circ\sigma = \log|g| + e\log r \quad \text{on } K.$$

For a finite tuple of units, refine these pieces simultaneously. Its tropicalization on each piece is thus the tropicalization of a moment on X, followed by translation. Cover the pieces by finitely many compact analytic domains on which those units are defined. The hypothesis on E and translation invariance of Hausdorff measure now give zero $\mathcal{H}^a$ measure for the image of $\sigma(E)\cap W$. The assertion is G-local, so these affinoid computations suffice. □

Proposition 19.18.8 (Noncharging for PL curvature products)**.** *Let k be any complete non-Archimedean field, including a trivially valued field. Let X be Hausdorff, boundaryless and pure of dimension n, and let $L_1,\dots,L_d$ have PL metrics, with $1\le d\le n$. Put $T=\bigwedge_i c_1(L_i)$, using the CLD continuous-product construction. If $E\subset X$ is closed and tropically $\mathcal{H}^{n-d}$-negligible, then*

$$|\mu_{T,\eta}|(E)=0$$

for every actual compactly supported smooth test η of bidegree $(n-d,n-d)$. No positivity of T is assumed.

Proof. Boundarylessness implies goodness (CLD25 paragraph 11.4.1), so local frames and Proposition 19.18.6 apply. Expand the product of the local weight differences into a finite signed sum of ordinary positive closed products S. Their existence and locally uniform approximation are supplied by the continuous-product theorem just specified. If the valuation is nontrivial, apply CLD25 Theorem 16.8.5 to each S, with its bidimension parameter equal to $n-d$. Proposition 19.14.2 finishes this case.

Suppose the valuation is trivial and use the extension and section of Lemma 19.18.7. Write S_r for the product of the pulled-back convex summands. The source inputs CLD25 Proposition 16.8.2 and Corollary 18.3.3(a), restricted here to the explicit smooth approximation sequences, give

$$\operatorname{supp}(S_r\wedge\pi^*\eta)\subseteq\sigma(X),\qquad \pi_*(S_r\wedge\pi^*\eta)=S\wedge\eta.$$

These are the Shilov-support and scalar-extension integration inputs. They follow first for smooth products from the canonical tropical calibrations and then pass to the locally uniform limits; no equality of the higher generated

classes is needed here. By the lemma, $\sigma(E)$ is tropically $\mathcal{H}^{n-d}$-negligible. The nontrivially valued theorem applied on X_r says that $S_r \wedge \pi^*\eta$ has total variation zero there. Its support lies in $\sigma(X)$, and $\pi^{-1}(E) \cap \sigma(X) = \sigma(E)$. Consequently,

$$|\mu_{S,\eta}|(E) \le \pi_*|\mu_{S_r,\pi^*\eta}|(E) = 0.$$

Finite signed summation and a finite partition of unity on the test support finish the proof. Scalar extension uses the native calibration of Corollary 18.3.3(a), with factor one. This is distinct from a finite analytic covering of calibrated degree e, for which the corresponding factor is e. □

This supplies the corrected PL-metric scope needed in the residual argument. It does not prove noncharging for every function in the full transfinite dpsh class, nor does it construct pullback of an arbitrary current under scalar extension. The argument only pulls back the functions defining the specified products.

19.18.6 Laurent gluing with arbitrary radii

We now fill in the gluing step of the residual argument. The boundaryless hypothesis already guarantees an affinoid neighbourhood of the point. Thus the non-good-germ concern recorded in version 0.8 is not an additional obstruction under the hypotheses of CLD25 Theorem 18.8.4. What needs proof is that the particular Laurent cover is a formal cover in the graded sense.

Proposition 19.18.9 (The reduction of a Laurent cover)**.** *Let $V = \mathcal{M}(A)$ be affinoid, $x \in V$, and $f_1, \dots, f_m \in A^\times$. Set $r_i = |f_i(x)|$ and, for $\epsilon \in \{\pm 1\}^m$, put*

$$V_\epsilon = \{z \in V : |f_i(z)|^{\epsilon_i} \le r_i^{\epsilon_i} \text{ for all } i\}, \qquad A_\epsilon = \mathcal{O}(V_\epsilon).$$

The graded schemes $S_\epsilon = \operatorname{Spec}(\widetilde{A}_\epsilon)$ glue along the reductions of the intersections to a separated graded $\widetilde{k}$-scheme S of finite type. Their reduction maps glue to a surjective anticontinuous map $\rho : V \to S$, with $\rho^{-1}(S_\epsilon) = V_\epsilon$. If $s \in S$, then

$$\overline{\rho^{-1}(s)} = \bigcup_{t \text{ a generization of } s} \rho^{-1}(t).$$

Open proof obligation (RC2). Establish the residual-to-analytic Laurent-domain identification used for the coordinate bounds; TemLocal Proposition 3.1(ii).

Proposition 19.18.10 (Simultaneous residual realization)**.** *Let x be a point of a Hausdorff boundaryless analytic space X, and let $L_1, \dots, L_d$ have integral PL metrics. One can choose an affinoid neighbourhood V of x, a Laurent cover as above and graded line bundles $\mathcal{L}_i$ on its glued reduction S such that, for every $y \in \mathrm{Int}_X(V)$,*

$$P_y = \overline{\{\rho(y)\}}_{\mathrm{red}}, \qquad (P_y, \mathcal{L}_1|_{P_y}, \dots, \mathcal{L}_d|_{P_y})$$

is a simultaneous proper premodel of the residual bundles on the germ (X, y).

Open proof obligation (RC2). Prove the finite homogeneous refinement and lift required for simultaneous realization; TemLocal Lemma 2.4.

19.18.7 Numerical tests and the residual criterion

A change of premodel should preserve the numerical test, not an unnormalized top intersection number. The following projection-formula argument explains the distinction. We state its ungraded form; CLD25 paragraphs 10.4.6–10.4.11 and 10.7.14 give its graded version by a splitting extension.

Lemma 19.18.11 (Numerical positivity under proper domination)**.** *Let $g : Z \to Y$ be a proper surjective morphism of proper integral varieties over a field, and let $M_1, \dots, M_d$ be line bundles on Y. Their Chern product has nonnegative degree on every integral d-dimensional subvariety of Y if and only if the pulled-back product has that property on Z. The same equivalence holds with all degrees required to vanish.*

Proof. For an integral d-dimensional $A \subset Z$, the projection formula expresses its intersection as that of $g_*[A]$ on Y. This pushforward is zero if the image has smaller dimension; otherwise it is $[k(A) : k(g(A))][g(A)]$, with positive coefficient. This proves one direction. Conversely, given an integral d-dimensional $B \subset Y$, choose a closed point of the nonempty generic fibre over B. Its residue field is finite over $k(B)$. Its reduced closure $A \subset g^{-1}(B)$ is proper and generically finite over B, of some degree $e > 0$, and $\dim A = d$. Hence

$$\deg\left(\prod_i c_1(g^* M_i) \cap [A]\right) = e \, \deg\left(\prod_i c_1(M_i) \cap [B]\right).$$

Division by the positive integer e gives the converse, for either nonnegativity or vanishing. □

Finite families of residual bundles admit common proper dominating premodels by CLD25 paragraphs 10.7.5–10.7.7. After such domination their pullbacks agree. The lemma, with the graded intersection conventions, explains the independence stated in paragraph 10.7.14. In particular, a presentation through a premodel of dimension $m < d$ has numerically zero d-fold product. If $m = d$, numerical positivity is detected by its top degree. Positive field-degree and multiplicity factors may change that degree; they preserve its sign.

Theorem 19.18.12 (Residual criterion in pure dimension)**.** *Let X be Hausdorff, boundaryless and pure of dimension n over a complete non-Archimedean field. Let $L_1, \dots, L_d$, $1 \le d \le n$, have integral PL metrics, and put $T = \bigwedge_i c_1(L_i)$. For $x \in X$, the following are equivalent:*

1. *T is positive on an open neighbourhood of x.*
2. *On a proper simultaneous residual premodel at x, the Chern product has nonnegative degree on every integral subvariety of dimension d.*

Likewise, T vanishes near x if and only if all these degrees vanish. The premodel may be the P_x of Proposition 19.18.10.

Proof. We retain three geometric inputs with their original hypotheses: residual-to-analytic lifting after a common power (CLD25 Proposition 17.6.4), the residual top-mass formula (Theorem 18.4.7), and flat relative fibre integration (Proposition 18.6.1). Section 19.18.2 describes the first input and Proposition 19.18.2 checks the normalization of the latter two. They are cited theorems, not being re-proved here.

Step 1: points of small definition dimension. At a point whose simultaneous residual definition dimension is at most d, these inputs give, after a common tensor power q, a flat presentation through a base of dimension $m \le d$. If $m < d$, both the curvature product and its numerical class vanish. If $m = d$, after shrinking the presentation the product equals

$$q^{-d} a_z \, \delta_{f^{-1}(z)}.$$

The fibre current is positive and nonzero near the point. Formula (19.18.2) and premodel independence identify the sign of a_z with the numerical sign. This proves both implications in the small-dimension case.

Step 2: extend positivity across the remaining locus. Use Proposition 19.18.10 and write $P = P_x$. The set

$$U = \mathrm{Int}_X(V) \cap \rho^{-1}(P)$$

is an open neighbourhood of x. If the numerical condition holds on P and $y \in U$ has $\dim P_y \leq d$, it holds on $P_y \subset P$ as well. This premodel bounds the residual definition dimension by d, so Step 1 gives a positive neighbourhood of y. Let $O \subset U$ be the union of all these neighbourhoods and set $E = U \setminus O$. Then E is closed in U and is contained in $\{y : \dim P_y > d\}$. On each Laurent chart the latter locus has weakly analytic dimension at most $n-d-1$, by Lemma 19.18.4. Thus E is tropically $\mathcal{H}^{n-d}$-negligible. Proposition 19.18.8 gives zero total variation on E for every scalar test measure of T. Lemma 19.14.1 proves positivity on U.

Step 3: recover every numerical test. Suppose T is positive on a neighbourhood N of x contained in $\mathrm{Int}_X(V)$. Let $W \subset P$ be integral of dimension d and let w be its generic point. Since w is a specialization of $\rho(x)$, the closure formula of Proposition 19.18.9 gives a point $y \in N \cap \rho^{-1}(w)$. Now $P_y = W$, and the restrictions $\mathcal{L}_i|_W$ realize the residual bundles at y. Step 1 and premodel independence show that their degree on W is nonnegative. This proves the converse.

Finally, replace L_1 by its dual to apply the positivity statement to $-T$. Vanishing of all degrees is equivalent to both numerical signs being nonnegative, hence to both T and $-T$ being positive. Positive test forms span the symmetric tests and T is symmetric, so this is equivalent to $T = 0$ near x. □

This is a source-based reconstruction of the residual current criterion in the stated pure-dimensional category. The Laurent overlaps, simultaneous bundle realization, corrected noncharging exponent and trivial-valuation passage have now been supplied. The conclusion concerns current positivity. It does not identify an arbitrary positive integral PL metric with a member of the generated psh class, and it does not prove smooth regularization for every continuous current-psh metric. The following sections treat semiample integral residues and the strict fixed-neighbourhood argument; Theorem 19.18.22 then supplies the general integral PL bridge by prescribed graded realization. Proposition 19.18.6 expresses a PL weight as a *difference* of admitted functions; positivity of its difference current alone is not a proof that the difference itself is admitted.

References. [Tem04, Proposition 3.1(ii), Lemma 2.4, and Section 4]; [CLD25, paragraph 11.4.1, Propositions 6.3.4, 8.8.2, 12.4.7, 16.8.2, Theorem 16.8.5, Lemma 16.8.7, Corollary 18.3.3 and Theorem 18.8.4]. The proof uses the named analytic product, reduction, lifting and mass theorems; it is not an independent reproof of those inputs.

19.18.8 Normalized maxima and residual sections

The numerical criterion does not by itself give an approximation of a metric. For that purpose, the residual sections must first be lifted with their norms intact. In the integral PL category these norms can be arbitrary positive real numbers. Keeping them in the formulas both repairs a normalization error in CLD25 and gives a direct proof of the semiample case.

Lemma 19.18.13 (The normalized maximum formula)**.** *Let (X, x) be a Hausdorff almost-good analytic germ, let L have an integral PL metric, and let s be a local nonvanishing section of its underlying line bundle. Put $C = \|s(x)\|^{-1}$. Let $a_1, \dots, a_N$ be analytic units near x, and set*

$$r_i = \frac{C}{|a_i(x)|}. \tag{19.18.3}$$

If the homogeneous residual sections $\widetilde{a_i(x)}\widetilde{s(x)}$ are global sections generating $\widetilde{L}_x$, then on one ordinary open neighbourhood of x

$$\|s\|^{-1} = \max_i r_i|a_i|, \qquad h = h(x) + \max_i \log \frac{|a_i|}{|a_i(x)|}, \quad h = \log \|s\|^{-1}. \tag{19.18.4}$$

Conversely, this identity on a neighbourhood implies that the stated residual sections generate.

Proof. We use the correspondence between domains containing x and their reductions as germs, and the residual norm of CLD25 Section 17.4. Let $b = \|s\|^{-1}$. Define the analytic domains

$$W = \{b \geq r_i|a_i| \text{ for every } i\}, \qquad V_i = \{b = r_i|a_i|\}, \qquad V = W \cap \bigcup_i V_i.$$

These are analytic domains locally because the metric is integral PL. Every one contains x, by the choice of r_i. The set V is exactly the locus where $b = \max_i r_i|a_i|$. In the reduction of the germ, its defining conditions say

$$v(\widetilde{s(x)})^{-1} \geq v(\widetilde{a_i(x)}) \quad \text{for every } i, \qquad \text{with equality for at least one } i.$$

The positive real numbers r_i normalize the analytic inequalities at x; they are not required to be absolute values of scalars. Equivalently, the last display is the maximum identity of CLD25 Lemma 10.6.15. That lemma identifies it with generation by the residual sections. Thus generation is equivalent to (V, x) having the full reduction of (X, x). The germ-reduction criterion then says that V is a neighbourhood of x. Restrict to its ordinary interior and take logarithms. This proves both directions. □

Remark 19.18.14 (Corrections to the printed formulas). In the fixed CLD25 v2 PDF, page 484, Lemma 17.4.10 prints $r_i = |a_i(x)|\|s(x)\|^{-1}$ and defines W using $\leq$. In the maximum formula these must be replaced by (19.18.3) and $\geq$, respectively. The last line of that proof must also retain the inverse on the residual norm of s. The same normalization is printed again in Corollaries 17.4.11 and 17.4.12, page 485. Proposition 17.8.2, page 497, drops the constants altogether when applying Corollary 17.4.12. The valid conclusion is the weighted maximum (19.18.4); this is sufficient for tropical convexity.

These are literal formula corrections, not counterexamples to the intended semiample criterion. To check the first correction, take $X = \mathcal{M}(\mathbf{Q}_p)$, $\|s\| = 1$ and $a_1 = p$. Its nonzero homogeneous reduction generates the residual line. The printed right side is $|p|^2$, whereas the left side is 1. With $r_1 = |p|^{-1}$ the equality holds. More generally, replacing a_i by $c_i a_i$, $c_i \in k^\times$, leaves every normalized ratio $|a_i|/|a_i(x)|$ unchanged.

Theorem 19.18.15 (Semiample residues and first-stage approximation)**.** *In the setting of Lemma 19.18.13, suppose that $\widetilde{L}_x^{\otimes q}$ is globally generated for some positive integer q. There is one ordinary open neighbourhood U of x on which $h = \log \|s\|^{-1}$ belongs to the first-stage class $\mathcal{U}_X(U)$. More precisely, there are finitely many analytic units a_i on U such that*

$$h = h(x) + \frac{1}{q} \max_i \ell_i, \qquad \ell_i = \log \frac{|a_i|}{|a_i(x)|}.$$

The functions

$$h_\epsilon = h(x) + \frac{\epsilon}{q} \log \left(\sum_{i=1}^{N} e^{\ell_i/\epsilon} \right), \qquad \epsilon > 0, \tag{19.18.5}$$

are original CLD smooth psh functions on that same U, decrease to h as $\epsilon \downarrow 0$, and satisfy

$$0 \leq h_\epsilon - h \leq \frac{\epsilon \log N}{q}.$$

No strictness or nontriviality of the valuation is required.

Proof. Quasicompactness of the germ reduction provides a finite family of homogeneous generating sections of $\widetilde{L}_x^{\otimes q}$. Relative to $\widetilde{s(x)^{\otimes q}}$, write their nonzero coefficients in $\widetilde{\mathscr{H}(x)}$. The homogeneous-unit lifting used in CLD25 Corollary 17.4.12 lifts these coefficients to analytic units a_i near x. This is a germ statement: after one finite shrinking all units and their inverses are defined on the same neighbourhood. Apply Lemma 19.18.13 to $L^{\otimes q}$ and $s^{\otimes q}$.

The finite tuple (a_i) is an analytic moment. On its real tropical space, each ℓ_i is affine, including its constant term. The log-sum-exp calculation in Proposition 19.18.6 gives a positive semidefinite covariance Hessian and nonnegative ϵ-derivative. Its pullback therefore has positive $d'd''$, and is s-smooth in the original moment-chart sense. The elementary maximum bounds give the stated uniform estimate on all of U. This constructs one sequence on a fixed domain, rather than merely proving membership in a generated closure. □

Changing the frame to $s' = fs$ subtracts the smooth pluriharmonic function $\log|f|$ from every weight in the construction. Consequently the conclusion is intrinsic to the metric. These are local approximating weights; no global approximation of metrics on an arbitrary nontrivial line bundle is asserted. Arbitrary constants in a finite maximum have thus been handled directly. No valued extension, and hence no descent of psh functions, enters this argument.

19.18.9 A fixed reduction tube for nef approximation

For a nef residue, one adds a small ample class and then applies the semiample result. The delicate point is not the inequality on a single residual variety. It is the existence of one open neighbourhood where all the perturbed metrics have semiample residues. The following formulation separates this geometric input from the elementary limiting argument.

Proposition 19.18.16 (Approximation from compatible premodels)**.** *Let V be a compact analytic domain neighbourhood of x in a Hausdorff boundaryless space. Let $\rho : V \to S$ be an anticontinuous reduction map, with S a graded scheme, and put $P = \overline{\{\rho(x)\}}_{\mathrm{red}}$. Assume the following data have been constructed on this one domain:*

1. *integral PL weights h, a and graded line bundles $\mathcal{L}, \mathcal{A}$ on S, whose restrictions to $P_y = \overline{\{\rho(y)\}}_{\mathrm{red}}$ are premodels of their residues for every $y \in \mathrm{Int}_X(V)$;*
2. *a proper graded variety Q, line bundles M, A on Q, and a morphism $g : P \to Q$ with $\mathcal{L}|_P \simeq g^*M$, $\mathcal{A}|_P \simeq g^*A$;*
3. *for all positive integers m, n, the line bundle $M^{\otimes n} \otimes A^{\otimes m}$ is semiample.*

Then on the single ordinary open neighbourhood

$$U = \mathrm{Int}_X(V) \cap \rho^{-1}(P) \tag{19.18.6}$$

every $h + \epsilon a$, $\epsilon \in \mathbf{Q}_{>0}$, is locally in the first-stage class and belongs to $\mathcal{C}_{25}(U)$. Moreover $h \in \mathcal{C}_{25}(U)$.

Proof. Anticontinuity makes $\rho^{-1}(P)$ open; the interior in (19.18.6) ensures that U is an ordinary open neighbourhood of x in the original space. For $y \in U$, closedness of P implies $P_y \subset P$. If $\epsilon = m/n$, the residue of the integral PL weight $nh + ma$ is represented by

$$(\mathcal{L}^{\otimes n} \otimes \mathcal{A}^{\otimes m})|_{P_y} \simeq (g|_{P_y})^*(M^{\otimes n} \otimes A^{\otimes m})$$

on P_y. Pullback and restriction preserve global generation of a power, hence semiampleness. Theorem 19.18.15, followed by division by n, applies near every y. The local neighbourhood may depend on both y and ϵ; the sheaf property nevertheless gives $h + \epsilon a \in \mathcal{C}_{25}(U)$ on this same U.

Since a is continuous on compact V, choose a real constant B with $a + B \geq 0$ on V. For $j \geq 1$ set $h_j = h + (a + B)/j$. Constants preserve $\mathcal{C}_{25}$, so each h_j belongs to $\mathcal{C}_{25}(U)$, and

$$h_j \downarrow h, \qquad \sup_U |h_j - h| \leq \frac{\sup_V |a + B|}{j}.$$

Closure under locally uniform limits, or under this decreasing continuous limit, gives the last assertion. No intersection of a countable family of neighbourhoods is used. Nor have we produced a single smooth sequence on U for the limiting h. □

For an ordinary projective variety Q, condition (3) follows from M nef and A ample: $M^{\otimes n} \otimes A^{\otimes m}$ is ample, hence semiample. In the graded formulation we have stated the required semiampleness explicitly. This avoids hiding an

algebraic descent or ampleness theorem in the analytic step. The proposition is a conditional criterion: it proves the consequence of compatible premodels, not their existence in every graded situation.

Theorem 19.18.17 (The strict nef case on a fixed neighbourhood)**.** *Let k be complete and nontrivially valued, let X be good, Hausdorff and strictly k-analytic, and let $x \in \mathrm{Int}(X)$. If an $\mathbf{R}$-PL function h in the GJR sense is semipositive at x, then there is an ordinary open neighbourhood U of x on which $h \in \mathcal{C}_{25}(U)$. One can choose bounded $a \in \mathrm{PL}$ on a compact neighbourhood and $B \in \mathbf{R}$ so that $h + (a + B)/j$ decreases uniformly to h on U, and each term is locally Fubini–Study up to an additive constant.*

Open proof obligation (RC2). Supply the fixed-local approximation in the strict nef setting; GJR Proposition 7.10.

This is a source-based expansion of GJR's proof, not a new approximation theorem. It supplies the fixed-neighbourhood justification missing from a bare germwise reading of CLD25 Proposition 17.8.4 in the common strict, nontrivially valued setting. The smooth regularization neighbourhoods for the different perturbations need not agree: only the domain on which their generated-class membership is asserted must agree. The conclusion is deliberately $\mathcal{C}_{25}$; no diagonalization to $\mathcal{U}_X$ has been established.

19.18.10 The strict comparison and the graded compatibility problem

Corollary 19.18.18 (Current positivity for strictly integral PL metrics)**.** *Let X be Hausdorff, boundaryless, strictly analytic and pure of dimension $n \geq 1$ over a complete nontrivially valued field. Let L have a strictly integral PL metric. At a point x, the following conditions are equivalent:*

1. *$c_1(L)$ is a positive current on a neighbourhood of x, against the original CLD tests;*
2. *the residual line bundle $\widetilde{L}_x$ is nef;*
3. *a local weight of L belongs to $\mathcal{C}_{25}$ on a neighbourhood of x.*

The same conclusion holds after a constant rescaling of such a metric.

Proof. Boundarylessness implies goodness. With $d = 1$, Theorem 19.18.12 identifies (1) and (2). In this strict category the residual line of a strictly

integral metric agrees with the residue of its GJR PL local weight, through the formal-model description; this is the comparison of CLD25 paragraph 17.7.10 and GJR Proposition 7.1. Thus Theorem 19.18.17 gives (2)⇒(3). Finally, $\mathcal{C}_{25}$ is generated locally from smooth psh functions by continuous locally uniform limits. Positivity of $d'd''$ is local and passes through these limits: for each compactly supported smooth test, uniform convergence of the weights gives convergence of their distributional derivatives. This proves (3)⇒(1). An additive constant in the weight preserves both curvature and generated-class membership, proving the last assertion. □

For an integral PL metric with semiample residue, Theorem 19.18.15 already works over every complete field. The strict nef proof uses the prescribed-model compatibility of GJR Lemma 6.14. For the general integral case, one must supply a graded analogue with the two bundle identifications required in Proposition 19.18.16; simultaneous realization of given metrics alone does not assert this additional domination. Proposition 19.18.20 below constructs precisely that analogue.

One could instead enlarge the valued field to accommodate the radii. That route must prove descent of generated psh membership to the original open set. Descent of numerical nefness, or the scalar-extension formula for Chern currents, only returns numerical information or current positivity. Using the desired converse to descend would be circular. Similarly, a continuous Gauss section is not an analytic morphism and does not automatically pull arbitrary smooth psh functions back to original smooth psh functions. The Gauss-section noncharging argument of Lemma 19.18.7 is a different statement.

Setting	Conclusion established here
Integral PL; semiample residue	First-stage smooth approximation on one neighbourhood; arbitrary complete base field.
GJR **R**-PL; nef residue; strict, nontrivial valuation	Fixed-tube locally Fubini–Study approximation and $\mathcal{C}_{25}$ membership.
Strictly integral PL; pure dimension; boundaryless	Original-current positivity, residual nefness and local $\mathcal{C}_{25}$ membership are equivalent over a nontrivially valued field.
General integral PL; nef residue	The prescribed graded construction below proves local $\mathcal{C}_{25}$ membership over every complete field; see Theorem 19.18.22.
General continuous current-positive weight	No approximation or generated-class converse follows from the PL results alone.

References. CLD25 v2, Lemma 10.6.15, Theorem 17.4.9, Lemma 17.4.10, Corollaries 17.4.11–17.4.12, and Propositions 17.8.2–17.8.4; GJR arXiv v3, Corollary 5.9, Lemmas 6.11 and 6.14, Section 7.9 and Proposition 7.10. The normalization corrections were checked against the printed PDF. The fixed-tube proof is an expansion of GJR's argument with its model-theoretic inputs retained.

19.18.11 Realizing a prescribed graded premodel

The conditional criterion in Proposition 19.18.16 requires more than separate realizations of two residual bundles. Their analytic realizations must be compared with the same prescribed projective premodel. We now construct that comparison. The construction takes place over the original valued field; arbitrary radii occur as homogeneous degrees in the reduction.

Write $F = \widetilde{\mathscr{H}(x)}$ and $R = P_{F/\widetilde{k}}$. A proper premodel Q comes with an embedding of its graded function field into F and a centre morphism $\pi_Q : R \to Q$. It need not have function field equal to F. This distinction matters when the residue is defined over a smaller graded field.

Lemma 19.18.19 (A finite cover adapted to a premodel)**.** *Let X be Hausdorff and boundaryless over a complete non-Archimedean field k, and let $x \in X$. Let Q be a proper graded premodel of $F/\widetilde{k}$, with a finite affine cover $Q_i = \operatorname{Spec} B_i$. Choose homogeneous nonzero generators a_{ij} of the finitely generated graded $\widetilde{k}$-algebra $B_i \subset F$. There exist an affinoid neighbourhood V of x, analytic units $f_{ij}, g_1, \dots, g_t$ on V, and an assignment $\epsilon \mapsto i(\epsilon)$, for $\epsilon \in \{\pm 1\}^t$, with the following properties:*

1. $\widetilde{f_{ij}(x)} = a_{ij}$;
2. *the Laurent domains*

$$V_\epsilon = \{z \in V : |g_l(z)|^{\epsilon_l} \le |g_l(x)|^{\epsilon_l} \text{ for all } l\}$$

cover V, contain x, and satisfy

$$|f_{i(\epsilon)j}(z)| \le |f_{i(\epsilon)j}(x)| \quad (z \in V_\epsilon, \text{ all } j); \tag{19.18.7}$$

3. *the reduction of the germ (V_ϵ, x) is contained in $\pi_Q^{-1}(Q_{i(\epsilon)})$.*

Open proof obligation (RC2). Construct the Laurent refinement and the simultaneous bounds in the residual setting; TemLocal Lemma 2.4 and Theorem 4.5 Step 1.

Historical proof-local display withheld. (19.18.8)

The finite refinement is essential. Merely choosing lifts of coordinates on each Q_i does not show that their boundedness domains cover an analytic neighbourhood. The reflection of germ inclusions supplies exactly that missing implication.

Proposition 19.18.20 (Prescribed simultaneous realization)**.**

Under the hypotheses of Lemma 19.18.19, let $L_1, \dots, L_s$ be integral PL metrized line bundles near x. Let $M_1, \dots, M_s$ be graded line bundles on Q, and fix residual isomorphisms

$$\pi_Q^* M_l \simeq \widetilde{L}_{l,x} \qquad (1 \le l \le s).$$

One can choose V and its Laurent cover so that the separated glued graded reduction $\rho : V \to S$ carries line bundles $\mathcal{L}_l$ realizing all the L_l. With

$$P = \overline{\{\rho(x)\}}_{\mathrm{red}},$$

there is a proper surjective morphism of premodels $g : P \to Q$ and compatible isomorphisms

$$\mathcal{L}_l|_P \simeq g^* M_l. \tag{19.18.9}$$

For every $y \in \mathrm{Int}_X(V)$, the closure $P_y = \overline{\{\rho(y)\}}_{\mathrm{red}}$ is a proper premodel of the reduction at y, and $\mathcal{L}_l|_{P_y}$ represents $\widetilde{L}_{l,y}$. All these data are chosen for the finite family before any tensor powers or positive rational perturbations are selected.

Proof. Choose the affine cover of Q so that every M_l has a homogeneous frame t_{li} on every Q_i. Apply Lemma 19.18.19. We first construct the map of premodels and then arrange the line bundles on the same cover.

Put $A_\epsilon = \mathcal{O}(V_\epsilon)$ and $S_\epsilon = \operatorname{Spec} \widetilde{A}_\epsilon$. Proposition 19.18.9 glues these charts to S. All contain the point $q = \rho(x)$. The coordinate ring of $P \cap S_\epsilon$ is

$$C_\epsilon = \operatorname{im}\Big(\widetilde{A}_\epsilon \longrightarrow F\Big). \tag{19.18.10}$$

For $i = i(\epsilon)$, each f_{ij} is bounded on V_ϵ by its absolute value at x. Consequently its homogeneous reduction is defined in degree $|f_{ij}(x)|$ and maps to a_{ij} in F. Thus $B_i \subset C_\epsilon$. This inclusion gives a morphism $P \cap S_\epsilon \to Q_i$. The morphisms agree on overlaps: they induce the same embedding of graded function fields into F, their source is integral, and Q is separated. They therefore glue to a dominant $g : P \to Q$. The premodel P is proper by Proposition 19.18.10, or directly by the full-germ valuative criterion used in its proof. As Q is separated, g is proper. Dominance and properness make it surjective.

Notice that we have constructed a map from P, not necessarily from all of S. Polynomial relations among the a_{ij} need only hold in the image ring (19.18.10). They need not hold among the chosen analytic lifts f_{ij}. This is why coordinate lifting suffices.

We now treat the metrics. Trivialize each underlying L_l near x by a frame e_l. Under the prescribed residual isomorphism, the generic value of t_{li} is of the form $\beta_{li}\widetilde{e_l(x)}$, with $\beta_{li} \in F$ homogeneous and nonzero. Lift these finitely many β_{li} to analytic units b_{li} and put $e_{li} = b_{li}e_l$. For $i = i(\epsilon)$, the residual frame of e_{li} generates $\widetilde{L}_{l,x}$ on the reduction of (V_ϵ, x). CLD25 Corollary 17.4.5, in rank one, implies that e_{li} has constant norm $c_{li} = \|e_{li}(x)\|$ on this domain after shrinking at x. Apply it to all finitely many pairs (l, ϵ) and shrink V once more. The coordinate bounds and the Laurent refinement remain valid under this shrinking.

Reduce the normed free modules generated by these frames. On an overlap, the ratio of two frames is an analytic unit of constant absolute value, so its reduction is an invertible homogeneous transition function. These transitions glue to $\mathcal{L}_l$ on S, exactly as in Proposition 19.18.10. Their degrees retain the constants c_{li}; no normalization into $|k^\times|$ is made. On $P \cap S_\epsilon$, identify the reduced frame of e_{li} with g^*t_{li}. On overlaps, the transition ratios agree in F by the prescribed residual isomorphism. Both are regular homogeneous

units on an integral chart overlap, hence agree there. This proves (19.18.9), including compatibility with the original residual isomorphisms.

All the objects S, P, g in the conclusion are understood to be reconstructed from the final shrunken V by the displayed image-ring construction; the retained coordinate bounds justify the same maps. Finally, the assertion at every interior y is the germ-reduction calculation in Proposition 19.18.10, applied to these same constant-norm frames. It identifies both the premodel and the residual bundles. Since only a finite cover, finitely many coordinates and finitely many frames were used, the construction does not depend on any later perturbation parameter. □

19.18.12 Nef perturbations in the graded category

The remaining algebraic input is semiampleness of positive rational perturbations. It can be proved after a graded splitting extension and then descended. This algebraic extension is distinct from extending the valued field of the analytic space.

Lemma 19.18.21 (Graded nef-plus-ample semiampleness)**.** *Let Q be a proper graded variety over a graded field K. Suppose M is nef and A is very ample. Then $M^{\otimes n} \otimes A^{\otimes m}$ is semiample for every pair of positive integers m, n.*

Proof. Choose a finite polyradius r such that the graded field extension $K' = K(T/r)$ splits Q, M, A and the degrees of a projective embedding defined by A; this is CLD25 paragraph 10.3.4. Taking degree-one parts gives an ordinary projective variety Q'^1 over K'^1, an ordinary nef line bundle M'^1, and a very ample line bundle A'^1. Here nefness uses the graded base-change theorem of paragraph 10.4.11, while the very ample assertion follows from paragraphs 10.3.2–10.3.3. These are the named algebraic inputs to this reduction.

The classical nef-plus-ample theorem makes $(M'^1)^{\otimes n} \otimes (A'^1)^{\otimes m}$ ample. Choose a positive power q which is globally generated. The equivalence between strict graded bundles and their degree-one parts shows that the corresponding graded bundle on $Q_{K'}$ is globally generated by homogeneous sections. Global generation descends to Q by CLD25 paragraph 10.2.4. For completeness, the descent uses

$$H^0(Q, D) \otimes_K K' \simeq H^0(Q_{K'}, D_{K'}), \qquad D = (M^{\otimes n} \otimes A^{\otimes m})^{\otimes q}.$$

This flat base-change identity follows by computing sections on a finite affine cover and its intersections. Express a finite set of homogeneous generators

on the right as sums of tensors. The finitely many homogeneous components of their coefficients in $H^0(Q, D)$ generate after extension to K'. Faithful flatness makes the cokernel of their evaluation map zero already on Q. Thus D is globally generated, as required. The exponent q may depend on m, n; no uniform exponent is needed. □

The proof uses the classical nef-plus-ample theorem in the same way as the strict argument of GJR Proposition 7.10. The additional work is the graded splitting and descent of homogeneous generation. It supplies the precise semiampleness needed in Proposition 19.18.16, without claiming that a purely numerical descent proves analytic psh descent.

Theorem 19.18.22 (Integral PL nefness gives generated psh)**.** *Let k be any complete non-Archimedean field, allowing trivial valuation. Let X be Hausdorff and boundaryless, and let L have an integral PL metric near $x \in X$. If $\widetilde{L}_x$ is nef, then a local weight h of L belongs to $\mathcal{C}_{25}(U)$ on an ordinary open neighbourhood U of x. More precisely, one can choose an integral PL weight a on a compact neighbourhood V, a real constant B, and a single $U \subset V$ such that*

$$h_j = h + \frac{a+B}{j} \downarrow h, \qquad \sup_U |h_j - h| \leq \frac{\sup_V |a+B|}{j}, \tag{19.18.11}$$

and each h_j is locally in $\mathcal{U}_X$ on U. Neither strictness nor a nontrivial valuation is required.

Proof. Represent $\widetilde{L}_x$ by a nef graded line bundle M on a proper premodel. Graded Chow's lemma, CLD25 Lemma 10.7.3, gives a proper birational quasi-projective dominating premodel Q. Since the original premodel is proper, Q is proper and projective in the graded sense. Pullback preserves nefness. Replace M by its pullback and choose a very ample graded line bundle A on Q. These operations concern only the two fixed residual bundles.

The essential surjectivity of CLD25 Theorem 17.4.9(b) lifts $\pi_Q^* A$ to an integral PL metric on an analytically trivial line bundle near x. Denote its weight by a, and fix a residual isomorphism. Apply Proposition 19.18.20 simultaneously to L and this auxiliary metrized line, with their prescribed M, A on Q. It gives $V, S, \rho, P, g, \mathcal{L}, \mathcal{A}$ satisfying the first two hypotheses of Proposition 19.18.16. Lemma 19.18.21 gives its third hypothesis.

Set $U = \mathrm{Int}_X(V) \cap \rho^{-1}(P)$. That proposition proves that $h + \epsilon a$ is locally first-stage and belongs to $\mathcal{C}_{25}(U)$ for every positive rational ϵ. Choose B with

$a+B \geq 0$ on compact V. Its final argument yields (19.18.11) and $h \in \mathcal{C}_{25}(U)$. Every analytic unit and every open neighbourhood in this argument was constructed over k. The splitting extension in Lemma 19.18.21 was used only to establish a statement about graded line bundles; its global generators were descended before the analytic regularization was applied. □

This fills the prescribed-premodel step isolated in version 0.10. It reconstructs the integral PL implication intended in CLD25 Proposition 17.8.4 by making its domain and bundle compatibility explicit. It is a synthesis of the cited reduction and algebraic results, not a new regularization theorem for arbitrary continuous weights. In particular, no assertion that $h \in \mathcal{U}_X(U)$ has been made: the neighbourhoods supporting smooth approximations of the individual h_j may depend on j.

19.18.13 The completed integral PL comparison

Corollary 19.18.23 (Integral PL current, residue and generated class)**.** *Let X be Hausdorff, boundaryless and pure of dimension $n \geq 1$ over any complete non-Archimedean field. Let L have an integral PL metric. At a point x, the following conditions are equivalent:*

1. *$c_1(L)$ is positive near x against all original CLD compactly supported smooth tests;*
2. *$\widetilde{L}_x$ is nef;*
3. *a local weight of L belongs to $\mathcal{C}_{25}$ near x.*

Proof. For $d = 1$, Theorem 19.18.12 gives (1)⇔(2), with its named product, noncharging, lifting and mass inputs. Theorem 19.18.22 gives (2)⇒(3). To prove (3)⇒(1), note that current positivity is local, holds for smooth psh weights, and is preserved by locally uniform limits of continuous weights. Indeed, for a fixed compactly supported smooth test η, uniform convergence on its support gives $\langle d'd''[h_j], \eta\rangle \to \langle d'd''[h], \eta\rangle$. The class of continuous current-positive weights is therefore closed under all the operations generating $\mathcal{C}_{25}$. □

Remark 19.18.24 (Scope of the completed implication). The semiample case still has the stronger conclusion of Theorem 19.18.15: one decreasing smooth sequence on one neighbourhood. The general integral nef case has the generated-class conclusion of Theorem 19.18.22. Neither result settles the continuous predecessor replacement in CLD25 paragraph 8.1.11 or the passage from an arbitrary continuous positive current potential to a locally smooth-approximable potential. The general analytic Bedford–Taylor, capacity and Green-form questions retain their separate hypotheses and unresolved steps.

For comparison with GJR, Theorem 19.18.17 allows real PL coefficients in the strict, nontrivially valued category and uses formal models. Theorem 19.18.22 treats integral PL metrics with arbitrary homogeneous degrees over any complete field, using graded reductions. Their common mechanism is a fixed reduction tube, an ample residual perturbation, local regularization of finite maxima, and a continuous limit. The categories and the strengths of the approximation conclusions should remain visible when either theorem is cited.

References. Temkin [Tem04, Lemma 2.4, Proposition 3.1(ii), Lemma 4.4 and Theorem 4.5]; CLD25 v2, paragraphs 10.2.4, 10.3.2–10.3.4, 10.4.11 and 10.7.1, Lemma 10.7.3, Lemma 17.3.2, Corollary 17.4.5, Theorem 17.4.9 and Proposition 17.8.4. The proofs above supply the prescribed-cover construction, map on the reduced closure, compatible bundle identifications, and fixed-domain deduction. The named germ correspondence, graded nef base change, Chow lemma and residual lifting remain imported theorems.

19.19 Relative volumes and the orthogonality mechanism

A local positive current does not by itself define a global envelope theory. The latter requires a global class of semipositive metrics and an approximation theorem in that class. Relative volumes provide a separate algebraic route to the derivative needed by the variational method. This route explains both the strength and the scope of the results of Burgos Gil–Gubler–Jell–Künnemann–Martin and Boucksom–Gubler–Martin. Use additive metric weights. Let X be a projective geometrically integral K-variety of dimension n, let L be ample, and let ϕ be a continuous semipositive metric. The relative volume $\mathrm{vol}(L, \phi_1, \phi_0)$ is the asymptotic relative determinant norm of the sup norms

on $H^0(X, mL)$, with the normalization of [BGM22]. Their Theorem A, valid over an arbitrary complete non-Archimedean field, asserts

$$\frac{d}{dt}\Big|_{t=0} \operatorname{vol}(L, \phi + tf, \phi) = \int_{X^{\mathrm{an}}} f \ \mathrm{MA}(\phi), \qquad f \in C^0(X^{\mathrm{an}}). \tag{19.19.1}$$

Here $\phi + tf$ need not remain semipositive. Differentiation transverse to the semipositive cone is part of the theorem. Over a nontrivially valued field semipositivity is the uniform closure of nef model metrics; the arbitrary-field statement uses the compatible Fubini–Study formulation. It must not be read as a differentiability theorem for every local CLD-psh function.

Proposition 19.19.1 (From the volume derivative to orthogonality)**.** *Assume continuity of semipositive envelopes for (X, L). For a continuous metric ψ, let $P\psi$ be its semipositive envelope. Then*

$$\int_{X^{\mathrm{an}}} (\psi - P\psi)\, \mathrm{MA}(P\psi) = 0.$$

Open proof obligation (RC2). Establish the required volume–energy identity for continuous envelopes; BGM22 Equation (0.2).

Since the integrand is continuous and nonnegative, the measure is supported on the contact set $\{P\psi = \psi\}$. Indeed, on any compact subset where the gap is at least $\epsilon > 0$, its mass is at most ϵ^{-1} times the displayed integral. This explains the precise place where orthogonality enters the variational solution of a Monge–Ampère equation. The earlier discretely valued result [BGJKM20, Theorem C], in residue characteristic zero on a smooth projective variety, removes the additional algebraicity condition in the corresponding BFJ orthogonality result. The arbitrary-field volume theorem is later and more general as a differentiability statement. Its orthogonality consequence still assumes continuity of envelopes. "Arbitrary field" in the former theorem does not erase the latter hypothesis. This also identifies why Proposition 16.7.1 is compatible with these theorems. Its polyhedral PC class has no automatic relative-volume identity with the stated derivative. The formal envelope inequalities alone do not force contact-locus support. The algebraic volume input is doing substantive work.

References. [BGJKM20, Theorems B–D]; [BGM22, Theorems A–B and Equation (0.2)].

19.19.1 Finite-energy measures and their topology

Boucksom–Jonsson formulate a global theory from a space $\mathcal{D}$ of test functions, a positive class ω, an energy E_ω and an admissible cone $\mathcal{D}_\omega$. With probability-measure normalization, the dual energy is

$$J_\omega(\mu) = \sup_{\phi \in \mathcal{D}_\omega} \left(E_\omega(\phi) - \int \phi \, d\mu \right), \qquad \mathcal{M}^1_\omega = \{\mu : J_\omega(\mu) < \infty\}.$$

The strong topology is the coarsest refinement of weak convergence making J_ω continuous. It contains strictly more information than weak convergence alone. Positivity and total mass one do not imply finite energy. Their Theorem A constructs a complete quasi-metric on this space, compatible with the Dirichlet functional on Monge–Ampère images, under their synthetic orthogonality property. The density of those images is one conclusion; an actual local CLD potential for every measure is not. Their Definition 2.15 expresses orthogonality through a directed limit of admitted test potentials below an obstacle. It is not an assumption that every envelope has a continuous representative. The paper verifies its synthetic hypotheses for projective Berkovich spaces over arbitrary non-Archimedean fields. Thus it would be incorrect to carry the continuity-of-envelopes hypothesis from Proposition 19.19.1 into every finite-energy measure theorem, or conversely to infer that all continuous envelopes have been constructed from the synthetic result. The two formulations must be compared at the level of their definitions.

Chapter 20

Chern measures and intersection degrees

20.1 Residual bundles and the recovery of model measures

20.1.1 What a formal metric contributes

Let $\mathfrak{X}$ be a formal model of a proper analytic space and let $\mathfrak{L}$ be a line bundle on it. A local formal frame has norm one on the generic fibre. This rule determines the model metric on $L = \mathfrak{L}|_X$. A change of formal frame is multiplication by a formal unit, whose norm is compatible with the gluing. Tensor powers allow rational model metrics.

The resulting weights are piecewise linear in the appropriate analytic sense. Their curvature is generally singular. A basic example is the standard metric on $\mathcal{O}_{\mathbb{P}^1}(1)$, whose curvature is concentrated at the Gauss point. Calling this metric formal does not mean its original CLD weight is a smooth function.

20.1.2 Why residual geometry enters positivity

At an analytic point, a PL metric determines residual line-bundle data on a suitable reduction of the germ. Positivity of that data is tested by degrees on residual curves. This can see geometry invisible in one real coordinate picture. If the residual variety contains a curve on which the line bundle

has negative degree, a numerical semipositivity assertion fails even when a chosen local polyhedral presentation looks harmless.

CLD12 develops the residual construction and uses residual positivity to obtain approximation results and identify model Monge–Ampère measures. It does not thereby prove every converse between continuous current positivity and model semipositivity. Chapter 19 develops the later model and curve tests; Chapter 19 states the stronger residual comparison claimed in CLD25 with its precise regularity scope.

20.1.3 The special-fibre formula

For orientation, assume a normal proper flat model over a discrete valuation ring, with special fibre $\sum_Y m_Y Y$, and integral model line bundles $\mathfrak{L}_1, \dots, \mathfrak{L}_n$. In the usual model-measure normalization,

$$c_1(\overline{L}_1) \cdots c_1(\overline{L}_n) = \sum_Y m_Y \deg_Y(\mathfrak{L}_1 \cdots \mathfrak{L}_n)\, \delta_{\xi_Y}.$$

Here ξ_Y is the divisorial point associated with the component Y. Rational model metrics introduce the corresponding tensor-power denominators. The conventions for ξ_Y and the component multiplicities must be retained together; omitting m_Y while keeping the same normalized valuation changes the formula.

The mass is the generic-fibre intersection degree. In particular, it does not acquire an extra factor $-\log|\pi|$ merely because the underlying absolute value has that scale. That logarithmic scale enters the values of vertical model functions and local heights; the Chern measure itself is normalized to have algebraic degree as mass. A detailed blow-up calculation in Section 20.6 checks both facts simultaneously.

20.1.4 How the analytic and model constructions meet

The comparison is a theorem, with two constructions to compare. One side comes from approximating local metric weights and taking limits of differential products. The other side is a finite sum of algebraic intersection degrees. The proof identifies the analytic mass near a divisorial point with the corresponding residual intersection number and shows that no other mass remains. Locality, Poincaré–Lelong, and tropical degree calculations are all used in this passage.

Once this comparison is established for suitable model metrics and the appropriate continuity theorem is available, uniform limits extend the agreement to a larger class of semipositive metrics. It remains necessary to say which approximation is being used: local smooth approximation, global approximation on one line bundle, or approximation by semipositive models. Their equivalence is not part of the notation $c_1(\overline{L})$.

References. [CLD12, §§6.1–6.9]; [CL06].

20.2 Metrics and residual curvature in CLD25 Chapters 17–18

20.2.1 Vector bundles first, curvature products for line bundles

CLD25 Chapter 17 develops metrics on vector bundles, their PL forms, and residual bundles. The statements about curvature products in CLD25 Chapter 18 principally use line bundles and first Chern currents. The presence of vector-bundle metrics in the foundations should not be read as a complete higher-Chern-form or Bott–Chern theory for every such metric.

For a line bundle, a metric is locally a weight, but the transition rule is constrained by analytic units. Residual reduction attaches geometric data to PL weights and makes numerical positivity available. Formal metrics and strictly integral PL metrics are compared in the appropriate nontrivially valued strict analytic category. Extending a conclusion from strictly integral PL to integral or real PL data requires the relevant reduction, tensor, or descent argument.

20.2.2 Relative Monge–Ampère and residual intersections

The model-measure formula of Chapter 20 is a top-degree case. CLD25 develops curvature products of PL metrics as structured currents and calculates them using residual intersection data. Relative formulas allow products to be evaluated along fibres. This is the mechanism that feeds the complete-intersection and abelian applications.

The central distinction is between a numerical residual class and an actual metric. Residual numerical triviality can force a curvature current to vanish in a specified theorem, but it does not make the metric canonically trivial.

Constants and algebraically nontrivial degree-zero data remain relevant to heights and pairings.

20.2.3 The canonical current of a curve is not a probability measure

Section 18.2 treats a different geometric metric: the semi-metric on the canonical bundle induced from Temkin's Kähler seminorm. Over an algebraically closed nontrivially valued field, the basic example on the affine line is

$$\|dT\|(\eta_{a,r}) = r.$$

At a rigid point the seminorm vanishes. Hence this is not a finite continuous metric of the sort used in the elementary BT recursion. Its logarithm is nevertheless locally integrable in the source construction, and its restriction to suitable skeletal pieces is PL.

Theorem 18.2.16 identifies its curvature on a smooth analytic curve with a canonical skeletal current, evaluated using a skeleton adapted to the test. The adapted skeleton may change when the test changes. On a compact curve, the degree of the canonical bundle is $2g - 2$, so this object is not by definition a positive probability measure. In particular, it should not be confused with the normalized admissible measure used in Arakelov theory on a metrized graph or with the canonical probability measure of a polarized dynamical system.

This example is important for the learning programme: a natural geometric norm can be singular and fail to be continuous at a dense set, while still admitting a meaningful curvature current. The required integrability and support arguments are part of the theorem. They cannot be replaced by an informal appeal to the continuous theory.

20.3 Metrics, curvature, and the first substantial applications

20.3.1 A metric is locally a function, but globally more than curvature

Let L be a line bundle with a continuous metric. For a nonvanishing local frame e, set

$$h_e = -\log \|e\|.$$

If $e' = fe$ with f invertible, then

$$h_{e'} = h_e + v(f), \qquad v(f) = -\log |f|. \tag{20.3.1}$$

The unit logarithm $v(f)$ is original smooth, being a moment-map coordinate, and has $\mathrm{d}'\mathrm{d}''[v(f)] = 0$. Hence the local currents $\mathrm{d}'\mathrm{d}''[h_e]$ glue to the first Chern current $c_1(L, \|\cdot\|)$. This gluing uses a smooth harmonic change of weight and does not require a kernel theorem for arbitrary continuous harmonic multipliers. The trivialization rule is why a local Hessian becomes a global curvature.

For a nonzero rational or meromorphic section s, the Poincaré–Lelong formula in our normalization is

$$\mathrm{d}'\mathrm{d}''[-\log \|s\|] + \delta_{\mathrm{div}(s)} = c_1(L, \|\cdot\|), \tag{20.3.2}$$

interpreted where the locally integrable current is defined. Equivalently, $\mathrm{d}'\mathrm{d}''[\log |f|] = \delta_{\mathrm{div}(f)}$ for a meromorphic function in the trivial-metric case. This is consistent with the concavity of $v(f)$ on a torus Gauss section: the positive divisor appears with a minus sign in $\mathrm{d}'\mathrm{d}''[v(f)]$.

Changing the metric to $e^{-c}\|\cdot\|$, with $c \in \mathbb{R}$, adds c to every local weight and leaves curvature unchanged. It does change the metrized line bundle and can change a local height. Thus curvature is an invariant of metric data, not a complete replacement for those data.

20.3.2 The standard metric on the projective line

Example 20.3.1. On $\mathbb{P}^1_K$ with homogeneous coordinates $[Z_0 : Z_1]$, the standard model metric on $\mathcal{O}(1)$ satisfies, on the chart $z = Z_1/Z_0$,

$$\|Z_0\|(x) = \frac{1}{\max(1, |z(x)|)}.$$

On the torus Gauss skeleton, with $t = v(z)$, its weight is

$$h(t) = \log \max(1, e^{-t}) = \max(0, -t).$$

Its left slope is -1 and its right slope is 0. The one-dimensional corner formula gives one unit of curvature at $t = 0$. Analytically this is

$$c_1\big(\mathcal{O}(1), \|\cdot\|_{\mathrm{std}}\big) = \delta_{\xi_G}, \tag{20.3.3}$$

where ξ_G is the Gauss point of the closed unit disc. The identity on all of $\mathbb{P}^{1,\mathrm{an}}$ also follows from the model formula in Section 20.6; the skeleton computation identifies the slope and its sign.

The section Z_0 vanishes at infinity. Therefore

$$\mathrm{d}'\mathrm{d}''[-\log \|Z_0\|] + \delta_\infty = \delta_{\xi_G}.$$

Both sides have total mass one after the divisor term is included. Integrating the displayed Hessian alone gives zero, as Stokes requires on the proper curve. The pole of the Green function at infinity is part of the global calculation and must not be lost when using the real line chart.

20.3.3 What an original GK delta-metric requires

A piecewise smooth metric has local weights that can be represented by piecewise smooth functions on tropical charts. The original GK definition of a *delta-metric* imposes an additional condition: the piecewise Hessian on the tropical image must come from a piecewise smooth ambient $(1,1)$-superform in the prescribed way. This is [GK17, Definition 9.9]. Its purpose is to ensure that the complete curvature, including the corner part, is a delta-form with the required pullback behavior.

The characterization in [GK17, Proposition 9.11] is functorial: a first Chern delta-form must realize the Chern delta-current after every allowed pullback, with the equality taking place in GK's delta-current space, not only after restriction to original smooth tests. The resulting curvature is d'- and d''-closed. Piecewise linear metrics satisfy the original condition because

their interior Hessian is zero. Formal/model metrics therefore provide the fundamental examples. It is inaccurate to replace this statement by "every piecewise smooth metric is an original GK delta-metric." The later Mihatsch category incorporates piecewise smooth functions more systematically, as explained in the previous section.

20.3.4 Positivity has a geometric meaning

For a convex smooth weight on a real chart, positivity is simply positivity of its Hessian. For a piecewise smooth weight, the facewise Hessians and the corner contributions both enter. On a line, convexity means nonnegative second derivatives on the pieces and nonnegative slope jumps. This local calculation is the prototype of the metric positivity criteria.

For piecewise linear metrics in the hypotheses of [GK19, Theorem 6.10], model semipositivity is equivalent to the stated functorial positivity conditions, to positivity of the Chern delta-form, and to the relevant curve tests. The adjective *functorial* is essential in that theorem. Its list of equivalences should not be shortened to arbitrary positivity of a current on one fixed space. The later work of Gubler–Rabinoff and CLD develops additional analytic and residual criteria; these have their own scope, discussed in Section 20.6.

20.3.5 Comparison with model intersection numbers

On a proper n-dimensional variety with formally metrized line bundles $\overline{L}_1, \dots, \overline{L}_n$, GK identifies the wedge of the Chern delta-forms with the Chambert–Loir measure obtained from intersection numbers on a model:

$$c_1(\overline{L}_1) \wedge \cdots \wedge c_1(\overline{L}_n) = \mathrm{MA}(\overline{L}_1, \dots, \overline{L}_n). \tag{20.3.4}$$

This is [GK17, Theorem 10.5]. It does not require the model line bundles to be nef for the equality to make sense: in general the measure is signed. Semipositivity is what makes the coefficients nonnegative.

This comparison is a major reason to learn the calculus. A wedge product defined by tropical local data computes a measure whose atoms and masses come from algebraic intersection theory on the special fibre. Section 20.6 explains the model formula; Section 22.2 uses it in local heights.

Remark 20.3.2 (Constant rescaling). Let $\overline{L}' = (L, e^{-c}\|\cdot\|)$ for a real constant c. The weight changes from φ_e to $\varphi_e + c$, and $\mathrm{d}'\mathrm{d}''[c] = 0$, so $c_1(\overline{L}') = c_1(\overline{L})$. Whenever the local-height recursion and degree formula apply on a proper n-fold, rescaling one metric by e^{-c} changes the local height by

$$c \deg_X(L_1 \cdots L_n),$$

where the displayed line bundles are the other n entries. This follows by taking $\rho = c$ in (22.2.4); it does not follow from the curvature alone.

20.4 Fubini–Study weights and mixed Chern measures

20.4.1 Sections produce a metric

Let L be a line bundle and let $s_0, \dots, s_N$ be sections of $L^{\otimes m}$ with no common zero. Choose real weights a_i. On an open set with frame e of L, write $s_i = f_i e^{\otimes m}$ and put

$$\phi_e = \frac{1}{m} \max_i \bigl(\log|f_i| + a_i\bigr), \qquad \|e\| = e^{-\phi_e}. \tag{20.4.1}$$

Use $\log 0 = -\infty$. The maximum is finite because the sections have no common zero. Under $e' = ge$, the coefficients become $f_i' = f_i g^{-m}$, so $\phi_{e'} = \phi_e - \log|g|$. Hence the local formulas define a metric.

Near a point, any section vanishing at that point is dominated in the maximum by a nonvanishing section after shrinking. The relevant nonvanishing coefficients are analytic units. Thus (20.4.1) is locally a maximum of affine functions of unit logarithms. This explains its piecewise affine character and positive corner curvature. Arbitrary real a_i give real weighted FS data; to regard the metric as a formal or rational model metric over the original field, one must impose the corresponding value-group and denominator conditions.

20.4.2 Smoothing the maximum without losing the chart conditions

On a real chart, $\max(\ell_0, \dots, \ell_N)$ can be approximated by smooth convex regularized maxima. For instance, log-sum-exp gives a convenient local estimate

$$\max_i \ell_i \le \varepsilon \log \sum_i e^{\ell_i/\varepsilon} \le \max_i \ell_i + \varepsilon \log(N+1).$$

This formula illustrates uniform approximation and convexity on the chart. Near a zero of a section, it should not be used to pretend that $\log|f_i|$ is a smooth finite coordinate. A compatible regularized-maximum construction discards dominated terms and agrees with the surviving affine term where it is separated. CLD's FS regularization provides the analytic construction under its stated hypotheses.

On $\mathbb{P}^1$, the standard weight $\max(0,-t)$ is particularly instructive. Smooth it only in a small interval around $t=0$, leaving it equal to its affine branches outside. Its second derivative is a nonnegative measure of total mass one, since the endpoint slopes remain -1 and 0. As the interval shrinks, these measures converge weakly to δ_0. In analytic terms, the curvature tends to the Gauss-point mass. The need to keep the affine branches is also what permits smoothness in the original sense near the rigid endpoints.

20.4.3 Three legitimate meanings of a mixed Chern expression

The notation

$$\mu = c_1(L_1, \|\cdot\|_1) \wedge \cdots \wedge c_1(L_n, \|\cdot\|_n)$$

does not define itself. There are several constructions, with comparisons on their common domains.

For *smooth semipositive metrics*, the local positive $(1,1)$-forms $\mathrm{d}'\mathrm{d}''\phi_{i,e}$ glue to $c_1(\overline{L}_i)$. Their ordinary wedge is a top-degree form and hence a measure.

For *continuous metrics whose local weights lie in* $\mathcal{C}_{25}$, use the recursion of Proposition 13.1.4 with background $[1]_X$. Smooth unit-logarithm frame changes have zero Hessian, so the local products glue. In top degree the resulting positive current is a Radon measure. Metrics given as controlled differences of admissible positive metrics can be treated by the corresponding multilinear signed theory once its independence statements have been established.

For *formal/model metrics*, the special-fibre formula gives an atomic measure, while GK constructs it as a product of Chern delta-forms. The equality of these constructions is a comparison theorem. The model definition does not rely on pretending the original curvature current was smooth.

20.4.4 What uniform approximation does to the measure

Suppose globally defined smooth semipositive metrics $\|\cdot\|_{i,j}$ on the fixed L_i converge uniformly in their weights to $\|\cdot\|_i$. On every trivializing neighbourhood their weights satisfy the hypotheses of the continuous multiplier and BT theorems. Consequently

$$\bigwedge_{i=1}^{n} c_1(L_i, \|\cdot\|_{i,j}) \rightharpoonup \bigwedge_{i=1}^{n} c_1(L_i, \|\cdot\|_i).$$

Independence of approximating sequences follows from the intrinsic recursive construction; it is not inferred just from the existence of some weakly convergent subsequence.

For uniform limits of semipositive FS or model metrics, the model-theoretic measure is likewise defined using its continuity theorem. To compare it with the CLD product, compare first on the admissible common class and then pass to the uniform limit using continuity on both sides. Thus the proof has two inputs: equality at the approximating level and convergence of each construction. A raw current inequality alone does not supply either input.

20.4.5 Why the total mass is the intersection degree

Let Y/K be smooth projective of dimension n. In the smooth intersection comparison, one has

$$\int_{Y^{\mathrm{an}}} c_1(\overline{L}_1) \wedge \cdots \wedge c_1(\overline{L}_n) = \deg_K(L_1 \cdots L_n).$$

For a globally smoothly approximable semipositive tuple as above, every approximating measure has this mass. Properness makes Y^{an} compact, so the constant function 1 is an admissible test for the top-degree current. Weak convergence therefore preserves the mass.

This explains the statement studied in the earlier discussion: global approximation plus the smooth degree formula gives the total mass formula. The word *global* cannot be dropped in this short argument. On a noncompact open space, vague convergence can lose mass at infinity; for example $\delta_j \to 0$ on compact tests in $\mathbb{R}$, although each measure has mass one.

References. [CLD12, §§6.3–6.9]; [CLD25, §§8.7, 17.8, 18.8]; [GK17, Theorem 10.5].

20.5 Total variation and the curve estimate

20.5.1 The norm of a signed measure

For a finite signed Radon measure ν, write its Jordan decomposition as $\nu = \nu^+ - \nu^-$, with mutually singular positive measures. Its total variation measure is $|\nu| = \nu^+ + \nu^-$, and

$$\|\nu\|_{\mathrm{TV}} = |\nu|(X) = \nu^+(X) + \nu^-(X).$$

Equivalently, it is the supremum of $\sum_i |\nu(E_i)|$ over finite measurable partitions, or the supremum of $|\int f\, d\nu|$ over bounded measurable f with $|f| \le 1$. For $\nu = \sum a_i \delta_{x_i}$ at distinct points, the norm is $\sum |a_i|$. Its signed mass, by contrast, is $\sum a_i$.

If μ_0, μ_1 are positive finite measures, then

$$|\mu_1 - \mu_0| \le \mu_1 + \mu_0, \qquad \|\mu_1 - \mu_0\|_{\mathrm{TV}} \le \mu_1(X) + \mu_0(X).$$

Cancellation can make the inequality strict. For example $\mu_0 = \mu_1 \neq 0$ gives zero on the left.

20.5.2 The bound $2 \deg L$ and its hypotheses

On a smooth projective analytic curve, let two admissible semipositive metrics on the same line bundle L have curvature measures μ_0, μ_1. Their local weight difference $g = \phi_1 - \phi_0$ is a global continuous function, and

$$\mathrm{d}'\mathrm{d}''[g] = \mu_1 - \mu_0.$$

Each positive measure has mass $\deg_K L$. Therefore

$$\|\mathrm{d}'\mathrm{d}''[g]\|_{\mathrm{TV}} \le 2 \deg_K L. \tag{20.5.1}$$

The signed mass of $\mathrm{d}'\mathrm{d}''[g]$ is zero, but its total variation need not be zero. Inequality (20.5.1) measures how much positive and negative curvature can move while preserving the degree.

The bound does not hold for an arbitrary continuous function g without the hypothesis that its Hessian is the difference of these two positive measures of controlled mass. It is a measure estimate after the curvature construction and degree comparison have been established, not a separate general regularization theorem.

20.5.3 What the estimate buys in an integral

For a continuous test coefficient a,

$$\left| \int a \, \mathrm{d}'\mathrm{d}''[g] \right| \leq \|a\|_\infty \|\mathrm{d}'\mathrm{d}''[g]\|_{\mathrm{TV}} \leq 2 \deg_K L \, \|a\|_\infty.$$

Thus a uniform error in a potential or coefficient produces a controlled error against this curvature difference. For smooth functions on a proper curve, integration by parts gives

$$\int a \, \mathrm{d}'\mathrm{d}''g = \int g \, \mathrm{d}'\mathrm{d}''a.$$

Extensions to nonsmooth functions require the admissible approximation or multiplier theorem; the formal symmetry of the display alone does not justify them. This is the analytic use of total variation in curve energy and approximation arguments.

20.6 Model measures with the original absolute value

20.6.1 The special-fibre formula

Let K now be discretely valued, $R = K^\circ$, and $\lambda = -\log|\pi| > 0$ for a uniformizer. Let $\mathcal{X}$ be a normal projective flat model of a projective n-fold X, with special fibre $\sum_Y m_Y Y$. Each component determines a divisorial point ξ_Y, whose valuation extends the original valuation of K, so $v_{\xi_Y}(\pi) = \lambda$.

If $\mathcal{L}_i$ extends $L_i^{\otimes e_i}$, the model measure is

$$\mu = \frac{1}{e_1 \cdots e_n} \sum_Y m_Y \deg_{\widetilde{K}}\big(c_1(\mathcal{L}_1) \cdots c_1(\mathcal{L}_n) \cap [Y]\big) \delta_{\xi_Y}. \tag{20.6.1}$$

The residual degree includes residue-field degrees. There is no extra factor λ multiplying this Chern measure in the normalization used here: its mass is the algebraic intersection degree. The scale λ does appear in values of logarithmic model functions and in lengths of skeleton edges. Keeping both is what makes the slope formula agree with (20.6.1).

Relative nefness makes the coefficients nonnegative. Without nefness, the same formula defines a signed measure. The equality with the analytic CLD/GK construction on the common class is the content of the measure

comparison, and compatibility with base change is needed when using the algebraically closed version of the GK theorem over a smaller ground field.

20.6.2 A blow-up with the scale still visible

Blow up $\mathbb{P}^1_R$ at a rational smooth point of the special fibre. The resulting special fibre is $F + E$, where E is exceptional, and

$$F \cdot E = 1, \qquad F^2 = E^2 = -1.$$

The generic fibre is still $\mathbb{P}^1_K$. The model line $\mathcal{O}(E)$, with its canonical generic trivialization, defines a function $g = -\log \|1\|$ with

$$g(\xi_F) = 0, \qquad g(\xi_E) = \lambda.$$

The intervening skeletal edge has length λ. Its slope from F to E is therefore $+1$, not $+\lambda$. The outgoing slope at the other end is -1, and

$$\mathrm{d}'\mathrm{d}''[g] = \delta_{\xi_F} - \delta_{\xi_E}.$$

This agrees with $E \cdot F = 1$ and $E^2 = -1$. Normalizing $\lambda = 1$ hides the distinction between value and slope, but is unnecessary.

More generally, $D = aF + bE$ gives values $a\lambda, b\lambda$ and curvature

$$(b - a)\delta_{\xi_F} + (a - b)\delta_{\xi_E}.$$

Its mass is zero. If the curvature is positive, then $a = b$, and $D = a\,\mathrm{div}(\pi)$ gives a constant model function. Thus even this simple example separates a metric constant from its vanishing curvature.

References. [CL06, §2]; [GK17, Theorem 10.5 and Remark 12.7].

20.7 Hessians, corner measures, and mixed mass

20.7.1 The smooth calculation fixes the factorial

On $\mathbb{R}^n$, write

$$\mathrm{d}'\mathrm{d}''u = \sum_{i,j} u_{ij}\, d'x_i \wedge d''x_j, \qquad \Omega = \bigwedge_{i=1}^{n} (d'x_i \wedge d''x_i).$$

Expanding the nth power and using the exterior signs gives

$$(\mathrm{d}'\mathrm{d}''u)^n = n!\det(D^2u)\,\Omega.$$

There are $n!$ ways to choose the row indices, and the signed sum over column indices is the determinant. In this paired-order normalization, Ω is positive. If all d' factors are moved to the left, the factor $(-1)^{n(n-1)/2}$ must be inserted.

For $u(x) = \frac{1}{2}x^{\mathsf{T}}Ax$ with A positive semidefinite, the measure has constant density $n!\det A$. If A has rank less than n, the top-degree measure vanishes although $\mathrm{d}'\mathrm{d}''u$ can be nonzero. This returns to the warning in Chapter 7: lower-degree curvature is not determined by its self-top-degree mass.

20.7.2 The PL analogue uses subgradients

For a finite convex function u, its subgradient at x consists of covectors a such that

$$u(y) \geq u(x) + \langle a, y - x\rangle \quad \text{for all } y$$

in the relevant convex domain. For a maximum of affine functions, the subgradient at a point is the convex hull of the slopes of the active affine branches. The real Alexandrov Monge–Ampère measure measures the volume swept out by these subgradients. In the superform normalization above, the corresponding top-degree measure has the additional factor $n!$.

For $u(x, y) = \max(0, x, y)$, the subgradient at the origin is the triangle with vertices $(0, 0), (1, 0), (0, 1)$, of area $1/2$. Away from the origin, the subgradient is a segment or a point and has area zero. Consequently

$$(\mathrm{d}'\mathrm{d}''u)^2 = \delta_0.$$

The corner set is one-dimensional, but the top-degree product is concentrated where two independent slope changes meet. This is the convex-geometric prototype of the complete-intersection mass in the logarithmic maximum formula.

20.7.3 Mixed products are polarized intersections

Let $u = \max(0, x)$ and $v = \max(0, y)$. The subgradient of $su + tv$ at the origin is the rectangle $[0, s] \times [0, t]$, so its normalized top-degree mass is $2st$. On the other hand,

$$(\mathrm{d}'\mathrm{d}''(su + tv))^2 = s^2(\mathrm{d}'\mathrm{d}''u)^2 + 2st\,\mathrm{d}'\mathrm{d}''u \wedge \mathrm{d}'\mathrm{d}''v + t^2(\mathrm{d}'\mathrm{d}''v)^2.$$

Each self-square vanishes because only one real direction is involved. Comparing coefficients gives $\mathrm{d}'\mathrm{d}''u \wedge \mathrm{d}'\mathrm{d}''v = \delta_0$. Replacing the two slopes by primitive vectors produces the lattice determinant from tropical stable intersection.

This calculation explains why the tropical intersection and continuous convex-potential constructions agree on their common elementary examples. A theorem identifying the constructions globally must still handle charts, multiplicities, and limits. Agreement of one formula is a normalization check, not the full comparison theorem.

20.7.4 Why smoothing is local and why truncation is different

On a convex real domain, convolution with a nonnegative normalized kernel preserves convexity, but it is defined only on a smaller domain unless the function has been extended. This is the origin of the fixed-neighbourhood requirement in local approximation. A sequence whose domains shrink to the point does not give a uniform approximation theorem on an open neighbourhood.

Truncating a singular psh function by $\max(u, -M)$ is a different operation. It produces bounded functions, but their curvature measures can carry mass on the truncation level. As $M \to \infty$, deciding what mass remains and what mass is excluded from a non-pluripolar product is part of the definition and theorem. It cannot be settled by treating the truncations as uniformly convergent on a neighbourhood of the singular set.

20.7.5 The analytic logarithmic maximum

For $u = \log \max_i |f_i|$, the real maximum calculation explains the local convex structure on the complement of the common zero set. The analytic theorem must also establish local integrability, extension across the zero set, and the multiplicity of the resulting cycle. A regular sequence supplies the expected codimension, and the calibrated fibre comparison supplies the intersection multiplicity. The real determinant and subgradient calculations explain the shape of the answer; the analytic geometry proves that it is the correct answer for the given equations.

20.8 A global smooth approximation of a fixed Fubini–Study metric

The local regularized maximum of Chapter 12 gives a global construction when the local expressions come from one finite system of sections. The transition rule for a line-bundle frame is exactly the translation rule required by the regularization. This is a useful case in which local smooth approximation can be upgraded to global approximation without an additional gluing theorem.

Let X be a good analytic space in the original smooth-form category, let L be an analytic line bundle, and let $s_0, \dots, s_N$ be global sections of $L^{\otimes m}$ without a common zero, with $m \geq 1$. Fix real constants a_i. In a frame e, write $s_i = f_i e^{\otimes m}$ and put

$$\phi_e = \frac{1}{m} \max_{0 \leq i \leq N} \bigl(\log |f_i| + a_i\bigr).$$

Use the normalized regularized maximum $M_{\varepsilon,k}$ constructed in Chapter 12, with the same even one-variable kernel in every coordinate. We will use its four properties: convexity and coordinatewise monotonicity; translation covariance by the diagonal vector; the bound $\max \leq M \leq \max + \varepsilon$; and exact deletion of a coordinate lying more than 2ε below another coordinate.

Theorem 20.8.1. *For every $\varepsilon > 0$, the Fubini–Study metric above admits a global original smooth semipositive metric with local weights $\phi_{e,\varepsilon}$ satisfying*

$$0 \leq \phi_{e,\varepsilon} - \phi_e \leq \frac{\varepsilon}{m} \qquad \text{on every trivializing open set.}$$

The difference is independent of the frame. The metrics therefore converge uniformly on the whole space in the metric-ratio distance, even when X is not compact.

Proof. Fix $x \in X$ and a frame near x. Let $I_x = \{i : f_i(x) \neq 0\}$. This set is nonempty. Shrink the neighbourhood so that every f_i, $i \in I_x$, is a unit. Choose $i_0 \in I_x$. Since $|f_j| \to 0$ at x for $j \notin I_x$, a further shrinking gives

$$\log |f_j| + a_j < \log |f_{i_0}| + a_{i_0} - 2\varepsilon \qquad (j \notin I_x),$$

with the usual interpretation $\log 0 = -\infty$. On this neighbourhood define

$$\phi_{e,\varepsilon} = \frac{1}{m} M_{\varepsilon,|I_x|}\bigl((\log |f_i| + a_i)_{i \in I_x}\bigr).$$

This is original smooth: the finite logarithms are coordinates of a moment map by units, and M is a smooth real function. If two such neighbourhoods overlap, enlarge the coordinate list to the union of their surviving indices near a point of overlap. Every extra coordinate is either finite and inactive, or vanishes and remains inactive after shrinking. Exact deletion shows that both formulas give the same value. Thus the local constructions agree, including at zeros of sections.

If $e' = ge$, then each finite input changes by $-m \log |g|$. Diagonal translation covariance gives $\phi_{e',\varepsilon} = \phi_{e,\varepsilon} - \log |g|$. Hence these weights define a metric on L. Each input has zero $d'd''$, and the Hessian of M is positive semidefinite. The convex-composition formula of Chapter 12 proves $d'd''\phi_{e,\varepsilon} \geq 0$. This proves semipositivity. Finally, the maximum bound for M gives the stated estimate on each neighbourhood. Since the transition term is the same for the smoothed and original weights, their difference is global, and the estimate is uniform on all of X. □

This proof uses a common finite section system. It does not imply that every metric with locally smoothly approximable weights has a globally approximating sequence of metrics. General local-to-global approximation must also preserve the line bundle's transition data. Here that preservation is supplied by the diagonal translation identity.

Proposition 20.8.2. *Pullback preserves finite real-weighted Fubini–Study metrics. Tensor product also preserves this class, after passing to a common tensor exponent. The corresponding smooth approximations have positive curvature, and the uniform errors add under tensor product.*

Proof. Pullback takes the section system to its pullback, which still has no common zero: the original evaluation map from a trivial bundle onto $L^{\otimes m}$ is surjective, and pullback preserves this surjection. The local weight formula is simply composed with the analytic map.

For tensor product, first make both exponents equal by taking powers of the individual sections and multiplying their constants accordingly. If the resulting local lists are $A_i = \log |f_i| + a_i$ and $B_j = \log |g_j| + b_j$, the product sections have list $A_i + B_j$. The identity

$$\max_{i,j}(A_i + B_j) = \max_i A_i + \max_j B_j$$

identifies the metric with the tensor product. Curvatures of smooth metric weights add, so semipositivity is preserved. The triangle inequality gives

addition of uniform errors. The tensor product of the chosen smooth approximations need not equal the particular regularized maximum of the product section system; both are legitimate approximations of the same limiting metric. □

20.9 Metric variation, closedness and conservation of total mass

We next isolate the formal calculation used in degree comparisons. Work on a proper boundaryless pure n-dimensional analytic space where smooth integration and Stokes' theorem are available. All metrics in the next proposition are original smooth.

Proposition 20.9.1. *If two smooth metrics on L have curvature forms θ and θ', then $\theta' - \theta = d'd''u$ for a global smooth function u. For every smooth d'- and d''-closed form S of bidegree $(n-1, n-1)$,*

$$\int_X (\theta' - \theta) \wedge S = 0.$$

Consequently the total mixed Chern integral of a fixed tuple of line bundles is independent of the smooth metrics.

Proof. The differences of local weights agree on overlaps, because the two frame-change terms cancel. They define u, and differentiating gives $\theta' - \theta = d'd''u$. Closedness of S implies $d'd''(uS) = d'd''u \wedge S$. Stokes' theorem gives zero after integration. To compare two tuples, replace the metrics one at a time. The wedge of all unchanged Chern forms is closed under both differentials, so the preceding identity applies at every replacement. □

This argument proves metric independence, not the value of the integral. To identify that value with $\deg_K(L_1 \cdots L_n)$ still requires an intersection comparison or a Poincaré–Lelong induction with admissible integrability. These are supplied by the source theorems cited earlier. Once that normalization is known, every smooth semipositive metric tuple has the same algebraic mass.

Lemma 20.9.2 (From smooth tests to continuous tests)**.** *Let X be compact Hausdorff, let $\mathscr{S} \subset C(X,\mathbb{R})$ be uniformly dense, and let μ_j, μ be finite signed Radon measures with*

$$\sup_j \|\mu_j\|_{\mathrm{TV}} + \|\mu\|_{\mathrm{TV}} < \infty.$$

If $\int a\, d\mu_j \to \int a\, d\mu$ for every $a \in \mathscr{S}$, the convergence holds for every $a \in C(X,\mathbb{R})$.

Proof. Choose $b \in \mathscr{S}$ with $\|a-b\|_\infty < \eta$. If the displayed bound is M, then

$$\left|\int a\, d(\mu_j - \mu)\right| \le M\eta + \left|\int b\, d(\mu_j - \mu)\right|.$$

Take the upper limit in j and then let η tend to zero. □

In the algebraic CLD setting of Chapter 8, smooth functions are uniformly dense on compact spaces by the cutoff and partition argument there. Positive measures of a fixed degree have uniformly bounded total variation because total variation equals mass. Thus weak convergence as top-degree currents upgrades to weak convergence of Radon measures. This is often used implicitly when a current formula is stated as a measure formula.

Corollary 20.9.3. *Assume the proper algebraic CLD setting and the mixed-product construction for local uniform smooth psh limits established in Chapter 13. For a tuple of finite Fubini–Study metrics, their smoothed mixed Chern measures converge weakly to the intrinsic mixed measure of the original metrics. The limit is independent of the chosen regularizing kernels. Its mass is $\deg_K(L_1 \cdots L_n)$ whenever the smooth degree comparison is normalized as above.*

Proof. Theorem 20.8.1 gives uniformly convergent smooth semipositive metrics on the fixed line bundles. The local mixed-product theorem identifies their current limit and proves independence of the approximating sequences. The local limits glue because frame changes are smooth unit logarithms with zero Hessian. Positivity and the degree formula bound all masses. Lemma 20.9.2 upgrades convergence to continuous tests. Finally, test against the constant function one to recover the mass. □

There is no assertion of total-variation convergence in this result. Even on $\mathbb{R}$, positive smooth probability densities concentrating at the origin converge

weakly to δ_0 while their difference from δ_0 has total variation two. Likewise, smoothing a model metric can replace an atom by a diffuse measure without making the total-variation distance small. Weak convergence is the appropriate conclusion.

References. [CLD12, Sections 6.3–6.9]; [CLD25, Sections 17.8 and 18.8]; [GK17, Theorem 10.5]. The global approximation and the measure-theoretic passage are proved above; the algebraic degree comparison remains an explicitly cited input.

20.10 Integration by parts for metric differences

A global difference of metric weights is more flexible than a global psh function: its curvature is measured relative to a fixed line bundle. This leads to energy identities which connect the local differential calculus with arithmetic metric variation. We prove the identities in an explicit approximation domain. No general regularization theorem is hidden in the choice of that domain.

Let X be proper, pure n-dimensional and boundaryless, in the algebraic CLD setting where the preceding integration, positive-current and continuous-product theorems hold. Fix an original smooth semipositive metric on a line bundle L, with curvature θ. Write

$$\theta_u = \theta + \mathrm{d}'\mathrm{d}''u, \qquad V = \int_X \theta^n.$$

An admitted function in this section is a continuous global function u which is a uniform limit of global original smooth functions u_j with $\theta + \mathrm{d}'\mathrm{d}''u_j \geq 0$. Thus the metric with weights $\varphi_e + u$ is a uniform limit of smooth semipositive metrics on the same L. Locally its weights belong to $\mathcal{U}_X$. This global requirement is stronger than merely having local smooth approximants, and stronger than positivity of a curvature current.

Lemma 20.10.1. *The admitted domain contains constants and is convex. All mixed products of its curvature currents are well-defined, positive and closed, and*

$$\int_X \theta_{u_1} \wedge \cdots \wedge \theta_{u_n} = V.$$

Proof. Constants do not change curvature. If u_j, v_j are admissible smooth approximants, $(1-t)u_j + tv_j$ has curvature $(1-t)\theta_{u_j} + t\theta_{v_j} \geq 0$ for $0 \leq$

$t \le 1$, and approximates $(1-t)u + tv$ uniformly. Local continuous products give existence and compatibility with uniform limits. Changes of frame are smooth pluriharmonic functions, so these local products glue. For smooth approximants, Proposition 20.9.1 gives total mass V. Weak convergence of the positive measures and testing against one give the same formula in the limit. □

Proposition 20.10.2 (Integration by parts)**.** *Let $u, v, a_1, \dots, a_{n-1}$ be admitted, and put $S = \theta_{a_1} \wedge \cdots \wedge \theta_{a_{n-1}}$. Then*

$$\int_X u\,(\theta_v - \theta) \wedge S = \int_X v\,(\theta_u - \theta) \wedge S. \tag{20.10.1}$$

The equality also holds for differences of admitted functions in the two scalar positions, interpreting the curvature factors multilinearly.

Proof. First assume that all functions are smooth. Closedness of S and Stokes give

$$\int_X u\,\mathrm{d}'\mathrm{d}''v \wedge S = -\int_X d'u \wedge d''v \wedge S = \int_X v\,\mathrm{d}'\mathrm{d}''u \wedge S.$$

The second equality follows by the other integration by parts, or by applying J to the middle integrand and using symmetry of S. There are no boundary terms because X is proper and boundaryless.

Choose simultaneous global smooth approximants for the finitely many functions. Every expression such as $\theta_{v_j} \wedge S_j$ is a positive mixed measure of mass V and converges weakly to the corresponding continuous mixed measure. Uniform convergence of u_j permits multiplication: the error from $u_j - u$ is bounded by $V\|u_j - u\|_\infty$, and the remaining error tends to zero by weak convergence against the continuous function u. Treat the term with θ in the same way. Passing to the limit proves the displayed equality. Subtracting equalities proves its bilinear extension. □

This proof does not define a wedge of distributional first derivatives of arbitrary continuous functions. The smooth middle expression is used to establish an identity whose limiting terms are already defined mixed measures. That distinction is useful whenever a formal Dirichlet expression occurs in a non-Archimedean argument.

20.11 Energy and the variation of Monge–Ampère measures

Definition 20.11.1. For an admitted u, define the unnormalized energy

$$E_\theta(u) = \frac{1}{n+1}\sum_{j=0}^{n}\int_X u\,\theta_u^j \wedge \theta^{n-j}.$$

In particular $E_\theta(0) = 0$. We do not divide by V, so the definition is meaningful even when $V = 0$.

Theorem 20.11.2 (First variation and the difference formula)**.** *For admitted u, v put $h = u - v$ and $u_t = v + th$, $0 \le t \le 1$. Then*

$$\frac{d}{dt}E_\theta(u_t) = \int_X h\,\theta_{u_t}^n, \tag{20.11.1}$$

$$E_\theta(u) - E_\theta(v) = \frac{1}{n+1}\sum_{j=0}^{n}\int_X h\,\theta_u^j \wedge \theta_v^{n-j}. \tag{20.11.2}$$

Proof. All expressions along this segment are polynomials in t, by multilinearity of the continuous mixed products. Differentiation is therefore algebraic. Put $\Theta = \theta_{u_t}$. Differentiating the jth summand of the energy gives

$$\int_X h\,\Theta^j\theta^{n-j} + j\int_X u_t\,\mathrm{d}'\mathrm{d}''h \wedge \Theta^{j-1}\theta^{n-j}.$$

By Proposition 20.10.2, the second integral equals $j\int_X h(\Theta - \theta)\Theta^{j-1}\theta^{n-j}$. Thus the summand becomes

$$(j+1)\int_X h\,\Theta^j\theta^{n-j} - j\int_X h\,\Theta^{j-1}\theta^{n-j+1}.$$

Summing over j cancels consecutive terms and leaves $(n+1)\int_X h\Theta^n$. This proves the derivative formula. Integrate from zero to one and expand $\theta_{u_t} = (1-t)\theta_v + t\theta_u$. The coefficient of each mixed term is

$$\binom{n}{j}\int_0^1 t^j(1-t)^{n-j}\,dt = \frac{1}{n+1}.$$

The integral identity follows by j integrations by parts, or by the factorial formula $j!(n-j)!/(n+1)!$. This proves the difference formula. □

Corollary 20.11.3. *Energy is increasing on the admitted domain and satisfies*

$$|E_\theta(u) - E_\theta(v)| \le V\|u - v\|_\infty, \qquad E_\theta(u + c) = E_\theta(u) + cV.$$

Proof. All $n+1$ mixed measures in (20.11.2) are positive of mass V. If $u \ge v$, each summand is nonnegative. Bounding the absolute value of h gives the Lipschitz estimate. For a constant difference c, every curvature equals θ_u and every mass equals V, giving the translation formula. □

Proposition 20.11.4 (Concavity)**.** *The energy is concave on the admitted convex domain. If all functions along the segment are smooth, its second derivative is*

$$\frac{d^2}{dt^2} E_\theta(u_t) = -n \int_X d'h \wedge d''h \wedge \theta_{u_t}^{n-1} \le 0.$$

Proof. Differentiate (20.11.1) in the smooth case to get $n \int h \mathrm{d}'\mathrm{d}''h \wedge \theta_{u_t}^{n-1}$. Integration by parts gives the displayed expression. The form $d'h \wedge d''h$ is strongly positive of bidegree $(1,1)$, so its product with the semipositive curvature power has nonnegative integral. For continuous admitted endpoints, choose smooth approximants for both endpoints and use their affine segments. The Lipschitz estimate gives convergence of their energies at each of the three arguments in the concavity inequality. Passing to the limit proves concavity without assigning a separate meaning to the nonsmooth first-derivative integral. □

Combining concavity with the first variation gives the useful pair of bounds

$$\int_X (u - v)\theta_u^n \le E_\theta(u) - E_\theta(v) \le \int_X (u - v)\theta_v^n.$$

Indeed, the derivative of a differentiable concave function on $[0,1]$ is nonincreasing, so its integral lies between its two endpoint values. These inequalities concern energy, not pointwise comparison of the two measures.

Remark 20.11.5 (Relation to local heights and variational theories). The sum of mixed integrals in (20.11.2) is the differential-calculus expression that occurs when all factors of an intersection pairing are changed from one metric to another. Identifying it with an arithmetic or Deligne pairing requires that pairing's normalization and comparison theorem. The identities proved here use neither an adelic summation nor a claim that every semipositive model metric has a global original smooth approximation.

Global variational theories often define energy first on model or Fubini–Study metrics and extend it by order or completion. Their domains can be larger and their topology can be different. The present formulas provide a common calculation on the overlap of domains; they do not identify those completions. Likewise, energy concavity alone supplies neither a comparison principle for arbitrary bounded psh functions nor a solution of a Monge–Ampère equation.

References. [CLD12, Sections 6.3–6.9]; [CLD25, Sections 8.7 and 17.8]; [GK17, Sections 10–12]. The proofs combine continuous mixed-product convergence, smooth Stokes and elementary polynomial identities. Chapter 21 discusses the larger variational frameworks separately.

20.12 The graph Laplacian as an intersection matrix

The slope formula, model measure, and negative intersection pairing become the same calculation on a semistable curve. Keeping the length scale visible also resolves several normalization ambiguities in local heights. We first work on a finite connected compact metric graph Γ. Subdivide loops if necessary so that every edge has two distinct endpoints. Denote its edge lengths by $\ell_e > 0$.

For a continuous function which is C^2 on edges and has one-sided derivatives at vertices, set

$$\Delta f = -f''\,dt - \sum_v \left(\sum_{e \ni v} \partial_{e,v} f \right) \delta_v.$$

This is the nonnegative-operator convention: it is the negative of the curvature convention $\mathrm{d}'\mathrm{d}''f$ used for graph potentials in this book. The graph has no designated boundary here; leaf vertices contribute to the displayed sum. For a graph serving as an analytic domain with boundary, one must instead specify which tests vanish at the boundary.

Proposition 20.12.1. *For continuous edgewise C^2 functions f, g, with integrable second derivatives and endpoint derivative limits,*

$$\int_\Gamma f\, d\Delta g = \sum_e \int_e f' g'\, dt = \int_\Gamma g\, d\Delta f.$$

In particular Δf has total mass zero. If $\Delta f = 0$, then f is constant.

Proof. On an oriented edge $[0,\ell]$, integration by parts gives $-\int fg'' = \int f'g' - [fg']_0^\ell$. At the initial endpoint the outgoing derivative is $g'(0)$, and at the final endpoint it is $-g'(\ell)$. Thus the two atomic contributions in Δg cancel precisely the bracket term. Sum over all edges. Setting $f = 1$ proves zero total mass; setting $f = g$ when $\Delta f = 0$ proves $f' = 0$ on each edge. Continuity and connectedness make the edgewise constants equal. □

For a function affine on every edge, its vertex values $h = (h_v)$ determine it. The coefficient vector of Δh is Lh, where

$$(Lh)_v = \sum_{e=vw} \frac{h_v - h_w}{\ell_e}, \qquad h^{\mathsf{T}} L h = \sum_{e=vw} \frac{(h_v - h_w)^2}{\ell_e}.$$

Parallel edges are counted separately. In terms of an oriented incidence matrix B and $C = \operatorname{diag}(\ell_e^{-1})$, one has $L = BCB^{\mathsf{T}}$. Reversing an edge changes one column of B by a sign and leaves L unchanged. The kernel is the space of constant vectors, and the image is the hyperplane of vectors with coordinate sum zero.

Proposition 20.12.2 (The vertical divisor calculation)**.** *Let $\mathcal{X}$ be a regular proper split strictly semistable curve over a complete DVR R, with reduced special fibre $\sum_v C_v$. Assume distinct branches at each node belong to distinct components, after subdivision if needed. Put $\lambda = -\log|\pi|$ for a uniformizer. Every node gives an edge of length λ. For vertical divisors $D = \sum_v a_v C_v$ and $E = \sum_v b_v C_v$, their model functions have values $h_D(v) = \lambda a_v$ and $h_E(v) = \lambda b_v$, and*

$$\mathrm{d}'\mathrm{d}''h_D = \sum_v \deg(\mathcal{O}(D)|_{C_v})\,\delta_v,$$

$$\int_\Gamma h_D\,\mathrm{d}'\mathrm{d}''h_E = \lambda(D\cdot E) = -\sum_{e=vw} \frac{(h_D(v)-h_D(w))(h_E(v)-h_E(w))}{\ell_e}.$$

Proof. The off-diagonal intersection number $C_v \cdot C_w$ is the number of their nodes, since the model is regular and split semistable. The whole special fibre is the principal divisor of π, so its intersection with each component is zero. Hence C_v^2 is minus the number of edges incident to v. It follows that

$$\deg(\mathcal{O}(D)|_{C_v}) = \sum_{e=vw} (a_w - a_v).$$

The model-weight formula of Lemma 19.9.1 gives $h_D(v) = \lambda a_v$. The slope along $e = vw$ away from v is $(h_D(w) - h_D(v))/\lambda = a_w - a_v$. Summing

gives the first formula. Multiplying its version for E by h_D and summing over vertices gives $\lambda \sum_v a_v (E \cdot C_v) = \lambda (D \cdot E)$. Grouping the two endpoint contributions of each edge gives the last expression. □

Corollary 20.12.3. *One has $D^2 \leq 0$, with equality exactly when all coefficients a_v are equal. Thus the vertical intersection pairing is negative definite modulo the whole special fibre.*

This is the graph form of the vertical Hodge index statement. It is proved here under the split regular reduced-fibre hypotheses. With component multiplicities or nonsplit residue fields, the intersection matrix and graph weights must be adjusted; the unweighted formula should not be transplanted unchanged. In a model with a node of thickness m, the corresponding skeleton edge has length $m\lambda$; resolving that node replaces it by a chain of length-λ edges. Linear interpolation on the chain gives the same energy.

20.13 Solving the graph Green equation

Theorem 20.13.1. *For a finite signed atomic measure $\nu = \sum_v d_v \delta_v$ with $\sum_v d_v = 0$, there exists a continuous PL function g_ν such that*

$$\Delta g_\nu = \nu, \qquad \textit{equivalently} \qquad \mathrm{d}'\mathrm{d}'' g_\nu = -\nu.$$

It is unique modulo constants. Given a probability measure μ, the normalization $\int g_\nu \, d\mu = 0$ determines it uniquely.

Proof. Choose a vertex set containing the support of ν. The symmetric matrix L has kernel the constants, so its image is their orthogonal complement. The sum-zero condition gives $d \in \operatorname{im} L$. Solve $Lh = d$ and interpolate affinely on every edge. Its Laplacian is exactly ν. Any two solutions differ by a harmonic function, hence by a constant by Proposition 20.12.1. Subtracting the μ-integral imposes the normalization, since μ has mass one. □

The Green pairing of two degree-zero atomic measures is

$$\langle \nu, \eta \rangle_\Gamma = \int_\Gamma g_\nu \, d\eta.$$

It is independent of the additive constant and of the normalizing probability measure, since η has mass zero. Integration by parts gives symmetry and positivity:

$$\langle \nu, \eta \rangle_\Gamma = \sum_e \int_e g'_\nu g'_\eta \, dt, \qquad \langle \nu, \nu \rangle_\Gamma \geq 0,$$

with equality in the second expression only for $\nu = 0$. This positive Green pairing corresponds to the negative vertical intersection form with its sign reversed.

Example 20.13.2 (Two terminals and effective resistance)**.** For vertices $p \neq q$, put $\nu = \delta_p - \delta_q$ and choose $g_\nu(q) = 0$. The number

$$r(p, q) = g_\nu(p) - g_\nu(q) = \langle \nu, \nu \rangle_\Gamma > 0$$

is the effective resistance when an edge of length ℓ is a resistor of resistance ℓ. On a segment it is the distance. For two parallel paths of lengths a, b, a potential difference V produces total current $V/a + V/b$. Setting that current to one gives $r = ab/(a + b)$. These statements follow directly from $Lh = d$; no probabilistic interpretation is required.

Proposition 20.13.3 (Subdivision does not change the solution)**.** *Inserting a vertex with no charge into an edge leaves the PL solution, Green pairing and effective resistances unchanged.*

Proof. If the two new lengths are a, b, the zero-charge equation at the inserted vertex is $(h - h_0)/a + (h - h_1)/b = 0$. Hence $h = (bh_0 + ah_1)/(a + b)$, exactly linear interpolation. The endpoint currents are $(h_0 - h_1)/(a + b)$ and its negative, as before. The edge energy is

$$\frac{(h - h_0)^2}{a} + \frac{(h_1 - h)^2}{b} = \frac{(h_1 - h_0)^2}{a + b}.$$

Uniqueness modulo constants now proves the assertion for the full graph. □

20.14 Canonical graph measures and residual genus

Let R_e be the effective resistance between the endpoints of e after deleting its interior. If deletion disconnects those endpoints, set $R_e = +\infty$ and $(\ell_e + R_e)^{-1} = 0$. The resistance in the full graph is the parallel combination

$$r_e = \frac{\ell_e R_e}{\ell_e + R_e},$$

interpreted as $r_e = \ell_e$ for a bridge. Write $b = |E| - |V| + 1$.

Lemma 20.14.1 (Foster's identity)**.**

$$\sum_e \frac{r_e}{\ell_e} = |V| - 1, \qquad \sum_e \frac{\ell_e}{\ell_e + R_e} = b.$$

Proof. Let L^+ be the inverse of L on the sum-zero hyperplane, extended by zero on constants. If b_e is the incidence column for e, the defining Green equation gives $r_e = b_e^{\mathsf{T}} L^+ b_e$. Therefore

$$\sum_e \ell_e^{-1} b_e^{\mathsf{T}} L^+ b_e = \operatorname{tr}(L^+ B C B^{\mathsf{T}}) = \operatorname{tr}(L^+ L) = |V| - 1.$$

The last operator is the identity on a space of dimension $|V| - 1$ and zero on constants. Since $r_e/\ell_e + \ell_e/(\ell_e + R_e) = 1$, subtracting the first equality from $|E|$ gives the second. □

The canonical measure of a metric graph is the signed measure

$$\mu_{\mathrm{can}} = \sum_v \left(1 - \frac{\mathrm{val}(v)}{2}\right) \delta_v + \sum_e \frac{dt}{\ell_e + R_e}.$$

This explicit formula and its resistance-kernel characterization are classical; see Baker–Rumely, Section 14. Its mass is one: the vertex part has mass $|V| - |E| = 1 - b$, and Foster's identity makes the edge part have mass b. It is generally not positive. A trivalent vertex has coefficient $-1/2$.

A semistable curve carries more data than the unweighted graph: attach the residual genus $q(v) \geq 0$ to each vertex. Put $g = b + \sum_v q(v)$ and assume $g \geq 1$. The polarized canonical divisor and admissible probability measure are

$$K_\Gamma = \sum_v (2q(v) + \mathrm{val}(v) - 2)[v],$$

$$\mu_{\mathrm{ad}} = \frac{\delta_{K_\Gamma} + 2\mu_{\mathrm{can}}}{2g} = \frac{1}{g}\left(\sum_v q(v)\delta_v + \sum_e \frac{dt}{\ell_e + R_e}\right).$$

The identification of this measure with Zhang's admissible measure is the graph-theoretic input from admissible pairing theory. Its positivity and normalization are immediate from the formula, and can be checked without that identification: all displayed coefficients are nonnegative and the total mass is $(\sum q(v) + b)/g = 1$. Also $\deg K_\Gamma = 2g - 2$.

Example 20.14.2. For good reduction, the graph is a point with $q(v) = g$, so $\mu_{\mathrm{ad}} = \delta_v$. For a totally degenerate genus-one curve, the graph is a circle of length ℓ and all $q(v)$ vanish. The formula gives $\mu_{\mathrm{ad}} = dt/\ell$. For a tree with positive residual genera, every edge is a bridge, and the measure is $g^{-1}\sum_v q(v)\delta_v$. Thus neither total graph length nor the number of components alone determines the measure.

Three measures must now be distinguished: the generally signed μ_{can} of the bare graph, the positive probability measure μ_{ad} of the polarized graph, and the Chern measure of a specified metrized line bundle. An admissibly metrized dualizing line has Chern measure $(2g-2)\mu_{\mathrm{ad}}$, not a probability measure unless that degree is one. A general semipositive model line of degree d instead gives its own positive atomic measure of mass d. Equality with an admissible measure is a theorem about the chosen metric, not a consequence of the word canonical.

References. [Zh93, Appendix, especially Lemma a.6 and Theorem a.7]; [BRg, Sections 1, 4 and 14]. The finite-dimensional Green, energy, subdivision and Foster calculations above are included to make all signs and scale factors explicit. The full analytic admissible metric construction is cited, not reconstructed from a skeleton alone.

20.15 Green kernels for finite measures on a compact graph

The finite matrix calculation extends to measures which need not be atomic. This extension is useful for admissible metrics: the target curvature may have a density along the edges, whereas a model metric has atomic curvature. We give the functional-analytic construction on a finite connected compact metric graph Γ with positive edge lengths. It does not involve probability theory.

Fix $z \in \Gamma$, inserting it as a vertex if necessary. Let H_z be the real vector space of continuous functions u on Γ whose restriction to each edge is in H^1 and for which $u(z) = 0$. Put

$$\mathcal{E}(u,v) = \sum_e \int_e u'v'\,dt, \qquad \|u\|_H^2 = \mathcal{E}(u,u).$$

The derivatives here are weak derivatives on real intervals. Continuity at vertices is imposed separately; the construction does not impose a Kirchhoff condition on an arbitrary member of H_z.

Lemma 20.15.1. *The space H_z is a Hilbert space. With d the path metric and $D = \operatorname{diam}\Gamma$,*

$$|u(x) - u(y)|^2 \le d(x,y)\mathcal{E}(u,u), \qquad \|u\|_\infty \le \sqrt{D}\,\|u\|_H.$$

Proof. Integrate u' along a shortest path from y to x. Cauchy–Schwarz bounds the square of the integral by the path length times its derivative energy, which is at most the total energy. Taking $y = z$ gives the second estimate. A Cauchy sequence in the energy norm is therefore uniformly Cauchy, and its edge derivatives converge in L^2. On each edge, the fundamental theorem for H^1 functions identifies the uniform limit with the function obtained by integrating the limiting derivative and the limiting endpoint value. The limit has matching vertex values and vanishes at z. It belongs to H_z and the convergence is in energy norm. Definiteness follows because zero energy makes the function constant on a connected graph, and its value at z is zero. □

Theorem 20.15.2. *For every finite signed Radon measure ν on Γ with $\nu(\Gamma) = 0$, there is a unique $g_\nu \in H_z$ such that*

$$\mathcal{E}(g_\nu, v) = \int_\Gamma v\,d\nu \quad (v \in H_z).$$

Equivalently, $\Delta g_\nu = \nu$ in the weak graph sense. The same equation holds against all continuous edgewise H^1 tests, without a condition at z. Moreover,

$$\|g_\nu\|_H \le \sqrt{D}\,\|\nu\|_{\mathrm{TV}}, \qquad \|g_\nu\|_\infty \le D\,\|\nu\|_{\mathrm{TV}}.$$

Proof. Lemma 20.15.1 bounds the linear functional $v \mapsto \int v\,d\nu$ by $\sqrt{D}\|\nu\|_{\mathrm{TV}}\|v\|_H$. The Hilbert-space representation theorem gives its unique representing vector and the first bound; the second follows from the sup-norm estimate. Subtracting $v(z)$ from a general test leaves its derivative unchanged and does not change its integral against ν, because the latter has mass zero. This proves the assertion about all tests. For a smooth edgewise function, integration by parts recovers precisely the convention $\Delta = -\mathrm{d}'\mathrm{d}''$ of Section 20.12. □

The necessary mass condition can also be read directly from the equation: the constant test has zero derivative, so $\int 1\,d\nu = 0$. On a single-point graph the condition forces $\nu = 0$ and the normalized solution is zero. The nontrivial case is the graph with edges considered below.

20.15.1 Construction and symmetry of the kernel

For $y \in \Gamma$, apply the theorem to $\delta_y - \delta_z$ and denote the solution by k_y. Define

$$j_z(x, y) = k_y(x).$$

Proposition 20.15.3. *The function j_z is continuous on $\Gamma \times \Gamma$, is symmetric, vanishes when either argument is z, and satisfies*

$$\Delta_x j_z(x, y) = \delta_y - \delta_z, \qquad |j_z(x, y)| \le \sqrt{d(x, z) d(y, z)}.$$

Proof. The representing-vector identity gives $k_y(x) = \mathcal{E}(k_x, k_y) = k_x(y)$. The evaluation functional at x has norm at most $\sqrt{d(x, z)}$, so $\|k_x\|_H \le \sqrt{d(x, z)}$ and Cauchy–Schwarz gives the stated bound. Likewise, the functional $v \mapsto v(x) - v(x')$ has norm at most $\sqrt{d(x, x')}$; hence

$$\|k_x - k_{x'}\|_H \le \sqrt{d(x, x')}.$$

This proves continuity of the representing vectors in H_z and therefore joint continuity of their inner products. The differential equation and normalization are the defining properties of k_y. □

Corollary 20.15.4. *The normalized potential and energy pairing are*

$$g_\nu(x) = \int_\Gamma j_z(x, y)\, d\nu(y),$$
$$\mathcal{E}(g_\nu, g_\omega) = \iint_{\Gamma^2} j_z(x, y)\, d\nu(x)\, d\omega(y)$$

for finite signed measures of mass zero. The second expression is independent of z and positive definite when $\omega = \nu$.

Proof. The continuous bounded map $y \mapsto k_y \in H_z$ can be integrated against a finite signed measure. Pairing that integral with $v \in H_z$ gives $\int v\, d\nu$, so uniqueness identifies it with g_ν. Evaluation is continuous on H_z, giving the first formula. The second follows by pairing and Fubini; the kernel is bounded and both measures have finite total variation. Changing the normalization point adds only a constant to each solution, which leaves energy unchanged. Finally, zero energy implies $g_\nu = 0$, and hence ν vanishes on all continuous edgewise H^1 functions. These include the PL functions on arbitrary subdivisions, which are uniformly dense in $C(\Gamma)$. Thus $\nu = 0$. □

20.15.2 Normalization by a probability measure

Let μ be any positive Radon measure of mass one. The word probability specifies only this normalization; no stochastic construction is used. Set

$$a(x) = \int j_z(x,t)\, d\mu(t), \qquad c = \iint j_z(s,t)\, d\mu(s) d\mu(t),$$
$$g_\mu(x,y) = j_z(x,y) - a(x) - a(y) + c.$$

Theorem 20.15.5. *This is the unique continuous symmetric Green kernel with energy-class sections satisfying*

$$\Delta_x g_\mu(x,y) = \delta_y - \mu, \qquad \int g_\mu(x,y)\, d\mu(x) = 0.$$

It is independent of the auxiliary point z. Its sections are in general neither PL nor smooth.

Proof. Integration of the defining equation for j_z gives $\Delta a = \mu - \delta_z$. Subtract to obtain the equation for g_μ. Symmetry is inherited from j_z, and integration in x cancels all four terms because $\int a\, d\mu = c$. If another normalized kernel has the same equation, the difference of its sections has zero energy and is constant. The normalization makes this constant zero. This also proves independence of z. A measure with a nonzero density on an edge requires a nonzero distributional second derivative there, so its potential need not be PL. □

Proposition 20.15.6 (Weak convergence of measures and uniform convergence of potentials)**.** *Suppose ν_j and ν have mass zero, $\nu_j \rightharpoonup \nu$ against $C(\Gamma)$, and their total variations are bounded uniformly. Then $g_{\nu_j} \to g_\nu$ uniformly, and their self-energies converge.*

Proof. Pointwise convergence follows by testing against $j_z(x,\cdot)$. Uniform continuity of j_z on the compact product and the total-variation bound make the potentials equicontinuous. A finite net in Γ upgrades pointwise convergence to uniform convergence: control the finitely many values on the net, then the oscillation on each neighboring ball. Finally split

$$\int g_{\nu_j}\, d\nu_j - \int g_\nu\, d\nu = \int (g_{\nu_j} - g_\nu)\, d\nu_j + \int g_\nu\, d(\nu_j - \nu).$$

The first term tends to zero by uniform convergence and bounded total variation, and the second by weak convergence. □

The scope of this theorem is a fixed compact metric graph. A classical point of a Berkovich curve can lie at infinite distance along a ray outside such a graph, and its logarithmic Green function need not be continuous. To pass from the graph construction to an admissible metric on the analytic curve, one uses the curve-theoretic comparison between the Laplacian, the retraction, and the Chern measure. That comparison, and the treatment of divisor singularities, are additional analytic theorems. The Hilbert-space proof does not establish a higher-dimensional non-Archimedean Green theorem.

References. [BRg, Zh93]. The argument above combines the elementary graph energy estimate with Hilbert-space representation and bounded-kernel integration; it supplies the measure extension of the preceding finite-matrix construction.

Chapter 21

Canonical and toric metrics

21.1 Abelian varieties: residual geometry plus a real quadratic form

21.1.1 The uniformization picture

After the appropriate hypotheses and extensions in the uniformization theorem, an abelian analytic space is described using an extension

$$0 \longrightarrow T \longrightarrow E \longrightarrow B \longrightarrow 0$$

and a discrete lattice M with $A^{\mathrm{an}} \simeq E^{\mathrm{an}}/M$. The torus T supplies real tropical directions; B has good reduction and supplies residual algebraic geometry. The skeleton of A is a real torus of dimension equal to the toric rank, which can be smaller than $\dim A$.

This is a useful test for every theory in the series. In good reduction, the skeleton can be a point but an ample line bundle still has positive top-degree mass. In total degeneration, the real torus carries the relevant continuous distribution of mass. A general abelian variety combines both effects.

21.1.2 The canonical metric is not simply a quadratic function

For a line bundle with a cubist canonical metric, the pullback to E decomposes into a formal metric coming from B and a real quadratic contribution in the toric directions. Schematically, with the notation of CLD25 Chapter 19,

$$c_1(p^*L) = c_1(q^*M_B) + \tau^*\mathrm{d}'\mathrm{d}''\left(\tfrac{1}{2}q_L\right). \tag{21.1.1}$$

The affine part of the weight does not contribute to curvature. The quadratic form q_L encodes the polarization in the tropical directions; the residual line bundle M_B supplies the good-reduction contribution.

The map τ is naturally harmonic in the enlarged framework. It need not be original CLD-smooth. This is precisely the issue behind the correction of the canonical delta-metric examples in GK, acknowledged by GJR. A formula using harmonic coordinates should not be relabelled as an original smooth formula without proving that coordinate comparison.

21.1.3 Positivity and canonical measure

For an ample line bundle, the canonical metric is semipositive in the established geometric theories. In the CLD25 description, the positivity separates into the real quadratic and residual numerical conditions. The stated general comparison in Proposition 19.3.1 depends on the residual curvature comparisons from CLD25 Chapter 18; that dependency should remain visible when auditing the argument.

The canonical top-degree measure on A is the Haar measure on its canonical skeleton, normalized to have total mass $\deg_L(A)$. In the good-reduction case this is an atom. In the totally degenerate case it is a translation-invariant density on a real torus. The intermediate case has a lower-dimensional real support with a coefficient carrying the residual intersection degree.

Example 21.1.1 (A Tate elliptic curve)**.** For a Tate parameter q with $0 < |q| < 1$, the skeleton is a circle of length $\ell = -\log|q|$. If L has degree $d > 0$, its canonical measure is $d\,dt/\ell$ on that circle. The normalization is forced by the total degree: integrating the density gives d. Rescaling the absolute value changes both dt and ℓ, so their ratio has the required invariant total mass.

21.1.4 Relation to Gubler's earlier work

Canonical measures on abelian varieties and their tropical distributions were a major part of Gubler's work before and alongside the differential-form theories. CLD25 places these phenomena inside its current and harmonic-coordinate calculus. This is a synthesis and an additional analytic interpretation, not evidence that the underlying canonical measures first appeared in 2025.

The distinction between the ambient abelian variety and a subvariety is also important. The ambient canonical measure is translation invariant on its skeleton. A subvariety has its own tropical support, multiplicities, and possible degeneration dimensions; one cannot replace its measure by ambient Haar measure restricted set-theoretically. This leads to the tropical canonical-measure and equidistribution programme discussed next.

21.2 The toric pluripotential theory of Burgos Gil–Gubler–Jell–Künnemann

21.2.1 Why toric symmetry is analytically powerful

On the dense torus, an invariant metric can be encoded by a real function on $N_{\mathbb{R}}$. With the weight convention used here, positivity is expressed through convexity after choosing the corresponding trivialization; other toric references use a concave metric function with the opposite sign. The fan controls the behaviour at infinity, so the correct domain is the extended tropical toric space N_{Σ}, not just $N_{\mathbb{R}}$.

The boundary strata are essential. A function may be convex on the open real vector space but fail the extension conditions required by a metric on the complete toric variety. Likewise, mass can concentrate near or on strata at infinity. The extended topology and the sheaf of forms must be part of the definition.

21.2.2 The complex comparison and the positivity cones

The comparison paper relates tropical superforms and currents with suitable invariant complex toric objects. This makes complex analytic estimates available in the tropical setting, with carefully matched positivity and symmetry conventions. It also exposes an important difference from a naive analogy: real strong positivity in middle degree does not span all symmetric forms. The Plücker example in Chapter 7 is a concrete manifestation.

One should therefore transfer a theorem through the actual comparison functor and its hypotheses. The statement that tropical (p, q)-forms resemble complex forms does not identify every positive cone or every distributional

property. This is why the ordinary-positive coefficient estimate is the safe input for the continuous multiplier argument.

21.2.3 A genuine background-current BT theorem

Theorem 4.1.2 of the toric pluripotential paper constructs products

$$\mathrm{d}'\mathrm{d}''u_1 \wedge \cdots \wedge \mathrm{d}'\mathrm{d}''u_q \wedge T$$

for the stated locally bounded tropical psh functions and a positive closed tropical current T. It includes positivity, locality, symmetry, and the relevant continuity properties. This is a substantial arbitrary-background theorem in its tropical toric category.

For these tropical psh functions, local boundedness has particularly strong regularity consequences: finite psh functions in the local real convex picture are continuous, and the extended-boundary condition is part of the theory. Thus this theorem should not be described as merely the unresolved discontinuous bounded case of an arbitrary Berkovich psh class. Its domain is a specific, well-developed convex and toric setting.

The paper also treats unbounded products under additional hypotheses on singular loci. The conditions preventing excess intersection of singular sets are part of those theorems. They cannot be dropped to define a wedge of arbitrary singular currents.

21.2.4 What comparison with Berkovich geometry yields

Tropicalization relates the toric psh functions and measures to invariant non-Archimedean metrics. In the continuous classes where the comparison theorem applies, the mixed products agree after the appropriate pullback or pushforward interpretation. This gives explicit solutions and formulas in toric and related abelian settings.

The remaining step for a general analytic space is not simply to choose a toric chart once. A function or current may require refinements, different local presentations, and compatibility with all tests. A tropical background current representing one chart must descend through the relations between charts. The representation-independence problem in Chapter 24 is exactly where the special toric theorem meets the general analytic programme.

References. [BGJK]; [BGJK25, Theorems 4.1.2, 4.2.2 and Sections 5–7].

21.3 Canonical measures, equidistribution, and local heights

21.3.1 Gubler's canonical-measure programme

For a subvariety Z of an abelian variety, the canonical mixed measure is not generally a restriction of ambient Haar measure. Gubler describes its tropical pushforward using weighted real polyhedral pieces and the residual geometry of the Raynaud extension. If $d = \dim Z$ and the good-reduction abelian part has dimension b, the dimensions appearing in the general description can range from $d - b$ to d in the source theorem, subject to nonnegative dimensions.

In total degeneration, $b = 0$, so the full d-dimensional tropical picture is available. In mixed reduction, some mass can occur in smaller real dimensions. This is why arguments based on dimension in a real torus need additional care outside the totally degenerate case.

The paper explicitly corrects an earlier claim that the tropical image is always pure-dimensional in this general abelian setting. The corrected theorem retains its polyhedral description and measure formula. This author-acknowledged correction is a useful example of how to distinguish a lost auxiliary claim from the surviving main result.

21.3.2 Why tropical equidistribution can prove arithmetic statements

A small generic family of algebraic points has Galois-orbit measures converging to the normalized canonical measure under the relevant equidistribution hypotheses. Tropicalization pushes this convergence to a real torus, where the limiting measure has an explicit polyhedral density. The arithmetic assumption of small height thereby becomes a geometric assertion about the distribution of mass.

In Gubler's totally degenerate Bogomolov argument, difference maps on powers of a subvariety interact with this distribution. After the appropriate reduction by stabilizers, a generically finite difference map must transport canonical mass compatibly with degree. On suitable tropical pieces, the map's rank behaviour conflicts with the distribution forced by a hypothetical dense family of small points. The contradiction excludes that family.

This is a proof mechanism, not a substitute for the full argument with its stabilizer and genericity hypotheses. Its relevance here is that tropical multiplicities and canonical measures have arithmetic force before one introduces a full differential-form algebra. CLD and GK later provide local curvature and intersection languages compatible with these measures.

21.3.3 Toric heights and convex duality

For a semipositive toric metric, the real metric function has a Legendre–Fenchel dual on the moment polytope, often called its roof function. Local toric height formulas express intersection heights as integrals of these concave roof functions, with lattice-normalized volume and the standard factorial conventions. Gubler–Hertel extends the local-height and induction formulas to arbitrary rank-one non-Archimedean absolute values in the stated toric setting.

The elementary reason convex duality enters is that the slopes of the metric function encode characters, while its values record the norm. The moment polytope organizes those slopes. Mixed intersection numbers then correspond to mixed convex-geometric data. The numerical output is a height, whereas GK's local calculus also retains intermediate Chern and Green objects.

21.3.4 The constants that curvature forgets

If one replaces a metric by e^{-c} times that metric, the local weight increases by c and the curvature does not change. The local height against a fixed positive mixed measure changes by

$$c \deg(L_1 \cdots L_n).$$

This is already visible in the projective-line example above. A theory of actual norms or adelic line bundles therefore carries more information than the collection of curvature currents. A comparison between currents cannot by itself identify a Deligne pairing with its norm.

21.4 A reading route through the Gubler programme

For the local differential problem, read the algebraic-chart presentation first, then GK's definitions of preforms, relations and closed generators. Work through the corner formula before reading the local-height construction. The positivity paper should be read with the ordinary/strong/weak cone distinction already in place.

For harmonic coordinates, start with model functions and residual numerical triviality, then read the definition of a harmonic tropicalization and the sheaf it generates. Only after that should one compare strong currents with original currents. The curve cohomology paper provides concrete calculations and a warning about confusing topological and algebraic genus.

For positivity, read the Gubler–Rabinoff PL lifting and curve criterion together with its quantifiers under analytic field extension. Compare the resulting theorem on the PL class with CLD25's generated classes and residual criterion. A theorem on arbitrary continuous functions needs an additional approximation or curve-detection input.

For global applications, retain the model definition of semipositivity and the proper ample setting of envelopes and variational methods. In the toric setting, current products, convexity, boundary strata, and global equations admit an explicit comparison. Chapter 24 explains how to extract further questions from these results without silently changing the class of objects.

21.5 Convex weights and the normalization of Monge–Ampère

Toric formulas become easier to compare once the two sign conventions are fixed. In this section $u \in N_{\mathbb{R}}$ is the tropical coordinate $-\log|\cdot|$. We use a convex local weight f. The concave metric function in Gubler–Hertel is $\psi = -f$. If its moment polytope is $\Delta \subset M_{\mathbb{R}}$, the slopes of f lie in $P = -\Delta$. Lebesgue measure on $M_{\mathbb{R}}$ is normalized so that M has covolume one.

Proposition 21.5.1. *For a smooth function f in lattice coordinates on $N_{\mathbb{R}} \simeq \mathbb{R}^n$,*

$$(\mathrm{d}'\mathrm{d}''f)^n = n!\det(D^2 f)\, d'u_1 \wedge d''u_1 \wedge \cdots \wedge d'u_n \wedge d''u_n.$$

Proof. Expand $\mathrm{d}'\mathrm{d}''f = \sum_{i,j} f_{ij} d'u_i \wedge d''u_j$. A nonzero term in the nth power uses each primed and each double-primed index once. Choosing the order of the primed indices contributes $n!$ equal terms. The remaining permutation of the double-primed indices contributes its sign, so their sum is the determinant. The interleaved order displayed above is the positive-volume convention of Chapter 7. □

Thus the differential-form Monge–Ampère measure is $n!$ times the real Alexandrov measure. Omitting this factorial would already give the wrong degree for the standard simplex. The following calculation proves the atomic formula for finite polyhedral weights and fixes this normalization without using an analytic measure comparison.

21.6 Polyhedral Monge–Ampère by a gradient calculation

Let

$$f(u) = \max_{1 \le i \le s} \{\langle a_i, u\rangle + b_i\}, \qquad P = \mathrm{conv}(a_1, \dots, a_s),$$

where $a_i \in M_{\mathbb{R}}$ and P has dimension n. No rationality assumption is needed for the real calculation. At $x \in N_{\mathbb{R}}$ define the subdifferential

$$\partial f(x) = \{p : \ f(u) \ge f(x) + \langle p, u - x\rangle \text{ for every } u\}.$$

Lemma 21.6.1. *The subdifferential is the convex hull of the slopes active at x:*

$$\partial f(x) = \mathrm{conv}\{a_i : f(x) = \langle a_i, x\rangle + b_i\}.$$

Proof. Each active affine function supports f at x, so every convex combination of its slopes belongs to $\partial f(x)$. If p lies outside that convex hull, strict separation gives a vector v such that $\langle p, v\rangle$ exceeds every active $\langle a_i, v\rangle$. For sufficiently small $t > 0$, inactive affine functions remain below the maximum at $x + tv$. Hence

$$\frac{f(x+tv) - f(x)}{t} = \max_{i \text{ active}} \langle a_i, v\rangle < \langle p, v\rangle,$$

contradicting the subgradient inequality. □

Use the smooth convex functions

$$f_\epsilon(u) = \epsilon \log \left(\sum_{i=1}^{s} e^{(\langle a_i, u\rangle + b_i)/\epsilon} \right), \qquad 0 \le f_\epsilon - f \le \epsilon \log s.$$

The estimate is global on $N_{\mathbb{R}}$. It follows by factoring out the largest exponential and bounding the remaining sum between one and s.

Lemma 21.6.2 (The gradient parametrizes the slope polytope)**.** *For every $\epsilon > 0$, $\nabla f_\epsilon : N_{\mathbb{R}} \to \operatorname{int} P$ is a diffeomorphism.*

Proof. Let w_i be the corresponding positive exponential weights, normalized to sum to one. Differentiation gives

$$\nabla f_\epsilon = \sum_i w_i a_i, \quad D^2 f_\epsilon = \epsilon^{-1} \left(\sum_i w_i a_i a_i^t - \overline{a}\,\overline{a}^t \right), \qquad \overline{a} = \sum_i w_i a_i.$$

For a nonzero vector v, its quadratic value is ϵ^{-1} times the weighted variance of the numbers $\langle a_i, v\rangle$. This variance is positive because the a_i affinely span $M_{\mathbb{R}}$. The Hessian is therefore positive definite, and the gradient is locally invertible and globally injective by strict convexity. Its value lies in $\operatorname{int} P$ since all weights are positive.

Given $p \in \operatorname{int} P$, some Euclidean ball of radius $c > 0$ about p lies in P. The support function $h_P(u) = \max_i \langle a_i, u\rangle$ satisfies $h_P(u) - \langle p, u\rangle \ge c|u|$. Also $f_\epsilon \ge f \ge h_P + \min_i b_i$. Thus $f_\epsilon(u) - \langle p, u\rangle$ is coercive and has a minimizer. At that point its derivative vanishes, giving $\nabla f_\epsilon = p$. This proves surjectivity, and the inverse function theorem supplies a smooth inverse. □

Theorem 21.6.3 (The atomic formula)**.** *Let $\mathcal{V}$ be the finite set of vertices of the domains-of-linearity complex of f. Then, weakly as measures on $N_{\mathbb{R}}$,*

$$(\mathrm{d}'\mathrm{d}'' f_\epsilon)^n \longrightarrow n! \sum_{x \in \mathcal{V}} \operatorname{vol}_M(\partial f(x))\, \delta_x.$$

The total mass is $n!\operatorname{vol}_M(P)$.

Proof. For a continuous compactly supported test η, the change of variables $p = \nabla f_\epsilon(u)$ gives

$$\int \eta(u)(\mathrm{d}'\mathrm{d}'' f_\epsilon)^n = n! \int_{\operatorname{int} P} \eta(x_\epsilon(p))\, dp, \qquad x_\epsilon = (\nabla f_\epsilon)^{-1}.$$

For almost every $p \in P$, the function $f(u) - \langle p, u \rangle$ has a unique minimizer $x(p)$, which is a vertex. To see the exceptional set directly, use the finite polyhedral decomposition of f. If a positive-dimensional face consists of minimizers, then p belongs to its subdifferential, which lies in an affine space of dimension at most $n-1$: every tangent vector to that face has a prescribed pairing with p. There are finitely many such faces. Outside their subdifferentials and the boundary of P, the coercive function has a unique vertex minimizer.

For each such p, the coercive bound in Lemma 21.6.2 bounds all $x_\epsilon(p)$ for $0 < \epsilon \leq 1$. Uniform convergence $f_\epsilon \to f$ makes every cluster point a minimizer of $f - \langle p, \cdot \rangle$. Uniqueness gives $x_\epsilon(p) \to x(p)$. Dominated convergence applies because P has finite volume and η is bounded. The set of p with minimizer x is $\partial f(x)$ up to its lower-dimensional boundary. This gives the atomic formula. Taking the constant integrand one in the change-of-variables formula, and using that these subgradient polytopes partition P up to null sets, gives the total mass. □

The continuous convex-product theorem identifies this weak limit with $(\mathrm{d}'\mathrm{d}''f)^n$. Thus the atom is controlled by a dual polytope, rather than by the number of affine pieces meeting at the vertex. The same number of pieces can produce different masses when their slopes have different lattice geometry.

21.6.1 Mixed products

For finite convex functions, the subdifferential of a sum is the Minkowski sum of the subdifferentials. In the polyhedral case this follows from directional derivatives: the directional derivative at x is the support function of the active-slope polytope. Directional derivatives add, and support functions determine compact convex sets. Hence

$$\partial \left(\sum_i t_i f_i \right)(x) = \sum_i t_i \partial f_i(x) \qquad (t_i > 0).$$

On a common subdivision, apply Theorem 21.6.3 to $\sum_i t_i f_i$ and compare the coefficient of $t_1 \cdots t_n$. With mixed volume normalized by $V(P, \ldots, P) = \mathrm{vol}_M(P)$, the result is

$$\mathrm{d}'\mathrm{d}''f_1 \wedge \cdots \wedge \mathrm{d}'\mathrm{d}''f_n = n! \sum_x V(\partial f_1(x), \ldots, \partial f_n(x)) \delta_x.$$

Here the polynomiality of volume under Minkowski sums is the usual mixed-volume theorem. Polynomiality on the current side follows from multilinearity of the continuous products. The factorial is checked by setting all $f_i = f$. If the sum of the slope spans is lower dimensional, both sides vanish; otherwise the preceding full-dimensional calculation applies to their sum.

Example 21.6.4 (Simplex and box)**.** For $f(u) = \max(0, u_1, \dots, u_n)$, the only full-dimensional subdifferential is the standard simplex at the origin, of lattice volume $1/n!$. Hence $(\mathrm{d}'\mathrm{d}''f)^n = \delta_0$. For $g(u) = \sum_{i=1}^n a_i \max(0, u_i)$ with $a_i > 0$, the subdifferential at the origin is the box $\prod_i [0, a_i]$, so

$$(\mathrm{d}'\mathrm{d}''g)^n = n! \left(\prod_i a_i \right) \delta_0.$$

The first formula corresponds to the degree-one polarization on projective space; the second has the multinomial factor of a product polarization on $(\mathbb{P}^1)^n$. These comparisons use the toric measure theorem below.

21.7 From the real measure to the analytic toric measure

Let K be algebraically closed, complete and nontrivially valued, let Σ be a complete rational fan, and let L be a toric line bundle on the normal toric variety X_Σ. Write Ψ for the concave support function associated to a toric rational section. Gubler–Hertel's classification identifies continuous semipositive toric metrics with concave functions ψ such that $\psi - \Psi$ is bounded. The classification includes the extension to the toric boundary; it is not an assertion only about the dense torus.

Their measure comparison says, in our convex sign convention,

$$\mathrm{trop}_* \, c_1(L, \|\cdot\|)^n = (\mathrm{d}'\mathrm{d}''f)^n, \qquad c_1(L, \|\cdot\|)^n = \rho_*(\mathrm{d}'\mathrm{d}''f)^n, \qquad f = -\psi,$$

where ρ is the toric Gauss section, and the real measure is extended by zero on the boundary of the extended tropicalization. This is an imported analytic comparison theorem. The preceding gradient proof computes its right side in the polyhedral case; it does not by itself identify the analytic measure on tests that do not factor through tropicalization. The second equality is the part that locates the analytic measure on the Gauss section.

Remark 21.7.1 (Smooth on the real vector space is not smooth at the analytic boundary). The functions f_ϵ used above are smooth on $N_{\mathbb{R}}$. They need not give original CLD-smooth weights at boundary points of X_Σ^{an}. On the affine line, the expression

$$\epsilon \log(1 + |T|^{1/\epsilon})$$

extends continuously to $T = 0$, but is not locally constant there. Original smooth functions are locally constant at a rigid point in this setting, as explained in Chapter 8. Thus this convenient real regularization is not the global original-smooth approximation constructed in Chapter 20. The latter uses exact deletion in a regularized maximum to handle vanishing sections.

21.8 Roof functions and the information lost by curvature

The convex conjugate of f is $f^*(p) = \sup_u(\langle p, u\rangle - f(u))$. In the concave toric convention the roof is

$$\vartheta(m) = \inf_u(\langle m, u\rangle - \psi(u)) = -f^*(-m), \qquad m \in \Delta.$$

It is concave because it is an infimum of affine functions of m. For a PL weight, its graph is the upper concave envelope of the coefficient data in this sign convention. The roof contains values as well as slopes.

Proposition 21.8.1. *Replacing the metric by $e^{-c}\|\cdot\|$ replaces f by $f + c$, ψ by $\psi - c$, and ϑ by $\vartheta + c$. Its curvature measure is unchanged.*

Proof. The metric weight is minus the logarithm of the norm, so it increases by c. Taking the infimum in the roof formula adds the same constant. The differential $\mathrm{d}'\mathrm{d}''$ kills constants. □

Gubler–Hertel's diagonal toric local-height formula is

$$\lambda_{\overline{L}}^{\mathrm{tor}}(X_\Sigma) = (n+1)! \int_\Delta \vartheta(m)\, d\,\mathrm{vol}_M(m).$$

If all $n + 1$ metric factors are scaled by e^{-c}, the change is $(n + 1)c \deg_L(X)$, since $\deg_L(X) = n!\,\mathrm{vol}_M(\Delta)$. If only one factor of a mixed local height is scaled, the change is c times the degree of the remaining n line bundles. These are consistent formulas for different variations; they must not be confused.

Example 21.8.2. On $\mathbb{P}^1$ take the usual toric section of $\mathscr{O}(1)$ with $\Delta = [0,1]$, $\Psi(u) = \min(0,u)$, and $f = -\Psi = \max(0,-u)$. Its roof is zero and its curvature is the mass-one atom at the Gauss point. After the constant metric change above, the roof is the constant c, the curvature remains the same atom, and the diagonal toric local height changes by $2c$. This single example checks the sign of the roof, the factorial in dimension one, and the number of metric factors in a height.

References. The toric classification, measure comparison and height formula are [GH, Theorems 2.5.8, 2.5.10 and 2.6.6]. The real gradient and atomic calculations are proved here; the broader tropical current framework is [BGJK25, Sections 3–4].

21.9 Tate's limiting construction for metrics

The canonical metric is obtained by a contraction, before one chooses a differential-form theory. This separates its existence from the later question whether its curvature has an original smooth, weakly smooth, or delta-form representative.

Let X be a proper K-variety, let $F : X \to X$ be a morphism, and fix an isomorphism $\Phi : F^*L \simeq L^{\otimes q}$ with $q > 1$. The isomorphism is part of the data. For continuous metrics m_1, m_2 on L, define

$$d(m_1,m_2) = \sup_{x \in X^{\mathrm{an}}} \left| \log \frac{\|s(x)\|_{m_1}}{\|s(x)\|_{m_2}} \right|.$$

The ratio is independent of a nonzero local frame s. Properness makes the supremum finite. Identifying every metric with its weight difference from one fixed metric identifies this metric space with the complete Banach space $C(X^{\mathrm{an}},\mathbb{R})$.

Theorem 21.9.1. *There is a unique continuous metric m_{can} for which Φ is an isometry. Starting from any continuous metric m_0, form m_{j+1} by taking the qth root of the metric on $L^{\otimes q}$ transported from F^*m_j through Φ. Then m_j converges uniformly to m_{can}, and*

$$d(m_j,m_{\mathrm{can}}) \le \frac{q^{-j}}{1-q^{-1}} d(m_1,m_0).$$

Proof. Let $\mathcal{T}$ be the described operator. A weight difference u becomes $q^{-1}u \circ F$, so $d(\mathcal{T}m,\mathcal{T}m') \le q^{-1}d(m,m')$. Consequently

$$d(m_{j+1},m_j) \le q^{-j} d(m_1,m_0).$$

Summing the geometric series proves that the sequence is Cauchy and gives the error bound. Completeness gives a limit, and continuity of $\mathcal{T}$ makes it fixed. If two metrics were fixed, their distance would be at most q^{-1} times itself, hence zero. The fixed-point equation is exactly the assertion that Φ is an isometry. □

Corollary 21.9.2. *Suppose a class of continuous semipositive metrics is closed under pullback, positive tensor roots, and uniform limits. If it contains a starting metric on L, then m_{can} belongs to that class.*

Proof. Inductively every iterate belongs to the class. Theorem 21.9.1 supplies the required uniform convergence. □

The model definition of semipositivity has these stability properties in its proper setting. For ample L, a suitable positive tensor power has a globally generated model, providing a semipositive starting metric. This constructs canonical semipositivity by model approximation. It does not establish original smoothness of the limit: a uniform limit of original smooth functions need not be original smooth. Even a limit of smooth semipositive metrics would only establish the corresponding approximation property.

Proposition 21.9.3 (Dependence on the polarization isomorphism)**.** *Replace Φ by $a\Phi$, where $a \in K^{\times}$. With the transport convention above, the new canonical metric is $|a|^{-1/(q-1)} m_{\mathrm{can}}$. Its curvature is unchanged.*

Proof. A metric scaled by $c > 0$ on L scales by c on F^*L and by c^q on $L^{\otimes q}$. Since Φ was an isometry, the new isometry condition for $a\Phi$ is $|a|c^q = c$. Solving gives $c = |a|^{-1/(q-1)}$. A constant change of weight has zero curvature. □

For definiteness in the rest of this book, Φ denotes the map $F^*L \to L^{\otimes q}$, so the factor is $|a|^{-1/(q-1)}$. A rigidification removes this scalar ambiguity for the canonical constructions on abelian varieties. The invariant content is that changing the polarization isomorphism changes a constant of the metric; curvature alone cannot recover that constant.

21.10 Canonical measures and their normalization

Now assume X has dimension n, L is ample, and F is finite surjective. Let $\mu = c_1(L, m_{\mathrm{can}})^n$ be the measure constructed by the continuous semipositive model-metric theory. This construction, its continuity, and its projection formula are inputs independent of original smooth representability.

Proposition 21.10.1. *Writing $V = \deg_L(X) > 0$, one has $\deg F = q^n$, $\mu(X^{\mathrm{an}}) = V$, and $F_*\mu = \mu$.*

Proof. The algebraic projection formula gives $(\deg F)V = \deg((F^*L)^n) = q^nV$, hence the degree formula. The total-mass theorem gives $\mu(X^{\mathrm{an}}) = V$. The fixed metric identity gives $c_1(F^*\overline{L})^n = q^n\mu$ on the source. Pushing forward and using the measure projection formula gives

$$q^n F_*\mu = F_* c_1(F^*\overline{L})^n = (\deg F)\mu = q^n\mu.$$

No pullback of an arbitrary current is used: the pulled-back objects here are actual metrized line bundles and their defined Chern measures. □

Invariance alone does not characterize this measure. For $t \mapsto mt$ on $\mathbb{R}/\mathbb{Z}$, both Haar probability measure and the atom at zero are invariant. Hence an argument claiming Haar measure solely from invariance under multiplication is incomplete. Gubler's theorem supplies the additional geometry: for an abelian variety, the canonical measure is supported on its canonical skeleton and corresponds there to Haar measure, with mass equal to the intersection degree. The skeletal support and translation invariance are substantial parts of that theorem.

Lemma 21.10.2. *A finite Borel measure on a real torus invariant under a dense subgroup of translations is invariant under every translation. If its mass is V, it is V times Haar probability measure.*

Proof. For a continuous function f, translations by $a_j \to a$ give uniform convergence $f(\cdot + a_j) \to f(\cdot + a)$ on the compact torus. Taking integrals transfers invariance to a. To prove uniqueness, let m be Haar probability measure. Translation invariance and Fubini give

$$\int f\, d\mu = \int\!\!\int f(x + a)\, d\mu(x)\, dm(a) = V \int f\, dm.$$

□

21.10.1 The circle formula

On a circle of length ℓ, the normalized Green function for Haar measure is, for $0 \le t \le \ell$,

$$g(t) = \frac{t^2}{2\ell} - \frac{t}{2} + \frac{\ell}{12}.$$

The endpoint values agree. On the open edge $g'' = 1/\ell$; at the identified endpoint the derivative jumps from $1/2$ to $-1/2$, contributing $-\delta_0$ to the curvature. Therefore

$$\mathrm{d}'\mathrm{d}''g = \frac{dt}{\ell} - \delta_0, \qquad \int_0^\ell g(t)\frac{dt}{\ell} = 0.$$

The integral follows from $1/6 - 1/4 + 1/12 = 0$. This is a graph Green equation for a point of the circle. On a Tate elliptic curve, the canonical Chern measure of a degree-d line is $d\,dt/\ell$ on the skeleton. The formula for g does not by itself provide the logarithmic singularity at a chosen classical point of the analytic curve; constructing that analytic Green function additionally uses the attached analytic branches.

21.11 The same limiting argument for heights

Over a global field, choose a Weil height h_L satisfying $|h_L(FP) - q h_L(P)| \le C$. This bounded-error functoriality is a standard input of height theory. Then

$$\widehat{h}_L(P) = \lim_{j\to\infty} q^{-j} h_L(F^j P)$$

exists, satisfies $\widehat{h}_L(FP) = q\widehat{h}_L(P)$, and differs from h_L by at most $C/(q-1)$.

Proof. Consecutive terms differ by at most Cq^{-j-1}; sum the geometric series. Shifting the index gives the functional equation. If two functions satisfy this equation and differ by a bounded function, iterate and divide by q^j to show they agree. Thus the limit is independent of the initial height within its bounded equivalence class. If h_L is bounded below, the limit is nonnegative. □

For a symmetric ample line on an abelian variety, take $F = [m]$ and $q = m^2$. The theorem of the square gives the parallelogram identity for a Weil height

up to a bounded error. Applying it to $[m]^j P, [m]^j Q$, dividing by m^{2j}, and taking limits removes that error:

$$\widehat{h}(P+Q) + \widehat{h}(P-Q) = 2\widehat{h}(P) + 2\widehat{h}(Q).$$

This produces the quadratic Néron–Tate height. Over a number field, its zero points are torsion: if $\widehat{h}(P) = 0$, the orbit $[m]^j P$ has bounded Weil height and bounded degree over the ground field. Northcott finiteness makes two orbit points equal, so $(m^i - m^j)P = 0$. Conversely torsion gives zero by the scaling identity. Over a function field, this use of Northcott is unavailable in this form, and constant-field trace phenomena must be retained; one cannot carry over the zero-height characterization unchanged.

These metric and height constructions precede CLD. Gubler's canonical-measure programme links them to tropical distributions; CLD supplies currents and local curvature identities; GK adds products and local intersections; GJR enlarges the coordinates needed for canonical tropicalizations. The constructions address successive mathematical questions, and their chronology reflects a genuine dependence of ideas rather than four alternative names for one theory.

References. [Gub10, Section 3, Example 7.2 and Corollary 7.3]; [Gub07]; [GJR, Section 16 and Remark 16.4].

21.12 Canonical measures and two kinds of dimension

The real dimension of a canonical tropicalization of an abelian variety is its toric rank. The algebraic dimension is the toric rank plus the dimension of its good-reduction abelian part. Gubler's canonical-measure formula keeps track of both. Forgetting the second part would give an incorrect measure formula even for an abelian variety with good reduction.

In the setting of [Gub10], start with a discretely valued field and pass to the completed algebraic closure with the extended absolute value. Let A be an abelian variety of dimension g, with Raynaud uniformization

$$0 \longrightarrow T^{\mathrm{an}} \longrightarrow E \longrightarrow B^{\mathrm{an}} \longrightarrow 0, \qquad A^{\mathrm{an}} = E/M.$$

Here T is a split torus of rank r, B has good reduction and dimension b, and $g = r + b$. The tropicalization of the period group M is a full lattice $\Lambda \subset N_{\mathbb{R}} \simeq \mathbb{R}^r$, giving

$$\tau : A^{\mathrm{an}} \longrightarrow N_{\mathbb{R}}/\Lambda.$$

This construction uses the torus torsor and its canonical metric data. It is not a claim that A^{an} admits one global moment map by analytic units. On a proper connected abelian variety, global analytic functions are constant.

Theorem 21.12.1 (The polyhedral description of canonical measures)**.** *Let $X \subset A$ be an irreducible closed subvariety of dimension d in the stated source setting. There are finitely many rational simplices Δ_j in $N_{\mathbb{R}}/\Lambda$ whose union is $\tau(X^{\mathrm{an}})$, with*

$$\max(0, d - b) \leq \dim \Delta_j \leq \min(d, r).$$

For canonically metrized line bundles $\overline{L}_1, \dots, \overline{L}_d$ on A, one has

$$\tau_*\big(c_1(\overline{L}_1|_X) \cdots c_1(\overline{L}_d|_X)\big) = \sum_j c_j \lambda_{\Delta_j}.$$

Here λ_{Δ_j} is relative Lebesgue measure on the simplex, not an ambient r-dimensional measure unless its dimension is r. If all L_i are ample, the coefficients can be chosen strictly positive.

Open proof obligation (RC2). Prove the canonical measure and dimension conclusions in the stated setting; Gubler Theorem 1.1 is supplied.

21.12.1 Nondegenerate simplices in an alteration

Choose a semistable alteration $f : Y \to X^{\mathrm{an}}$ of generic degree e, in the formal-model setting of the source. A stratum S of the special fibre corresponds to a canonical simplex Δ_S in the skeleton, with

$$\dim S + \dim \Delta_S = d.$$

The map to A induces an integral affine map on Δ_S and a residual map from S to the good-reduction abelian part. The simplex is nondegenerate for f when both maps preserve the respective dimensions:

$$\dim f_{\mathrm{aff}}(\Delta_S) = \dim \Delta_S, \qquad \dim q_s \Phi_s(S) = \dim S.$$

The residual lift Φ_s is determined up to period translation, which does not change either dimension. This is the definition in [Gub10, Section 6.3].

Proposition 21.12.2. *A nondegenerate simplex of dimension s satisfies $d - b \le s \le \min(d, r)$.*

Proof. The residual image has dimension $\dim S = d - s$ and lies in a variety of dimension b. Thus $d - s \le b$. The injective affine map of the simplex into $N_{\mathbb{R}}$ gives $s \le r$, and $s \le d$ is automatic from the dimension formula for strata. □

For a single ample line bundle L with canonical metric, the source gives a density formula on each nondegenerate simplex. In its simplex coordinates, let $\ell_S : \mathbb{R}^s \to N_{\mathbb{R}}$ be the injective linear part of f_{aff}, let b_L be the positive definite bilinear form from the polarization, and set

$$\Lambda_S = \ell_S^{-1}(\Lambda), \qquad \Lambda_S^L = \{b_L(\ell_S(\,\cdot\,), \lambda) : \lambda \in \Lambda\} \subset (\mathbb{R}^s)^*.$$

These are full lattices in the source setting. For a measurable subset Ω of the relative interior of the simplex, [Gub10, Theorem 6.7] gives

$$c_1(f^*\overline{L})^d(\Omega) = \frac{d!}{(d-s)!}\, \deg_H(S)\, \frac{\operatorname{covol}(\Lambda_S^L)}{\operatorname{covol}(\Lambda_S)}\, \operatorname{vol}(\Omega).$$

The symbol $\deg_H(S)$ denotes the residual intersection degree defined from the proper residual cycle in the source's Section 5.17, with H the induced ample line bundle on the good-reduction part. It is not an undefined degree of an arbitrary open stratum. For ample L and a nondegenerate simplex it is positive. The density is the product of a residual algebraic degree and a real lattice-volume factor.

The formula is compatible with keeping the original absolute value. If all logarithmic values are rescaled by a positive constant c, then the period lattice and simplex coordinates scale by c, while b_L scales by c^{-1}. Thus Λ_S has covolume multiplied by c^s, Λ_S^L is unchanged in the corresponding dual coordinates, and $\operatorname{vol}(\Omega)$ is multiplied by c^s. These factors cancel. This is a change-of-coordinate check, not permission to renormalize a finite field extension independently.

21.12.2 Projection and the support of the measure

Over one fixed ground field, the projection formula gives

$$f_* c_1(f^*\overline{L}_1) \cdots c_1(f^*\overline{L}_d) = e\, c_1(\overline{L}_1|_X) \cdots c_1(\overline{L}_d|_X).$$

The measure downstairs is therefore computed by pushing the skeletal measure upstairs and dividing by the alteration degree. This is a computation of a measure, for which proper pushforward is available. It is not a theorem that arbitrary actual differential representatives descend through the same alteration. The ground-field distinction in Chapter 23 still applies if an extension was used before constructing the alteration.

Corollary 21.12.3. *For ample L_i, the support of the tropical pushforward of their canonical mixed measure is all of $\tau(X^{\mathrm{an}})$.*

Proof. Every simplex in Theorem 21.12.1 has positive coefficient. An open neighbourhood of any point of a simplex meets its relative interior in positive relative Lebesgue measure; for a zero-dimensional simplex this means a positive atom. Hence every point in the union belongs to the measure support. Conversely, the measure is supported on this finite union, which is closed. □

Remark 21.12.4. A measure containing pieces of different dimensions does not by itself show that its support is not pure-dimensional. For example, Lebesgue measure on $[0,1]$ plus a positive atom at zero has pure one-dimensional support but a zero-dimensional measure component. Likewise, the dimension interval in the canonical-measure theorem does not refute purity of the tropical image. The author's erratum records a gap in an earlier purity proof; it does not supply a counterexample. These are distinct conclusions.

21.12.3 The ambient abelian variety and Haar measure

When $X = A$, one has $d = g = r + b$, so the dimension inequalities force every nondegenerate simplex to have dimension r. The canonical measure is supported on the canonical skeleton, and its tropical pushforward is

$$\tau_* c_1(\overline{L})^g = \deg_L(A)\, m_{N_{\mathbb{R}}/\Lambda},$$

where $m_{N_{\mathbb{R}}/\Lambda}$ is Haar probability measure. This is the ambient calculation in [Gub10, Example 7.2]. The total degree fixes the scalar.

The real uniqueness argument is short. A finite measure invariant under the dense subgroup of rational-period translations is invariant under every translation, by uniform continuity of continuous tests. If ν is such a measure

and m is Haar probability, then for a continuous test a, Fubini and translation invariance give

$$\int a\,d\nu = \int\int a(x+y)\,d\nu(x)\,dm(y) = \nu(N_{\mathbb{R}}/\Lambda)\int a\,dm.$$

The geometric input is the translation invariance of the canonical measure, or equivalently the constant density obtained from the canonical-metric formula. Invariance under the single map $[m]$ alone would not suffice: a Dirac mass at zero is also fixed by its pushforward.

At good reduction, $r = 0$, the real torus is one point and this formula becomes a degree-weighted Dirac measure. At total degeneration, $b = 0$, the support has full real dimension g. Mixed reduction lies between these extremes. These examples explain why a top-degree measure comparison can be correct while a claim that one tropicalization retains every lower-degree differential object is false.

References. [Gub10, Theorem 1.1 and its erratum, Sections 5.17 and 6.3–6.8, Theorem 6.12, Example 7.2]. The density theorem is cited; its dimension, normalization and support consequences are proved here.

21.13 The variational passage to equidistribution

The local measures of this book become arithmetic tools when metric variation detects the distribution of small points. The final variational argument is elementary; obtaining its lower bound is the arithmetic theorem. We separate these two steps.

Lemma 21.13.1. *Let M be compact Hausdorff, μ_j probability measures, and $a_j \to a$. Let $f \in C(M)$ and suppose that for all sufficiently small positive and negative t, a function $H_f(t)$ satisfies*

$$\liminf_j \left(a_j + t\int f\,d\mu_j\right) \geq H_f(t), \qquad H_f(0) = a,$$

and is differentiable at zero. Then $\int f\,d\mu_j \to H_f'(0)$. The same proof applies to a net.

Proof. For $t > 0$, subtract a and divide by t to obtain

$$\liminf_j \int f\,d\mu_j \geq \frac{H_f(t) - H_f(0)}{t}.$$

For $t < 0$, division reverses the inequality and exchanges the lower and upper limits, giving the same quotient as an upper bound for $\limsup_j \int f\,d\mu_j$. Let t tend to zero from its two sides. The quantities are bounded by $\|f\|_\infty$, so these limits are finite, and differentiability makes the bounds equal. □

In the arithmetic application, a_j is the original point height and μ_j is the normalized Galois-orbit measure at one place. Changing the local weight by tf, with the place factor absorbed into t, changes the point height exactly by $t\int f\,d\mu_j$. Arithmetic bigness and the fundamental inequality provide the function H_f. Its derivative is the integral of f against the normalized Chern measure. These are the substantive results in the variational equidistribution method of Szpiro–Ullmo–Zhang and Yuan, and in Gubler's function-field tropical setting.

One cannot simply vary an arbitrary semipositive metric in both directions by an arbitrary continuous f and assume semipositivity persists. The arithmetic lower bound must apply to the permitted perturbations, or be obtained through a volume or envelope argument. The squeeze lemma proves equidistribution after that input; it does not prove the input.

Lemma 21.13.2. *If probability measures μ_j, μ on a compact space satisfy convergence against a uniformly dense vector subspace $D \subset C(M)$, then $\mu_j \rightharpoonup \mu$ against all continuous functions.*

Proof. For $f \in C(M)$ choose $g \in D$ with $\|f - g\|_\infty < \varepsilon$. Then

$$\left|\int f\,d\mu_j - \int f\,d\mu\right| \le 2\varepsilon + \left|\int g\,d\mu_j - \int g\,d\mu\right|.$$

First take the limit in j, then let ε decrease to zero. □

The uniform mass bound is essential in this density argument. It is the measure analogue of the coefficient estimates used earlier for currents. Neither density nor weak convergence alone permits products of singular currents; here only scalar tests of probability measures are involved.

21.14 Difference maps and the stabilizer

Let X be an integral closed subvariety of an abelian variety A over an algebraically closed field. Denote its stabilizer by G. After quotienting by the

positive-dimensional stabilizer, the relevant case has finite stabilizer. The next argument explains the generic finiteness needed in the Bogomolov proof, including in positive characteristic; separability is not required.

Proposition 21.14.1. *If G is finite, then for some integer N, the difference map*

$$\alpha : X^N \longrightarrow A^{N-1}, \qquad (x_1, \dots, x_N) \longmapsto (x_2 - x_1, \dots, x_N - x_{N-1})$$

is generically finite onto its image.

Proof. The set-theoretic intersection $\bigcap_{x \in X}(X - x)$ equals the stabilizer: membership means $X + t \subseteq X$, which is equality because both are irreducible of the same dimension. The noetherian topology gives a finite subcollection $x_1, \dots, x_N$ whose intersection has dimension zero. Indeed a descending chain of closed intersections stabilizes; if its current intersection is larger than the full one, choose one further translate that makes it smaller. The fibre of α over $\alpha(x_1, \dots, x_N)$ is identified with $\bigcap_i (X - x_i)$ by sending a common translation t to $(x_1 + t, \dots, x_N + t)$. Thus this fibre is zero-dimensional, possibly nonreduced. Upper semicontinuity of fibre dimension for the proper map α shows that its generic fibre is zero-dimensional. Since X^N is integral, this is generic finiteness onto the image. □

Notice what this argument does not say: the map need not be finite on every fibre. The diagonal is contracted to zero. The coexistence of generic finiteness and this contracted diagonal is precisely what the measure argument exploits.

21.15 The tropical measure contradiction

We state the inputs in the totally degenerate setting of Gubler's theorem. Let K be the function field of a projective integral variety over an algebraically closed constant field, regular in codimension one, with the product formula determined by an ample class. Suppose A/K is totally degenerate at a place v. Pass to the completed algebraic closure at v for analytic geometry. We use:

1. The tropicalization of a d-dimensional subvariety is a pure d-dimensional finite polytopal set in the tropical real torus.

2. The normalized canonical measure pushes forward to a measure with strictly positive Lebesgue densities on its top-dimensional cells, and no mass on lower-dimensional polyhedral sets.

3. Generic small nets of points equidistribute to this measure, and the same theorem applies to products and images under homomorphisms.

These are the tropical geometry and arithmetic theorems proved in Gubler's work. The following proof is the argument after these inputs.

Theorem 21.15.1. *A positive-dimensional integral subvariety $X \subset A$ with finite stabilizer cannot have Zariski-dense points of arbitrarily small Néron–Tate height.*

Proof. Suppose otherwise and put $d = \dim X > 0$. Choose N as in Proposition 21.14.1 and let $Y = \alpha(X^N)$. Then $\dim Y = Nd$. The external tensor product polarization on X^N has height equal to the sum of the heights of its coordinates. Dense small points on X therefore give dense small points on X^N. More explicitly, the product of a Zariski-dense set with itself is dense; directing finite avoidance conditions and height bounds gives a generic net $P_j \in X^N$ with height tending to zero. Its image is generic in Y, since inverse images of proper closed subsets of Y are proper closed subsets of X^N. Quadratic height estimates for the difference homomorphism make the image heights tend to zero. Let μ and ν be the normalized tropical canonical measures on $\mathrm{Trop}(X)^N$ and $\mathrm{Trop}(Y)$. Equidistribution and compatibility of normalized finite Galois-orbit measures with the map give

$$\alpha_{\mathrm{trop},*}\mu = \nu, \qquad \alpha_{\mathrm{trop}}(u_1, \dots, u_N) = (u_2 - u_1, \dots, u_N - u_{N-1}).$$

For completeness, a map of finite transitive Galois sets has fibres of equal cardinality, so the pushforward of uniform orbit measure is uniform orbit measure. Pushforward of weak convergence by a continuous map follows by testing against pullbacks of continuous functions. Choose a small compact d-dimensional polytope σ in the relative interior of a top cell of $\mathrm{Trop}(X)$, contained in one affine lift of the real torus. The product σ^N has dimension Nd and strictly positive μ-mass. If V is the d-dimensional tangent space of σ, the differential of α_{trop} on V^N kills the diagonal copy of V. Hence

$$\dim \alpha_{\mathrm{trop}}(\sigma^N) \leq (N-1)d < Nd.$$

The compact image $\tau = \alpha_{\mathrm{trop}}(\sigma^N)$ is a lower-dimensional polyhedral subset of $\mathrm{Trop}(Y)$, so $\nu(\tau) = 0$. But the measure identity implies

$$0 < \mu(\sigma^N) \leq \mu(\alpha_{\mathrm{trop}}^{-1}(\tau)) = \nu(\tau) = 0,$$

a contradiction. This last inequality uses a Borel set directly; no choice of a continuous cutoff equal only at a single point would suffice in its place. □

The complete theorem also treats stabilizers and zero-dimensional images. Gubler proves that total degeneration passes to the required abelian quotients and forces the constant-field trace to vanish. The trace theorem then identifies zero-height points with torsion in this setting. After quotienting by the stabilizer, the theorem above forces the remaining image to be a torsion point. Pulling back gives a torsion translate of an abelian subvariety. These trace and quotient assertions are cited geometric inputs; the number-field Northcott argument is not a substitute for them over function fields.

The proof also explains the limitation of the argument in mixed reduction. The canonical measure of a d-dimensional subvariety may have pieces of several tropical dimensions. A lower-dimensional image need not have measure zero. One must then compare the dimensions actually carrying canonical mass, not merely the algebraic dimensions of source and target. Gubler's later canonical-measure theorem supplies exactly the refined information needed to formulate this problem.

21.16 Tropical boundary conditions and logarithmic curvature

The real vector space $N_{\mathbb{R}}$ describes the dense torus. Passing to N_{Σ} adds strata, changes the test sheaf, and allows curvature supported on the boundary. A calculation made only in $N_{\mathbb{R}}$ can therefore lose a divisor term. We begin with a complete one-dimensional calculation.

For the fan consisting of the zero cone and the positive ray, write $N_{\Sigma} = \mathbb{R} \cup \{+\infty\}$. On the analytic affine line this coordinate is $t = -\log|z|$, and $z = 0$ maps to $+\infty$. A smooth tropical function on a neighbourhood of $+\infty$ is constant on a sufficiently long tail. A positive-degree form vanishes there: it must come from the zero-dimensional boundary stratum.

Proposition 21.16.1 (The boundary slope formula)**.** *Let $U = (a, +\infty]$. Let f be a finite convex nonincreasing function on (a, ∞), and extend it to $+\infty$ by its limit in $\mathbb{R} \cup \{-\infty\}$. Write $\mu = f''$ for its distributional second derivative on the open interval. The increasing one-sided derivatives have a limit $\ell \leq 0$ at $+\infty$. On U,*

$$d'd''[f] = \mu - \ell\, \delta_{+\infty}.$$

Both terms on the right are positive measures. If $f(+\infty)$ is finite, then $\ell = 0$.

Proof. A test $\eta \in A_c^{0,0}(U)$ vanishes near a and is equal to a constant c for large t. Its Hessian has ordinary compact support in (a, ∞), so $[f](d'd''\eta) = \int f(t)\eta''(t)\, dt$ is well-defined even when $f(+\infty) = -\infty$. Distributional integration by parts for a convex function gives, for R beyond the nonconstant part of η and chosen away from derivative jumps,

$$\int_a^R f\eta''\, dt = \int_{(a,R)} \eta\, d\mu - cf'(R).$$

On every tail $[b, \infty)$ the positive measure μ has finite mass, bounded by $-f'_+(b)$, since the derivative is increasing and at most zero. Letting $R \to \infty$ proves the formula. If $\ell < 0$, choose $\ell < \ell/2 < 0$; for all sufficiently large t, the derivative is at most $\ell/2$, so $f(t) \to -\infty$. Thus a finite boundary value forces $\ell = 0$. □

Example 21.16.2. The function $f(t) = -t$ has zero interior Hessian but $d'd''[f] = \delta_{+\infty}$. Under $t = -\log|z|$, it is $\log|z|$. This is the boundary contribution in Poincaré–Lelong. By contrast, $f(t) = e^{-2t}$ has boundary value zero, interior Hessian $4e^{-2t}dt$, and no boundary atom. Both functions are psh on U, but neither is tropical smooth near the boundary.

The second example is also a useful complex comparison. Its complex pullback is $|z|^2$, a smooth function at $z = 0$. Thus complex smoothness of an invariant pullback does not force the source function to be smooth for the tropical boundary sheaf. Boundary compatibility is a genuine condition, not merely continuity.

21.16.1 Psh functions on a general tropical toric variety

For a rational fan Σ, the BGJK psh class on $U \subset N_\Sigma$ consists of upper semicontinuous functions with values in $\mathbb{R} \cup \{-\infty\}$, convex on $U \cap N_\mathbb{R}$, and satisfying

$$u(p + \infty v) \leq u(p) \quad \text{whenever } [p, p + \infty v] \subset U,\ v \in |\Sigma|.$$

Here $p + \infty v$ is the limiting point in the stratum attached to the cone containing v in its relative interior. The theorem in [BGJK25, Theorem 3.1.4] identifies this class with continuous extended-real functions whose restriction to the dense stratum is convex. Continuity is taken in $\mathbb{R} \cup \{-\infty\}$, identified with $[0, \infty)$ by the exponential. In particular, a finite psh function is continuous and locally bounded. A function equal to $-\infty$ is not a bounded potential.

The proof of this boundary continuity is not a formal consequence of convexity on the dense stratum. It uses the compactified-ray inequalities and basic polyhedral neighbourhoods. In dimension one, convexity and a finite upper boundary limit force monotone decrease: a positive secant slope would force growth to $+\infty$. The higher-dimensional proof applies this observation along the cone directions and controls nearby transverse directions by convexity. We use the full theorem as an input when passing to the BT construction.

21.17 Invariant analytic smoothness can use additional coordinates

Proposition 21.17.1. *Let K be a complete non-Archimedean field and $t = -\log|T|$ on $\mathbb{G}_m^{\mathrm{an}}$. The function*

$$h = \min(0, t)^2$$

is original CLD smooth and invariant under the maximal affinoid torus action, but is not the pullback of a smooth real function by this one-coordinate tropicalization.

Proof. On the open analytic set $T \neq 1$, the two functions T and $T - 1$ are units. The ultrametric inequality gives

$$\min(0, -\log|T|)^2 = (-\log|T|)(-\log|T - 1|).$$

Indeed, for $|T| < 1$ the second factor is zero; for $|T| > 1$ the two factors agree; for $|T| = 1$ the first is zero. The right side is a smooth polynomial in the two tropical coordinates. Near $T = 1$, on $|T - 1| < 1$, we have $|T| = 1$ and $h = 0$. Hence the local smooth presentations glue across the omitted point.

The function factors through tropicalization, hence is invariant under the stated action. Tropicalization is surjective onto $\mathbb{R}$, so any function in that one-coordinate chart representing h would have to be $s \mapsto \min(0, s)^2$. Its second derivative jumps at zero; it is not smooth on $\mathbb{R}$. □

This is the example of [BGJK25, Example 2.3.5], with the local domains made explicit. In the consulted preprint the displayed map $T \mapsto (T, T-1)$ is written as a torus-valued map on all of $\mathbb{G}_m$. It is torus-valued only after deleting $T = 1$; the zero presentation above supplies the missing neighbourhood. The example itself remains valid. It disproves surjectivity of the fixed-chart smooth pullback onto all invariant analytic smooth functions, not injectivity of that pullback.

21.18 Transporting the BT construction through the complex torus

Suppose first that Σ is smooth. Write $\tau : X_\Sigma(\mathbb{C}) \to N_\Sigma$ for complex tropicalization, $U \subset N_\Sigma$ open, and $V = \tau^{-1}(U)$. Normalize d^c so that $dd^c = (i/\pi)\partial\bar{\partial}$. The source constructs a pullback with

$$\tau^* d' = \pi^{-1/2}\partial\tau^*, \qquad \tau^* d'' = \pi^{-1/2} i\bar{\partial}\tau^*, \qquad \tau^* d' d'' = dd^c \tau^*.$$

It preserves integration of top-degree forms. At boundary strata its image can be smaller than the invariant complex smooth forms, as the preceding $|z|^2$ example shows. The decisive theorem is instead a statement about the closed positive current cones.

Throughout this comparison, complex positivity means the middle cone used in [BGJK25, Section 2.1]: a form is a sum of $i^{p^2} a\, \alpha \wedge \overline{\alpha}$ with $a \geq 0$ and arbitrary $(p, 0)$-forms α, and a current is nonnegative on this cone in complementary degree. This convention matches ordinary Lagerberg positivity. It should not be read as changing silently to a different convention for positive currents in a complex reference.

Theorem 21.18.1 (The complex current comparison input)**.** *The pushforward τ_* is an isomorphism from the cone of closed positive complex currents on V invariant under the maximal compact torus and the real-structure involution F of [BGJK], to the cone of closed ordinary positive Lagerberg currents on U.*

Open proof obligation (RC2). Prove the positive closed current lifting/comparison with the prescribed support and invariance conditions; BGJK Theorem 7.1.5 is supplied.

Theorem 21.18.2 (Toric continuous BT products)**.** *For a closed positive Lagerberg current T of bidegree (p,p) on U, and finite psh functions $u_1,\dots,u_q$ with $p+q\le n$, there are local products*

$$u_1\,DDu_2\wedge\cdots\wedge DDu_q\wedge T,\qquad DDu_1\wedge\cdots\wedge DDu_q\wedge T,\qquad DD=d'd''.$$

The second is closed and positive. The products agree with the smooth formulas and are continuous when all potentials converge locally uniformly and the positive closed background currents converge weakly. These properties determine the products uniquely.

Open proof obligation (RC2). Prove the toric/complex function comparison and local decreasing regularization on the stated neighbourhoods; BGJK25 Proposition 3.2.1 and Theorem 3.3.4.

21.18.1 Unbounded potentials need a separate condition

In the unbounded theorem of [BGJK25, Theorem 4.2.2], the sets D_j containing $\{u_j=-\infty\}$ are closed unions of strata of positive codimension. If B is a closed union of strata containing $\operatorname{supp}T$, the hypothesis is

$$\dim\left(B\cap\bigcap_{j\in I}D_j\right)\le n-p-|I|\quad\text{for every } I\subseteq\{1,\dots,q\}.$$

The dimension includes the empty-index case. Under this proper-intersection condition the products exist and are continuous for decreasing sequences of the potentials with the background current fixed. The proof transfers the corresponding complex integrability theorem, using that a tropical stratum of real dimension d corresponds to a complex torus orbit of complex dimension

d. One must not replace the fixed background in this unbounded assertion by an arbitrary weakly converging sequence without another theorem.

For a nonsmooth fan, a smooth refinement gives a proper tropical toric map. Products of the scalar potentials can then be defined upstairs and pushed down, with independence proved by a common refinement and the projection formula. This is a specific toric descent theorem. It does not provide a general pullback of an arbitrary singular current to a resolution.

21.19 Truncation can discard divisor mass

For $u(t) = -t$ on a neighbourhood of $+\infty$, let $u_j = \max(u, -j)$. The boundary slope formula and the interior corner calculation give

$$DDu_j = \delta_j \ \rightharpoonup \ \delta_{+\infty} = DD[u].$$

However,

$$\mathbf{1}_{\{u>-j\}} DDu_j = \mathbf{1}_{\{t<j\}} \delta_j = 0.$$

Thus an extension defined by retaining the full decreasing-limit current and one defined by discarding the truncation-level mass give different answers. The latter is the mechanism underlying non-pluripolar products: it deliberately omits mass on the pole set. Calling both objects the same Monge–Ampère operator would conceal this choice.

Proposition 21.19.1 (The elementary monotonicity behind truncation)**.** *Suppose a measure-valued operator M is defined on bounded truncations $u_j = \max(u, -j)$, and is local on the sets $E_j = \{u > -j\}$: for $k \geq j$, $\mathbf{1}_{E_j} M(u_k) = \mathbf{1}_{E_j} M(u_j)$. Assume these sets are measurable and the measures positive. Then*

$$\nu_j := \mathbf{1}_{E_j} M(u_j) \leq \nu_k \quad (k \geq j).$$

Their increasing limit is a measure. It is locally finite if the masses $\nu_j(K)$ are uniformly bounded on each compact neighbourhood. Without that bound, the construction need not give a current with locally finite coefficients.

Proof. Since $E_j \subseteq E_k$, restriction of the positive measure ν_k to E_j equals ν_j by locality. Therefore $\nu_k - \nu_j$ is positive and supported outside E_j. The pointwise increasing limit on measurable sets is countably additive by monotone convergence for nonnegative series. Uniform local mass bounds give local finiteness. □

The proposition is measure theory once the stated locality is known. It does not prove that locality for every analytic psh class, independence of all choices of truncation, or a full-mass theorem. In the toric class the extended continuity makes E_j open, which simplifies this step. In a general unbounded analytic theory, the corresponding locality and exceptional-set statements are substantial additional inputs.

References. [BGJK25, Sections 2–4], in the consulted arXiv:2102.07392v1; [BGJK, Theorem 7.1.5].

21.20 Boundary mass and extension of toric currents

A tropical toric boundary changes the space of tests. Near a coordinate with value $+\infty$, a smooth function is eventually independent of that coordinate, and a positive-degree differential involving that coordinate vanishes. Consequently, a current may be well defined on all tropical tests although its invariant complex lift would have infinite mass near the corresponding divisor. The additional mass condition in the toric correspondence theorem is designed precisely for this phenomenon.

21.20.1 Weighted co-coefficients

Work in a smooth toric chart, with coordinates $u_1, \dots, u_n$ in a product of copies of $\mathbb{R} \cup \{+\infty\}$ and $\mathbb{R}$. For a current of bidegree (p,p), put $q = n - p$. If $|I| = |J| = q$, its co-coefficient T^{IJ} is the measure obtained by testing against a scalar multiple of the basis form indexed by I, J, with the usual sign normalization. It is defined on the locus where all coordinates occurring in $I \cup J$ are finite. Write

$$E^{I\cup J} = \bigcup_{i\in I\cup J} \{u_i = +\infty\}, \qquad w_{IJ}(u) = \exp\left(-\sum_{i\in I} u_i - \sum_{j\in J} u_j\right).$$

Definition 21.20.1 (**C**-finite local mass)**.** A positive tropical current has **C**-finite local mass if, in every toric coordinate chart, the image measures of $w_{IJ}|T^{IJ}|$ under the open inclusions from the above finite-coordinate loci are locally finite on the whole chart. For a current defined off a union E of stratum closures, the condition is required across E as well.

The letter **C** refers to the complex realization, not to an additional arbitrary norm on the tropical current. Indeed, on the dense torus $u_i = -\log|z_i|$, logarithmic forms contain dz_i/z_i. Conversion between logarithmic co-coefficients and ordinary complex co-coefficients therefore introduces exactly the factors $|z_i| = e^{-u_i}$ above. Fixed powers of 2 and π depend on the normalization of the complex differential operators and do not affect local finiteness.

Example 21.20.2 (Tropical continuity without finite complex mass)**.** On $U = (0, +\infty] \subset \mathbb{R} \cup \{+\infty\}$, define the positive $(0,0)$ current

$$T(g\, d'u \wedge d''u) = \int_0^\infty g(t) e^{2t}\, dt.$$

Every compactly supported tropical $(1,1)$ test vanishes near $+\infty$. On each fixed test-presentation space the integral is therefore bounded by a constant times the coefficient supremum. This defines a continuous current. Its weighted co-coefficient, however, is

$$e^{-2t} e^{2t}\, dt = dt,$$

which has infinite mass on every neighbourhood $(R, +\infty]$ of the boundary. It fails the **C**-finite condition. A positive complex lift would restrict on the punctured disc to a positive multiple of the function $|z|^{-2}$, whose mass near zero contains $\int_0^\varepsilon r^{-1}\, dr = +\infty$. Thus no positive complex lift exists. This current is not closed; its failure of closedness is essential.

Theorem 21.20.3 (Toric lifting and closedness)**.** *Let Σ be a smooth fan, $U \subset N_\Sigma$ open, and $V = \mathrm{trop}_\infty^{-1}(U)$ in the complex toric manifold. A positive Lagerberg current on U admits a positive invariant complex lift precisely when it has* **C***-finite local mass. Every positive closed Lagerberg current on U has this local mass property. On closed positive currents, the lift is unique after imposing the compact-torus invariance and the real involution used in the correspondence theorem.*

Open proof obligation (RC2). Prove lifting and locally finite mass at the boundary strata where the supplied BGJK propositions/theorem enter.

21.20.2 The toric extension theorem

Theorem 21.20.4 (Toric Skoda–El Mir)**.** *In the preceding smooth toric setting, let $E \subset U$ be the intersection with a union of stratum closures. Let T be a positive closed Lagerberg current on $U \setminus E$ with $\mathbf{C}$-finite local mass across E. Its coefficientwise extension by zero is a positive closed current on U.*

Proof. On the locus where the indices of a co-coefficient are finite, w_{IJ} is positive with reciprocal locally bounded. The weighted local mass assumption thus implies the unweighted local finiteness needed to extend that co-coefficient by zero on its own domain. These extensions define a positive tropical current $\widetilde{T}$, by the coordinate transformation rule and positivity under scalar cutoffs.

It remains to prove closedness. Put $D = \mathrm{trop}_{\infty}^{-1}(E) \subset V$. Because E is a union of stratum closures, D is an analytic subset of the complex toric manifold. Lift T on $V \setminus D$ by the closed positive correspondence theorem. The weighted mass condition is exactly finite complex local mass across D. The classical complex Skoda–El Mir theorem extends that lift by zero to a positive closed current $\widetilde{S}$ on V. The coefficient transformation identifies its tropical pushforward with $\widetilde{T}$. Since pushforward commutes with both differentials, $\widetilde{T}$ is closed. □

This is a proof of the tropical theorem conditional only on the stated complex extension theorem and the toric correspondence. It is not a proof of Skoda–El Mir from elementary real calculus. Its geometric hypothesis on E is also indispensable to this argument: an arbitrary closed subset of a tropical support need not lift to a complex analytic subset. Compare the direct Hausdorff-size criterion of Section 9.16, whose hypotheses and proof are different.

References. [BGJK, Theorem 7.2.4]. The complex Skoda–El Mir theorem is the explicit external extension input in that proof.

21.20.3 Decomposition by strata

Order-zero co-coefficients can be restricted to the Borel strata. For a positive tropical current, the restrictions are compatible with all toric coordinates and give a canonical decomposition

$$T = \sum_{\sigma \in \Sigma} T_\sigma.$$

The component T_σ gives no coefficient mass to the complement of the stratum $N(\sigma)$. Its topological support can nevertheless meet the boundary of that stratum. This distinction between concentration on a measurable stratum and support in its closure is the same distinction that occurs for an ordinary measure on an open interval.

Corollary 21.20.5. *If T is positive and closed, every component T_σ in this canonical decomposition is positive and closed.*

Proof. Positivity follows from the coefficient restriction construction. The dense-stratum component is the extension by zero of the restriction of T to that stratum. Theorem 21.20.3 supplies the weighted mass condition, so Theorem 21.20.4 makes that component closed. Subtract it and repeat on the strata of the next dimension, working in their toric neighbourhoods. At each stage the remaining current is a sum of positive stratum components, so it is positive; it is closed because the earlier components are closed. The same extension theorem applies. Induction over the finitely many strata proves the assertion. □

References. The canonical decomposition is [BGJK, Theorem 6.1.6]; its compatibility with closedness is Corollary 7.2.5 there. The co-coefficient transformation at boundary faces is an essential part of that construction.

The theorem explains why boundary pieces can be separated in toric current arguments. It does not justify separating an arbitrary positive closed current according to arbitrary measurable subsets: the derivative of a restriction usually has boundary terms. The special strata, weighted mass estimate, and analytic extension theorem account for the stronger conclusion here.

21.21 The toric projection formula with every curvature factor visible

Proper pushforward is particularly useful for changing a fan. Its compatibility with a BT product follows from the same operation on smooth tests and a fixed-neighbourhood limit. Writing all factors prevents a degree error when one potential is left undifferentiated.

Proposition 21.21.1. *Let $E : N'_{\Sigma'} \to N_\Sigma$ be a proper equivariant map between tropical toric varieties of dimensions n' and n, with both fans smooth. Let $U \subset N_\Sigma$ be open and $U' = E^{-1}(U)$. Let T be a closed ordinary positive current of bidegree (p,p) on U'. For finite psh functions $u_1, \dots, u_q$ on U, with $p+q \le n'$, one has*

$$E_*\big(DDE^*u_1 \wedge \cdots \wedge DDE^*u_q \wedge T\big) = DDu_1 \wedge \cdots \wedge DDu_q \wedge E_*T,$$
$$E_*\big(E^*u_1\, DDE^*u_2 \wedge \cdots \wedge DDE^*u_q \wedge T\big) = u_1\, DDu_2 \wedge \cdots \wedge DDu_q \wedge E_*T.$$

The bidegrees on the target are $(p+q+n-n', p+q+n-n')$ and $(p+q-1+n-n', p+q-1+n-n')$, respectively. If these indices lie outside the possible range, the corresponding current space is zero.

Proof. For smooth potentials, evaluate on a compactly supported test η on U. Properness makes $E^*\eta$ compactly supported, and by definition of pushforward the left side is T evaluated on the pullback of the full target product. Pullback commutes with DD on functions and with wedge product. This is the right side. The total number of curvature factors gives the displayed degrees.

In the continuous case choose local smooth psh approximations on fixed neighbourhoods of the target support and use a finite subdivision of the test by cutoffs. Properness ensures that the source tests remain in a common compact set. The pulled-back potentials converge uniformly on this compact set, and remain psh by the toric psh pullback theorem. Theorem 21.18.2 passes both sides to the limit. The argument proves a projection formula for a current already defined on the source; it does not construct a pullback of E_*T. □

In the consulted arXiv:2102.07392v1, Proposition 4.3.2 abbreviates the displayed product in a way that omits some DD operators. Remark 4.3.4 also prints the same undifferentiated leading factor on the right side for products

assigned different bidegrees. The formulas above are the degree-consistent versions. For a smooth refinement E and no background factor, the differentiated product downstairs must be

$$DDu_1 \wedge \cdots \wedge DDu_q = E_*\big(DDE^*u_1 \wedge \cdots \wedge DDE^*u_q\big).$$

The companion product has E^*u_1 undifferentiated on the right and u_1 undifferentiated on the left. These are local formula repairs, not failures of the smooth projection identity or of the limiting construction.

There is one further elementary qualification to positivity wording. A product $u_1 DDu_2 \wedge \cdots \wedge DDu_q \wedge T$ need not be positive if u_1 can be negative. For $u_1 = -1$ and a nonzero positive background it is negative. The differentiated product is positive without a sign condition on the potentials, whereas positivity of the product with an undifferentiated factor requires that factor to be nonnegative. The main product statement above imposes positivity only on the differentiated product.

References. [BGJK25, Proposition 4.3.2 and Remark 4.3.4], with version fixed to arXiv:2102.07392v1.

21.22 Quasiperiodic convex functions and real torus metrics

A totally degenerate abelian variety has a real torus as its canonical skeleton. The relevant potential on its universal cover is not periodic: its failure of periodicity is an affine function prescribed by the polarization. Separating the quadratic part from a periodic correction makes both positivity and normalization explicit. The following results are real statements in arbitrary dimension. Their analytic interpretation uses the uniformization and metric-comparison theorems cited at the end.

Let $V = \mathbb{R}^n$, let $\Lambda \subset V$ be a full lattice, and choose a positive-definite symmetric bilinear form b, with matrix H in fixed coordinates. Put

$$q(x) = \tfrac{1}{2} b(x, x), \qquad M = V/\Lambda, \qquad \theta = DDq.$$

A continuous periodic function u defines $f = q + u$ with automorphy rule

$$f(x + \lambda) - f(x) = b(x, \lambda) + q(\lambda), \qquad \lambda \in \Lambda.$$

Conversely this rule makes $f - q$ periodic. Since the right side is affine, the local Hessians DDf glue to a closed form or current on M. For smooth u,

the inequality $\theta + DDu \geq 0$ means that f is convex. For continuous u, we use this convexity as the definition in this real torus setting.

Lemma 21.22.1. *The affine functions $c_\lambda(x) = b(x,\lambda) + q(\lambda)$ satisfy*

$$c_{\lambda+\mu}(x) = c_\lambda(x+\mu) + c_\mu(x).$$

Adding a periodic function to q preserves these transition functions. Adding an affine function $\ell(x) + a$ changes c_λ by the constant $\ell(\lambda)$, while adding a constant alone leaves them unchanged.

Proof. Expand $q(\lambda+\mu) = q(\lambda) + q(\mu) + b(\lambda,\mu)$ and use symmetry of b. The statements about additions follow by subtracting the values at $x+\lambda$ and x. □

The cocycle is the real analogue of transition functions for a line bundle. In the non-Archimedean uniformization, integral slopes and the corresponding Raynaud data are additional requirements for it to come from a specified algebraic polarization. The real calculation does not manufacture that algebraic line bundle.

21.23 Global regularization on a real torus

Theorem 21.23.1. *Let u be continuous and Λ-periodic with $q+u$ convex. There are smooth periodic functions $u_j \to u$ uniformly such that $\theta + DDu_j$ is positive definite. Consequently continuous convex torus potentials belong to a single global uniform smooth-approximation domain.*

Proof. Choose nonnegative smooth compactly supported even kernels ρ_ε on V with integral one. Convolution $u_\varepsilon = u * \rho_\varepsilon$ is smooth and periodic and converges uniformly to u, since u is uniformly continuous on the compact torus. If $f = q + u$, then

$$f * \rho_\varepsilon = q + u_\varepsilon + a_\varepsilon, \qquad a_\varepsilon = \int q(y)\rho_\varepsilon(y)\,dy.$$

The first moments vanish by evenness. Convolution preserves convexity, so $q + u_\varepsilon$ is convex. For $0 < t < 1$, put $u_{\varepsilon,t} = (1-t)u_\varepsilon$. Then

$$DD(q + u_{\varepsilon,t}) = (1-t)DD(q+u_\varepsilon) + t\,DDq \geq t\theta > 0.$$

Take $\varepsilon \to 0$ and $t \to 0$. Boundedness of u gives uniform convergence. Every approximation is defined on the same torus and has the same automorphy rule after adding q. □

This argument is global because convolution respects translations by Λ. It does not extend unchanged to arbitrary tropical charts with changing tangent spaces, nor does it prove original-smooth regularization for every Berkovich current-psh function. Its geometric strength and its limitation are both visible in the translation symmetry.

21.24 The gradient map and total Monge–Ampère mass

Proposition 21.24.1. *If u is smooth periodic and $D^2(q+u) > 0$, then the gradient of $f = q + u$ is a diffeomorphism $V \to V^*$ and satisfies*

$$\nabla f(x+\lambda) = \nabla f(x) + H\lambda.$$

It descends to a diffeomorphism $V/\Lambda \to V^*/H\Lambda$.

Proof. The derivative identity follows by differentiating the automorphy rule. The positive Hessian is periodic, so compactness gives a uniform positive lower bound for its smallest eigenvalue. Hence f is strictly convex. For each $p \in V^*$, the function $f(x) - \langle p, x\rangle$ is coercive, because q is positive definite and u bounded. It has a unique minimizer, which satisfies $\nabla f(x) = p$. Thus the gradient is bijective. Its derivative is invertible everywhere, so the inverse function theorem gives a smooth inverse. Equivariance then gives the quotient diffeomorphism. □

Theorem 21.24.2. *Let dx be the coordinate Lebesgue measure and let* $\operatorname{covol}(\Lambda)$ *use this measure. For every continuous periodic u with $q+u$ convex, the continuous BT measure on M has total mass*

$$\int_M (\theta + DDu)^n = n! \det(H) \operatorname{covol}(\Lambda).$$

For $u = 0$ the measure is $n!\det(H)dx$, and its normalization to mass one is Haar probability measure on M.

Proof. For smooth strictly positive potentials, the local Hessian formula gives $(DDf)^n = n!\det(D^2 f)dx$. Proposition 21.24.1 and change of variables on the two tori give

$$\int_M \det(D^2 f)dx = \operatorname{covol}(H\Lambda) = \det(H)\operatorname{covol}(\Lambda).$$

For continuous u, use Theorem 21.23.1 and the continuous mixed-product convergence proved in Chapter 13. Compactness permits testing against the constant function one, so total mass passes to the limit. The last assertion follows because $D^2 q = H$ is constant. □

The equality of total masses is necessary for solving a Monge–Ampère equation, but is not an existence proof. The gradient construction above starts with a potential and computes its measure. Solving for a potential with a prescribed possibly singular measure is the additional nonlinear theorem in the real and non-Archimedean applications.

21.25 Uniqueness in the smooth strictly positive domain

Theorem 21.25.1. *Let u, v be smooth periodic potentials such that $\alpha = \theta + DDu$ and $\beta = \theta + DDv$ are positive definite. If $\alpha^n = \beta^n$, then $u - v$ is constant.*

Proof. Put $w = u - v$ and $S = \sum_{j=0}^{n-1} \alpha^j \wedge \beta^{n-1-j}$. The factorization of powers gives $\alpha^n - \beta^n = DDw \wedge S$. Since S is closed and M has no boundary, integration by parts yields

$$0 = \int_M w(\alpha^n - \beta^n) = -\int_M d'w \wedge d''w \wedge S.$$

Each summand in the last integrand is nonnegative. In particular the summand with α^{n-1} vanishes in integral. In coordinates diagonalizing the positive matrix of α at a point, this density is a positive constant times a positive-definite quadratic form in the first derivatives of w. For $n = 1$ it is simply the square of the derivative. A nonnegative continuous density with zero integral is zero everywhere. Thus $dw = 0$, and connectedness of the torus makes w constant. □

For continuous semipositive potentials, the same formal identity alone does not prove strictness: the mixed measure may degenerate where the gradient is nonzero, and a classical gradient may not exist. The general uniqueness theorem requires its own convex or pluripotential argument. The smooth result above should be cited with its strict positivity hypothesis, rather than extended by an unproved passage to equality in a limit.

21.25.1 Relation with abelian uniformization

For a totally degenerate polarized abelian variety, the polarization supplies the positive bilinear form and the automorphy data. Canonical weights have the quadratic form just described, up to the permitted affine normalization. Periodic continuous convex perturbations give the corresponding invariant semipositive metrics. The comparison of their Chern measures with these real Monge–Ampère measures is a geometric theorem; it includes the lattice and degree normalization. In mixed reduction, the Raynaud abelian part supplies additional residual intersection factors. A quadratic potential on the tropical torus alone does not encode them.

References. [BGJK25, Sections 7–8]; [Gub10]. The regularization, gradient normalization and smooth uniqueness proofs in this section are real calculations; the cited sources supply their analytic realization and the broader equation-solving theorems.

21.26 Convex duality, roof functions and toric heights

Curvature records slopes and their variation. A height also records the additive constants of a metric. Convex duality packages both kinds of information in a function on a bounded polytope. We derive the real-variable formulas first and then specify the comparison with Gubler–Hertel's toric local height. This separates the factorial normalization from the sign convention for the metric weight.

Let $M \simeq \mathbb{Z}^n$ be a lattice, let $N = \mathrm{Hom}(M, \mathbb{Z})$, and let $P \subset M_{\mathbb{R}}$ be a full-dimensional compact convex polytope. Lebesgue measure dp is normalized

by M. Its support function is $h_P(x) = \max_{p\in P}\langle p, x\rangle$ on $N_{\mathbb{R}}$. Consider finite convex functions f with $f - h_P$ bounded. Define

$$f^*(p) = \sup_{x\in N_{\mathbb{R}}} \big(\langle p, x\rangle - f(x)\big), \qquad \vartheta_f(p) = -f^*(p) \quad (p \in P).$$

We call ϑ_f the roof in this convex convention. It is concave and upper semi-continuous. Its domain is the polytope of slopes of f.

Proposition 21.26.1. *If $|f-h_P| \le C$ on $N_{\mathbb{R}}$, then f^* is finite on P, satisfies $|f^*| \le C$ there, and equals $+\infty$ outside P. Moreover*

$$f(x) = \sup_{p\in P}\big(\langle p, x\rangle + \vartheta_f(p)\big).$$

For two such functions f, g with the same P, one has

$$\|\vartheta_f - \vartheta_g\|_{P,\infty} = \|f - g\|_{N_{\mathbb{R}},\infty}.$$

Proof. The convex conjugate of h_P is zero on P and $+\infty$ outside P. On P, the inequality $\langle p, x\rangle \le h_P(x)$ gives an upper bound zero, attained at $x = 0$. If $p \notin P$, separation of p from the closed convex set P gives x with $\langle p, x\rangle > h_P(x)$; positive multiples of x make the supremum infinite. Reversing the inequalities $h_P - C \le f \le h_P + C$ under conjugation proves the domain and bounds.

At each x, a finite convex function on all of $N_{\mathbb{R}}$ has a supporting affine function. If its slope is p, then $f(y) \ge f(x) + \langle p, y - x\rangle$ for all y. The bounded asymptotics force $p \in P$, and this inequality gives $f^*(p) = \langle p, x\rangle - f(x)$. The reverse inequality for every p is the defining Fenchel inequality. Together they prove the reconstruction formula.

If $|f - g| \le \varepsilon$, conjugation gives $|f^* - g^*| \le \varepsilon$ on P. Applying the reconstruction formula in the other direction gives the reverse norm inequality. Hence equality holds. □

Thus uniform approximation of a metric weight is exactly uniform approximation of its roof in this fixed-polytope class. The roof does not discard constants: $\vartheta_{f+c} = \vartheta_f + c$. This is the information missing from a curvature measure.

21.26.1 The gradient map and total Monge–Ampère mass

Proposition 21.26.2. *Suppose f is smooth, has positive definite Hessian everywhere, and $f - h_P$ is bounded. Then its gradient is a diffeomorphism*

$$\nabla f : N_{\mathbb{R}} \xrightarrow{\sim} \operatorname{int} P.$$

Consequently, in the superform normalization,

$$\int_{N_{\mathbb{R}}} (DDf)^n = n! \operatorname{vol}_M(P).$$

Proof. Every tangent affine function to f has slope in P, by the asymptotic bound as in Proposition 21.26.1. The Hessian is invertible, so the gradient has open image; this image lies in $\operatorname{int} P$. For any p in that interior, there is $\delta > 0$ such that $h_P(x) - \langle p, x\rangle \geq \delta|x|$. Thus $f(x) - \langle p, x\rangle$ is coercive and has a minimum. Strict convexity makes its minimizer unique, and its derivative vanishes exactly when $\nabla f(x) = p$. This proves bijectivity. The inverse function theorem gives a smooth inverse.

The Jacobian determinant of the gradient is $\det D^2 f$. Change of variables gives $\int \det D^2 f \, dx = \operatorname{vol}_M(P)$. The factor $n!$ comes from expanding the nth wedge of the Hessian form, as in Section 21.5. □

For example, if $v_1, \dots, v_s$ are the vertices of P, the function $\log \sum_a e^{\langle v_a, x\rangle}$ has bounded difference from h_P and positive definite Hessian. Its Hessian is the covariance matrix of the vectors v_a with strictly positive weights. Full dimension ensures that no nonzero direction has zero variance.

The mass identity extends to all finite convex f in the stated asymptotic class by the Alexandrov definition. The union of its subdifferentials contains $\operatorname{int} P$, because the coercive minimization argument still applies, and is contained in P by the slope bound. The boundary of P has zero n-dimensional volume. Hence the total Alexandrov mass is $\operatorname{vol}_M(P)$, and the superform measure is $n!$ times that mass. This uses the classical Alexandrov measure theorem, including its agreement with the Hessian determinant in the smooth case.

21.26.2 Energy as the integral of a roof

Define the normalized convex energy by

$$\mathcal{E}_P(f) = n! \int_P \vartheta_f(p) \, dp.$$

It vanishes for h_P, is increasing in f, and satisfies $\mathcal{E}_P(f+c) = \mathcal{E}_P(f) + cD$, where $D = n!\,\mathrm{vol}_M(P)$. Proposition 21.26.1 also gives

$$|\mathcal{E}_P(f) - \mathcal{E}_P(g)| \le D\|f-g\|_\infty.$$

Proposition 21.26.3. *Let f_t be a smooth family of smooth functions with positive definite Hessians, the same polytope P, and bounded asymptotics. Assume $|\dot f_t|$ is uniformly bounded for t near zero. Then*

$$\frac{d}{dt}\Big|_0 \mathcal{E}_P(f_t) = \int_{N_\mathbb{R}} \dot f_0\,(DDf_0)^n.$$

Proof. For $p \in \operatorname{int} P$, let $x_t(p)$ be the unique point with $\nabla f_t(x_t) = p$. Differentiating $f_t^*(p) = \langle p, x_t\rangle - f_t(x_t)$ cancels the terms containing $\dot x_t$ and gives

$$\frac{d}{dt}\vartheta_{f_t}(p) = \dot f_t(x_t(p)).$$

The uniform derivative bound also bounds roof difference quotients, by the norm estimate. Dominated convergence on the finite-volume polytope permits differentiation under the integral. The change of variables $p = \nabla f_0(x)$ then proves the formula. The boundary of P has measure zero and does not enter this calculation. □

The positive-definite Hessian hypothesis gives the smooth inverse gradient maps used in this proof. Strict convexity alone would not justify the inverse-function step. An arbitrary path of PL maxima can have nondifferentiable corners moving through the support of its Monge–Ampère measure. One should then use the energy difference formula or uniform approximation, not evaluate an undefined pointwise derivative at a moving atom.

21.26.3 The toric metric convention and the factor $(n+1)!$

In Gubler–Hertel's convention, a toric section has a concave metric function ψ and a concave roof $\psi^\vee$ on the stability polytope Δ. To compare with our positive-Hessian convention, set $f = -\psi$ and $P = -\Delta$. Then

$$\vartheta_f(p) = \psi^\vee(-p).$$

The sign change on the slope lattice preserves lattice volume. It is not permissible to change ψ to $-\psi$ while keeping its slope polytope unchanged without this identification.

Theorem 21.26.4 (Toric local height; geometric comparison)**.** *For a proper normal toric variety of dimension n over a complete non-Archimedean field, a semipositive toric metric on a toric line bundle has toric local height*

$$\lambda_{\overline{L}}^{\mathrm{tor}}(X) = (n+1)! \int_{\Delta} \psi^{\vee}(m)\, d\,\mathrm{vol}_M(m) = (n+1)\mathcal{E}_P(f).$$

Here the toric local height is the difference from the canonical toric metric on the same line bundle, using the same auxiliary meromorphic sections. It is not an unnormalized local height independent of all choices by definition.

Open proof obligation (RC2). Supply the analytic-to-convex comparison, local-height induction and continuity in the prescribed metric class; the text offers GH Definition 2.6.1 and Theorem 2.6.6.

Example 21.26.5 (A one-dimensional normalization check)**.** Let $P = [0, d]$ with $d > 0$, and take $f(x) = \max(0, dx + a)$ for $a \geq 0$. Then

$$\vartheta_f(p) = \frac{a}{d}p, \quad DDf = d\delta_{-a/d}, \quad \mathcal{E}_P(f) = \frac{ad}{2}, \quad \lambda^{\mathrm{tor}}(f) = ad.$$

Indeed, the conjugate is $-ap/d$ on the interval, by maximizing at the corner $x = -a/d$. Integration gives the energy. Independently, with $h_P(x) = \max(0, dx)$, the curve energy formula gives

$$\frac{1}{2}\int_{\mathbb{R}} (f - h_P)(DDf + DDh_P) = \frac{1}{2}(0 \cdot d + a \cdot d) = \frac{ad}{2}.$$

Changing f to $f + c$ keeps curvature fixed, raises the roof by c, raises normalized energy by cd, and raises the self-height by $2cd$. Changing only one of the two height slots instead changes the height by cd.

For several line bundles, polarization replaces the single roof integral by the corresponding mixed integral. Its symmetry and multilinearity reflect those of local intersection theory. Gubler–Hertel extends the formulas to arbitrary rank-one non-Archimedean absolute values, so discreteness of the value group is not part of the toric height theorem. This is a different extension problem from enlarging a local sheaf of differential forms: the objects here are metrized line bundles and their numerical local heights.

References. [GH, Sections 2.4–2.6 and Appendix A]. The convex-domain, norm, gradient and variation calculations are proved above; the local-height identification retains its geometric comparison inputs.

21.27 Constructing toric potentials from a measure

The direct Monge–Ampère calculation starts from a convex potential and measures its subgradients. The inverse problem prescribes that measure. For finitely supported measures, the inverse problem reduces to a finite-dimensional convex minimization. This construction is particularly useful for understanding the existence theorem: the unknowns are the heights of finitely many supporting planes, and the prescribed masses are the volumes of the regions on which those planes dominate.

Let $P \subset M_{\mathbb{R}}$ be a compact convex body with nonempty interior, and let dp be lattice-normalized Lebesgue measure. Its support function is $h_P(x) = \sup_{p \in P} \langle p, x \rangle$. We first use the Alexandrov normalization $\mathrm{MA}_{\mathbb{R}}(f)(E) = \mathrm{vol}(\partial f(E))$; the top supercurrent is $n!\,\mathrm{MA}_{\mathbb{R}}(f)$.

Theorem 21.27.1 (A finite measure with prescribed masses)**.** *Let $x_1, \dots, x_s \in N_{\mathbb{R}}$ be distinct, and let $m_i > 0$ with $\sum_i m_i = \mathrm{vol}(P)$. There is a finite convex function f with $f - h_P$ bounded and*

$$\mathrm{MA}_{\mathbb{R}}(f) = \sum_{i=1}^{s} m_i \delta_{x_i}.$$

It is obtained by minimizing, modulo a common additive constant in $a = (a_i)$, the function

$$\Phi(a) = \sum_i m_i a_i + \int_P \max_i \bigl(\langle p, x_i \rangle - a_i \bigr)\, dp. \tag{21.27.1}$$

The minimizer is unique modulo that common constant.

Proof. Write $g_a(p) = \max_i (\langle p, x_i \rangle - a_i)$ on P. The function Φ is convex and continuous. Because the total masses agree, $\Phi(a + c\mathbf{1}) = \Phi(a)$. Normalize $\min_i a_i = 0$, so all $a_i \geq 0$. Choose C with $|\langle p, x_i \rangle| \leq C$ for all $p \in P$ and all i. Some $a_j = 0$, and hence $g_a(p) \geq \langle p, x_j \rangle \geq -C$. Consequently

$$\Phi(a) \geq \sum_i m_i a_i - C\,\mathrm{vol}(P).$$

Since every m_i is positive, the normalized sublevel sets are bounded and closed. A minimum exists. This coercivity argument does not require any general-position condition on the x_i.

The cells associated with a are

$$C_i(a) = \{ p \in P : \langle p, x_i \rangle - a_i \geq \langle p, x_j \rangle - a_j \text{ for every } j \}.$$

The equality set of two distinct planes lies in a hyperplane and has Lebesgue measure zero. Almost every $p \in P$ therefore has one active index. Differentiating the integral in a coordinate direction is justified by dominated convergence, since the difference quotient of a maximum is bounded by one. It gives

$$\frac{\partial \Phi}{\partial a_i} = m_i - \mathrm{vol}(C_i(a)).$$

At a minimizer, the derivative vanishes in every direction in $\mathbb{R}^s$. One may take an unrestricted representative, since the functional is constant along $\mathbf{1}$. Thus each cell has the prescribed volume.

Extend g_a by $+\infty$ outside P, and put

$$f(x) = \sup_{p \in P} \big(\langle p, x \rangle - g_a(p) \big).$$

The function g_a is continuous on P, convex, and closed after this extension. Hence $f^* = g_a$. Boundedness of g_a on P gives boundedness of $f - h_P$. Since $g_a(p) \geq \langle p, x_i \rangle - a_i$, one has $f(x_i) \leq a_i$. Equality holds on the nonempty cell $C_i(a)$, and therefore

$$f(x_i) = a_i, \qquad \partial f(x_i) = C_i(a).$$

Almost every point in the interior of P belongs to a unique active cell and is a differentiability point of g_a, with gradient x_i. The subgradient duality $p \in \partial f(x) \iff x \in \partial g_a(p)$ then implies that subgradients over points $x \notin \{x_1, \ldots, x_s\}$ occupy only a null subset of P. The boundary of a full-dimensional convex body also has Lebesgue measure zero. Thus the Alexandrov measure of f is exactly the asserted atomic measure.

For uniqueness of the minimizer, let a, b be two minimizers. Convexity implies equality in the integral convexity inequality at their midpoint. The pointwise nonnegative difference between the two sides consequently vanishes almost everywhere. At a point where the active indices of both maxima are unique, equality forces those indices to be the same. On the resulting full-measure set, $g_a - g_b$ belongs to the finite set $\{b_i - a_i\}$. By continuity, this holds everywhere on P. Since P is connected, $g_a - g_b$ is constant. Each $C_i(a)$ has positive volume, so its interior contains a point with the same unique active index for b; hence every $b_i - a_i$ equals that constant. □

This proof establishes uniqueness in the finite family used by the construction. Uniqueness among all convex solutions in the prescribed asymptotic

class is a further comparison theorem; it should not be inferred merely from the uniqueness of this finite-dimensional minimizer. The general uniqueness statement is part of the convex Monge–Ampère theorem cited below.

21.27.1 A compact-support existence theorem

Theorem 21.27.2. *Let μ be a positive compactly supported Radon measure on $N_{\mathbb{R}}$ of mass $\operatorname{vol}(P)$. There is a finite convex function f with $f - h_P$ bounded and $\operatorname{MA}_{\mathbb{R}}(f) = \mu$.*

Proof. Choose finitely supported positive measures μ_j of the same total mass, supported in a fixed compact set K, and converging weakly to μ. Such measures are obtained by partitioning K into Borel sets of diameter tending to zero and assigning each set's mass to one of its points. Ignore cells of zero mass. Apply Theorem 21.27.1 to obtain dual functions g_j on P.

All slopes of these maxima lie in K. For any Euclidean norms on the dual vector spaces, there is therefore one constant R such that every g_j is R-Lipschitz on P. Fix $p_0 \in P$ and add constants to arrange $g_j(p_0) = 0$. The functions are uniformly bounded by $R\operatorname{diam}(P)$. Arzelà–Ascoli gives a subsequence converging uniformly on P to a convex continuous function g.

Let $f_j = g_j^*$ and $f = g^*$, using $+\infty$ extensions off P. The elementary Legendre estimate gives

$$\sup_{x \in N_{\mathbb{R}}} |f_j(x) - f(x)| \le \|g_j - g\|_{C^0(P)}.$$

Thus the convergence is uniform even on all of $N_{\mathbb{R}}$, and $f - h_P$ is bounded. Local uniform convergence of finite convex functions implies weak convergence of their Alexandrov measures. Equivalently, one can use the continuous real Bedford–Taylor theorem together with the equality $(DDf)^n = n!\operatorname{MA}_{\mathbb{R}}(f)$. This standard convex-measure continuity is the one external analytic input in the limiting step. It yields $\operatorname{MA}_{\mathbb{R}}(f) = \mu$. □

Compact support was used to bound all slopes of the dual functions by one constant. For an arbitrary finite measure, atoms may escape every bounded set; the same compactness proof no longer gives uniformly Lipschitz roofs. The broader theorem permits unbounded metric potentials and requires an appropriate full-mass asymptotic condition. It is not the same assertion as existence of a continuous metric on a proper toric variety.

21.27.2 The one-dimensional formula

When $P = [\alpha, \beta]$ and $\sum_i m_i = \beta - \alpha$, the construction has a direct expression:

$$f(x) = \alpha x + \sum_i m_i \max(x - x_i, 0) + c.$$

The slope jumps by m_i at x_i, so $f'' = \sum_i m_i \delta_{x_i}$. The slopes at the two ends are α and β, giving the required bounded difference from h_P. The additive constant is the only freedom. This is the same slope-mass calculation that appears in metric-graph Green functions, but the boundary condition is now specified by a moment interval instead of a mean-zero normalization on a compact graph.

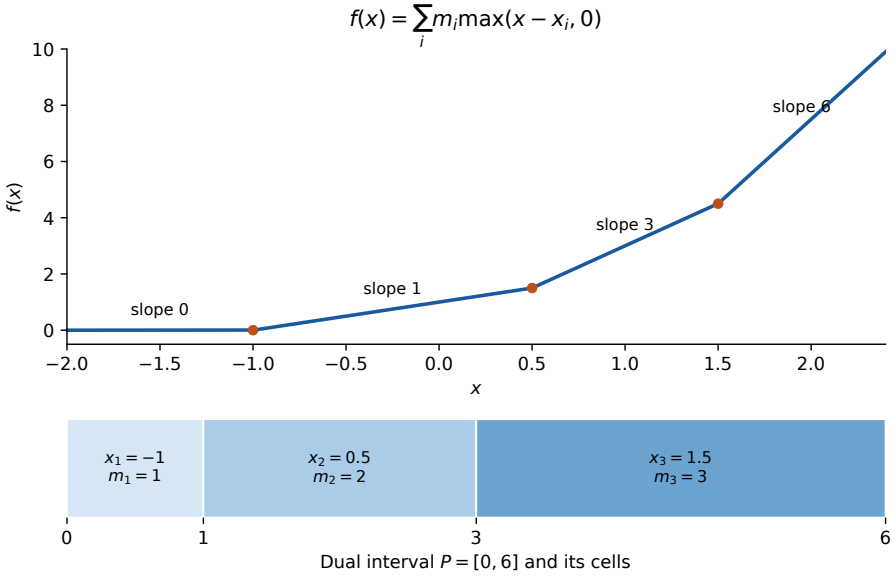

Figure 21.1: Prescribed atoms at $-1, 1/2, 3/2$ with masses $1, 2, 3$. The slope jumps of the primal potential are the lengths of the dual cells.

For a lattice polytope associated with an ample toric line bundle, the bounded convex functions constructed above correspond to continuous semi-positive toric metrics. Their non-Archimedean Chern measures are obtained by the tropical comparison theorem, with the factor $n!$ and the canonical section of tropicalization retained. The inverse construction on $N_{\mathbb{R}}$ does not assert that an arbitrary measure on the entire analytic toric variety is de-

termined by its tropical pushforward. The canonical invariant class and its section are part of the comparison.

References. This is a finite-dimensional proof of the compact-support case of the convex existence theorem used in [BGJK25, Theorem 6.2.13 and Appendix A]. The general theorem, its uniqueness, and its applications to toric metrics are treated there; the convex/metric dictionary is [GH, Theorem 2.5.8]. The minimization argument combines the Legendre correspondence with the volumes of the cells $C_i(a)$, and is included as a proof reconstruction rather than as a new existence result.

21.28 Toric metrics on subvarieties: the local weighted germ

A measure pushed to a tropical image does not by itself remember which analytic branch supplied its mass. This issue occurs both for subvarieties of abelian varieties and for subvarieties of toric varieties. It becomes essential when tropicalization is finite-to-one rather than injective.

21.28.1 The abelian case

In Gubler–Stadlöder's setting over an algebraically closed complete nontrivially valued field, Raynaud uniformization provides a lattice Λ, a real vector space $N_{\mathbb{R}}$, and affine cocycle functions z_λ. Continuous toric metrics on a line bundle L correspond to continuous functions satisfying

$$f(w+\lambda) = f(w) + z_\lambda(w).$$

When L is ample, convexity of f is equivalent to semipositivity of the metric. Their approximation theorem preserves this cocycle; ordinary convolution or an arbitrary polyhedral approximation without the cocycle would not define a metric on the quotient. For a closed subvariety $X \subset A$, the support S_X of the canonical measure is independent of the chosen ample L, and its map to the tropicalization is piecewise linear, surjective and finite-to-one. The measure formula on a polytopal decomposition of S_X has multiplicities depending on X, L and the face, but not on the chosen toric metric. The canonical metric gives a sum of Lebesgue measures on those faces. This statement does not say that all faces have dimension $\dim X$ or that all weights are one. The real Monge–Ampère measure on each face uses the affine space and normalization specified in that formula.

References. [GS23, Theorems 1.1–1.3, Proposition 3.8 and Corollary 1.4].

21.28.2 The toric-subvariety comparison

Lin considers a subvariety X of a toric variety Y over an algebraically closed complete nontrivially valued field. Put $d = \dim X$, and restrict to the torus locus. At a point x of the tropical skeleton, the relevant object is the weighted tropicalization of the analytic germ at x. A sufficiently small neighbourhood $U(x)$ gives a representative C_x of that germ. For a semipositive toric metric with tropical Green function g, Theorem A of [Lin26] gives

$$(\operatorname{trop}|_{U(x)})_*\big(c_1(L|_X, \|\cdot\|)^d|_{U(x)}\big) = \mathrm{MA}_{\mathrm{poly},C_x}(g).$$

On an open face Δ of dimension d, the corresponding formula reduces to $d!m_\Delta \,\mathrm{MA}_{\mathbb{R}}(g|_\Delta)$, transported by the face chart. Here the real measure is normalized by the face lattice and m_Δ is its tropical weight. On lower-dimensional faces the full weighted neighbourhood is generally needed. Restricting g to that face and taking its intrinsic real Hessian can lose transverse intersection mass.

Example 21.28.1 (Why a zero-dimensional restriction loses curvature)**.** On $\mathbb{R}$, let $g(t) = \max(0, t)$. Its restriction to the face $\{0\}$ is the constant zero function. Nevertheless $d'd''g = \delta_0$. The mass is the difference of the slopes on the two adjacent rays; it cannot be recovered from the value of the restricted function. This elementary example explains the need for a weighted germ. It is not a substitute for the higher-dimensional comparison theorem.

Lemma 21.28.2 (Pushforward does not identify branches)**.** *If a map $q : S \to P$ has distinct points s_1, s_2 with $q(s_1) = q(s_2)$, then equality of pushforward measures under q does not imply equality of measures on S.*

Proof. The distinct measures δ_{s_1} and δ_{s_2} have the same pushforward. □

Consequently a tropical equality becomes an analytic equality only after one has supplied a support theorem, branchwise local formulas, or a sufficiently faithful family of maps with compatible measures. The strong faithfulness and absolute continuity assumptions in Section 16.8 are one specific way of obtaining this control. They should not be suppressed when applying a tropical solution to an analytic equation.

References. [Lin26, Theorem A, Corollary B and Remark 9.8]; the two elementary examples above isolate the information lost by restriction or pushforward.

Part VI

Green objects, descent and limits

Chapter 22

Green objects and higher codimension

The geometric ingredients of the local Green construction are now available separately: completed residue fields and analytic fibres in Section 2.6, analytic flatness in Section 2.9, and Abhyankar dimension in Section 3.7. Proposition 2.6.4 gives the degree of a finite locally free fibre as a sum of lengths times residue-field degrees. In the argument below, proving that the required local map is finite and flat remains a geometric step; counting its underlying points would lose the multiplicity.

22.1 Bochner–Martinelli and Levine: what higher codimension changes

22.1.1 A complete intersection supplies a logarithmic maximum

Let X be a pure n-dimensional boundaryless analytic space in the source category. Let $f_1, \dots, f_r$ be a regular sequence defining a closed analytic subspace Y of pure codimension r. On $U = X \setminus Y$, set

$$u = \log \max(|f_1|, \dots, |f_r|).$$

This is finite and continuous on U. Its singularity along Y is exactly what is needed for a Green current. The source constructs the relevant products and extensions and states

$$\mathrm{d}'\mathrm{d}''\big(u(\mathrm{d}'\mathrm{d}''u)^{r-1}\big) = \delta_Y. \tag{22.1.1}$$

This is Theorem 18.7.2 of CLD25, explicitly attributed there to Mihatsch. For $r = 1$ it is Poincaré–Lelong.

The expression on the left has two levels. On U, the continuous-potential product is available. Extending the resulting current to X uses support and dimension results. The formula does not define an unrestricted product $(\mathrm{d}'\mathrm{d}''u)^r$ for every unbounded u on all of X. CLD itself points out this limitation immediately after the theorem.

22.1.2 The truncation argument and the nonformal step

For $\varepsilon > 0$ define

$$u_\varepsilon = \log \max(\varepsilon, |f_1|, \dots, |f_r|) = \max(\log \varepsilon, u).$$

The truncated function is finite and continuous. Its top relative curvature is described by a fibre over a small Gauss point in the parameter space. For a fixed test η of degree $(n-r, n-r)$, the support and dimension lemmas ensure that the differentiated test can be treated away from Y in the extension argument. On the relevant compact support, sufficiently small truncations agree with u.

The remaining step compares the calibrated fibre current with δ_Y. This uses the variation theorem from CLD25 Chapter 14 and the regular-sequence geometry. It is the step that retains the scheme-theoretic multiplicities. The equality is therefore a theorem about the analytic complete intersection, not merely an identity of real functions on a tropical support.

There are several local typographical slips in the printed proof, including the second expression for u_ε and dimension indices. The corrected truncation above is the one used in this exposition. The theorem is also available through Mihatsch's independent delta-form treatment, discussed in Chapter 16; the categories of representatives and tests must still be kept distinct.

22.1.3 The Green sign

With $\varphi = \min_i v(f_i) = -u$, the expression

$$\gamma = (-1)^{r-1}\varphi(\mathrm{d}'\mathrm{d}''\varphi)^{r-1} = -u(\mathrm{d}'\mathrm{d}''u)^{r-1}$$

has bidegree $(r-1, r-1)$ and satisfies $\mathrm{d}'\mathrm{d}''[\gamma] + \delta_Y = 0$ in the appropriate current realization. This computation reconciles the logarithmic-maximum convention in CLD25 with the valuation-minimum convention used in the delta-form literature. It also shows why the sign cannot be guessed from the divisor case without counting the $r-1$ additional factors.

22.1.4 Levine's formula on projective space

Let $X = \mathbb{P}^n$ and let $Y \simeq \mathbb{P}^{n-r}$ be the linear subspace defined by $x_0 = \cdots = x_{r-1} = 0$. On $U = X \setminus Y$, the rational projection

$$f : U \longrightarrow \mathbb{P}^{r-1}, \qquad [x_0 : \cdots : x_n] \longmapsto [x_0 : \cdots : x_{r-1}]$$

is a morphism. Give $\mathcal{O}(1)$ the standard formal metric, and write

$$\alpha = c_1(\mathcal{O}_{\mathbb{P}^n}(1)), \qquad \beta = c_1(f^*\mathcal{O}_{\mathbb{P}^{r-1}}(1)), \qquad h = \log \frac{\max_{0\le i\le n} |x_i|}{\max_{0\le i<r} |x_i|}.$$

The homogeneous ratios make h a well-defined function on U. Set

$$\omega = \sum_{j=0}^{r-1} \alpha^{r-1-j}\beta^j.$$

After the source's extension of $h\omega$ to a current Λ on X, Theorem 18.7.5 gives

$$\mathrm{d}'\mathrm{d}''\Lambda + \delta_Y = \alpha^r. \tag{22.1.2}$$

Away from Y, the algebra is transparent: $\mathrm{d}'\mathrm{d}''h = \alpha - \beta$, so

$$(\alpha - \beta)\sum_{j=0}^{r-1} \alpha^{r-1-j}\beta^j = \alpha^r - \beta^r = \alpha^r,$$

because β comes from a space of dimension $r-1$. The nonformal part identifies the singular contribution along Y. The proof blows up the centre of projection, uses Poincaré–Lelong for the exceptional divisor, and pushes the resulting intersection current down. The exceptional fibres supply degree one, producing δ_Y.

22.1.5 Why this does not solve every Green problem

The local formula uses a regular sequence of global functions on the chosen domain. The projective formula uses a specific linear cycle and a specific curvature term. A general homologically trivial cycle may not be globally a complete intersection, and local representatives may fail to glue in a prescribed differential-form sheaf. Even if a global Green current exists, it need not have an actual delta-form representative on the exact complement of the cycle.

Thus the formulas give substantial explicit cases and a proof mechanism. To reach a general strong Green statement, one must still specify the representative class, the full test class, the support condition, the gluing obstruction, and the descent under field extension. Chapter 24 turns these requirements into a precise comparison problem.

22.2 Green objects, star products, and local heights

22.2.1 The equation behind the construction

For the statements taken directly from original GK in this subsection and the next, work over a complete algebraically closed nontrivially valued field. The model examples can be compared after the base change just described. Mihatsch's statements below have their own analytic hypotheses, which we state separately.

For a codimension-p cycle Z, the integration current δ_Z has bidegree (p,p). A Green object g_Z has bidegree $(p-1,p-1)$ and satisfies an equation

$$\mathrm{d}'\mathrm{d}''g_Z + \delta_Z = \omega_Z, \tag{22.2.1}$$

where ω_Z belongs to a specified class of forms. One must always state that class. In classical complex arithmetic intersection it is a class of smooth forms; in GK it is a class of δ-forms; in the model theory discussed below, "forms" and "currents" are classes assembled from Chow groups of models. Sharing equation (22.2.1) does not make these categories identical.

For a metrized line bundle $\overline{L}$ with a nonzero meromorphic section s, the basic Green potential is $g_D = -\log\|s\|$, where $D = \operatorname{div}(s)$. The Poincaré–Lelong equation reads

$$\mathrm{d}'\mathrm{d}''[g_D] + \delta_D = c_1(\overline{L}).$$

It separates two sources of singularity: the zero or pole of the section, and the curvature of the metric. For a model metric, that curvature may itself be polyhedrally singular. This is precisely why the δ-calculus is useful.

Suppose D meets Z properly and the metric belongs to the GK class. The Green star product is

$$g_D * g_Z = g_D \wedge \delta_Z + c_1(\overline{L}) \wedge g_Z. \tag{22.2.2}$$

The first term means restrict the logarithmic potential to the cycle and push its current forward to X. Proper intersection ensures that this restriction is the permitted one. The second term is the action of an allowed δ-form on a current. These operations are part of the construction; the formula is not an invitation to multiply any two singular distributions. Applying $\mathrm{d}'\mathrm{d}''$ and using the Green equations gives

$$\mathrm{d}'\mathrm{d}''(g_D * g_Z) + \delta_{D\cdot Z} = c_1(\overline{L}) \wedge \omega_Z.$$

For two divisors, changing the order changes the representative by a d'- and d''-boundary. The class in the appropriate quotient is symmetric; integration on a proper space kills these boundaries by Stokes. This is the mechanism behind symmetry of local heights.

References. [GK17, Definition 11.1, §11.2, Propositions 11.4–11.5 and Corollary 11.6].

22.2.2 The local-height recursion and metric variation

Let X be proper of dimension n, and take $n+1$ metrized divisors $\widehat{D}_i$ with properly meeting supports, or the more flexible pseudodivisors of GK with empty total intersection of supports. The integral of their star product defines a local height. Its useful computational form is the recursion

$$\lambda_{\widehat{D}_0,\dots,\widehat{D}_n}(X) = \lambda_{\widehat{D}_0,\dots,\widehat{D}_{n-1}}(\operatorname{div}(s_n)) - \int_{X^{\mathrm{an}}} \log\|s_n\|\, c_1(\overline{L}_0)\cdots c_1(\overline{L}_{n-1}). \tag{22.2.3}$$

Each application replaces one intersection with a lower-dimensional cycle and one analytic integral. For model metrics, this agrees with the local height defined by model intersection theory.

If only the first metric is changed to $\|\cdot\|_0' = e^{-\rho}\|\cdot\|_0$, then

$$\lambda' - \lambda = \int_{X^{\mathrm{an}}} \rho\, c_1(\overline{L}_1)\cdots c_1(\overline{L}_n). \tag{22.2.4}$$

When the remaining metrics are semipositive, the mixed measure is positive and has mass $\deg_X(L_1\cdots L_n)$. Hence

$$|\lambda' - \lambda| \le \|\rho\|_\infty \deg_X(L_1\cdots L_n). \tag{22.2.5}$$

This estimate explains why uniform approximation can extend intersection constructions in a controlled positive class. A limit argument still needs the measures, positivity, and independence of approximation to be established; continuity of functions alone supplies none of those automatically.

References. [GK17, Propositions 12.4 and 12.6, Remark 12.7].

Example 22.2.1 (A height changes while curvature stays fixed)**.** Use the standard model metric on $\mathcal{O}_{\mathbb{P}^1}(1)$ from Example 20.3.1. Write $z = Z_1/Z_0$ and $t = -\log|z|$. The Green functions of the points 0 and ∞ are

$$g_0 = \max(0, t), \qquad g_\infty = \max(0, -t),$$

and both Chern measures are δ_{ξ_G}, where ξ_G is the Gauss point. Formula (22.2.3) gives

$$\lambda(0,\infty) = g_0(\infty) + \int g_\infty\, \delta_{\xi_G} = 0.$$

The closures of the two points in $\mathbb{P}^1_R$ are disjoint, giving the same model intersection. Now multiply the first norm by e^{-c}. Its Green function becomes $g_0 + c$, its curvature is unchanged, and its local height increases by c.

Thus even the simplest local height cannot be recovered from the two curvature measures alone. Later we shall encounter a further loss of information coming from degree-zero line bundles, but scalar changes already establish the point. A theory that retains metrized line bundles contains more arithmetic information than a theory of their Chern currents.

Remark 22.2.2 (The variation bound for a signed measure). Write $\mu = c_1(\overline{L}_1)\cdots c_1(\overline{L}_n)$ in (22.2.4). For a finite signed mixed measure, the general estimate is

$$|\lambda' - \lambda| \le \|\rho\|_\infty \|\mu\|_{\mathrm{TV}}.$$

If μ is positive, its total variation is its mass, and the degree formula gives (22.2.5). For signed μ, the signed mass need not control the total variation. Positivity is therefore essential to that particular degree bound.

22.2.3 Higher codimension: an explicit Green form and a length formula

Mihatsch supplies a particularly concrete higher-codimension construction. Let X be a good Hausdorff pure n-dimensional analytic space without boundary, and suppose $Z = V(f_1, \dots, f_r)$ is a complete intersection of codimension r. On $X \setminus Z$ set

$$\varphi = \min_i v(f_i), \qquad \gamma = (-1)^{r-1}\varphi(\mathrm{d}'\mathrm{d}''\varphi)^{r-1}.$$

Although φ is expressed using a minimum, the product is defined in the specified δ-algebra. The theorem states

$$\mathrm{d}'\mathrm{d}''[\gamma] + \delta_Z = 0, \tag{22.2.6}$$

including the corresponding integration identity against compactly supported δ-form tests. The codimension is visible in the exponent: γ has bidegree $(r-1, r-1)$, as a Green object should. For $r = 1$, it is the familiar logarithmic function $v(f)$.

A separate theorem recovers formal intersection lengths. Assume R is a DVR with $v(\pi) = 1$. Let $\mathfrak{X}$ be separated and flat over $\operatorname{Spf} R$, special, and pure of formal dimension $n+1$. Let $\mathfrak{Z}$ be a local complete intersection of pure codimension r, and let $\mathfrak{Y} \subset \mathfrak{X}$ be closed, Cohen–Macaulay, flat over R, and pure of formal dimension r. If $\mathfrak{Y} \cap \mathfrak{Z}$ is Artinian, the distance function defined by the ideal of $\mathfrak{Z}$ gives the same expression for γ, and

$$\int_{Y \setminus \partial Y} \gamma = \operatorname{length}_R \mathcal{O}_{\mathfrak{Y}\cap\mathfrak{Z}}, \qquad Y = \mathfrak{Y}^{\mathrm{an}}. \tag{22.2.7}$$

The theorem also proves the compact support needed for this integral. Flatness matters: a purely vertical formal subscheme can have empty generic fibre

while retaining a nonzero intersection length. The general local-complete-intersection Green statement appears separately as a conjecture in that paper; the proved length formula must not be confused with a proof of that whole conjecture.

References. [Mih24, Theorem 5.5, Conjecture 5.9, Corollary 5.10, and Theorem 5.11].

Example 22.2.3 (Intersection length and valuation scale)**.** In $\operatorname{Spf} R\langle x\rangle$, the sections $x = 0$ and $x = \pi^m$ have intersection ring

$$R\langle x\rangle/(x, x - \pi^m) \simeq R/(\pi^m).$$

Its R-length is m. The Green function $-\log|x|$ of the first section takes the value $-\log|\pi^m| = m\lambda$ at the generic point of the second, where $\lambda = -\log|\pi|$. Thus the logarithmic value equals the algebraic length under the normalization $v(\pi) = 1$; for the original absolute value it is the length multiplied by λ.

For global calculations, the 2025 BGK preprint adds another useful endpoint. Prescribed piecewise smooth Green data on an arbitrary projective variety can be expressed on a common extended tropicalization, and the corresponding local heights admit tropical formulas. The extended target includes strata at infinity; it is not merely one bounded graph. The result does not assert that every continuous singular metric is captured by one fixed finite tropicalization. It tells us that a finite collection of data in the stated class can be treated together, which is exactly what an intersection calculation requires.

References. [BGK25, Theorem F, Proposition 8.2.2, and Theorem 8.2.3].

22.3 Truncation for a coordinate complete intersection

The complete-intersection theorem combines a differential calculation with a geometric multiplicity calculation. To make both visible, we give the full truncation argument for the coordinate origin in arbitrary dimension. The one external measure input will be the standard projective model-measure formula of Chapter 20. This case explains the signs, the extension of the current and the convergence of the truncated curvature without assuming a general extension theorem.

Let K be complete, algebraically closed and nontrivially valued. Choose $a \in K$ with $0 < |a| < 1$, and put $X = (\mathbb{A}^r_K)^{\mathrm{an}}$, $r \geq 1$. Write $z_1, \dots, z_r$ for the coordinates and o for the K-rational origin. On $U = X \setminus \{o\}$ define

$$u = \log \max_i |z_i|, \qquad u_j = \log \max\bigl(|a|^j, |z_1|, \dots, |z_r|\bigr).$$

Each u_j is a finite Fubini–Study weight on the affine chart: it comes from the sections $a^j Z_0, Z_1, \dots, Z_r$ of $\mathcal{O}_{\mathbb{P}^r}(1)$. Theorem 20.8.1 makes it admissible for the local uniform smooth-potential calculus. The function u has the same property locally on U, because one coordinate is nonzero near each of its points.

Lemma 22.3.1 (Smooth forms near a rational point)**.** *Every original smooth function is locally constant near a K-rational analytic point. Every original smooth form of positive total degree vanishes on some neighbourhood of that point. For forms in one fixed finite local presentation, the vanishing neighbourhood may be chosen independently of the smooth coefficient functions.*

Proof. An original smooth presentation uses finitely many analytic units f_i. At a K-rational point x, the number $f_i(x)$ belongs to $K^\times$. Continuity gives a neighbourhood on which $|f_i - f_i(x)| < |f_i(x)|$. The ultrametric equality then gives $|f_i| = |f_i(x)|$ throughout that neighbourhood. Thus every tropical coordinate $-\log|f_i|$ is constant there. Smooth scalar composites are constant and their positive-degree differential factors vanish. Taking the intersection for the finitely many coordinates proves the uniform statement for a fixed presentation. □

The lemma is particular to the original smooth sheaf. It is not an assertion about all continuous functions near a rational point, nor about every enlarged differential-form sheaf. It explains why some logarithmic extensions are easier on original tests than on stronger test classes.

Lemma 22.3.2. *Let ξ_j be the Gauss point of the closed polydisc $|z_i| \leq |a|^j$. With the standard algebraic-degree normalization,*

$$(d'd''u_j)^r = \delta_{\xi_j} \quad \text{on } X.$$

Moreover $\xi_j \to o$ in X, and therefore these measures converge weakly on compactly supported continuous tests to δ_o.

Proof. The standard formal model of $\mathbb{P}^r$ has irreducible special fibre of multiplicity one, and $\deg_{\widetilde{\mathbb{P}^r_K}} \mathcal{O}(1)^r = 1$. The model-measure comparison therefore identifies its top Chern measure with the single Dirac mass at the standard Gauss point. Apply the projective automorphism

$$[Z_0 : Z_1 : \cdots : Z_r] \longmapsto [a^j Z_0 : Z_1 : \cdots : Z_r].$$

The pullback weight in the frame Z_0 is u_j, and the inverse image of the standard Gauss point is ξ_j. Functoriality for an analytic isomorphism proves the formula. This uses the model comparison, rather than inferring an analytic Dirac mass from a tropical vertex alone.

For a polynomial $f = \sum_\alpha a_\alpha z^\alpha$,

$$|f(\xi_j)| = \max_\alpha |a_\alpha|\,|a|^{j|\alpha|} \longrightarrow |a_0| = |f(o)|.$$

The analytic topology of affine space is generated by these evaluations, so $\xi_j \to o$. Evaluation of a continuous compactly supported test then proves convergence of the Dirac masses. □

Theorem 22.3.3. *The current $u(d'd''u)^{r-1}$ on U has a unique extension G of bidegree $(r-1, r-1)$ to X on original smooth tests. It satisfies*

$$d'd''G = \delta_o.$$

Consequently $\gamma = -G$ is a zero-curvature Green current for the coordinate origin.

Proof. A compactly supported test for G has bidegree $(1,1)$. By Lemma 22.3.1, it vanishes on a neighbourhood of o, so its support is a compact subset of U. Pair it with the current already defined on U. This defines G on all such tests. On a fixed finite presentation the neighbourhood of vanishing is common to all coefficients, so continuity reduces to continuity of the current on U. The inductive test topology then gives continuity on the full test space. If two extensions existed, their difference would be supported at o; every test vanishes near o, so that difference would be zero.

Let η be a smooth compactly supported scalar test. Its form $d'd''\eta$ vanishes near o. On its compact support, $\max_i |z_i|$ has a strictly positive minimum. For all sufficiently large j, the functions u_j and u therefore agree on a neighbourhood of this support. Locality of the admitted mixed product gives

$$\langle G, d'd''\eta\rangle = \left\langle u_j(d'd''u_j)^{r-1}, d'd''\eta\right\rangle = \left\langle (d'd''u_j)^r, \eta\right\rangle.$$

The second equality is the recursive mixed-product identity on the whole affine space, where u_j is finite and admissible. Lemma 22.3.2 identifies the last term with $\eta(\xi_j)$, which tends to $\eta(o)$. The distributional $d'd''$ convention gives $\langle d'd''G, \eta\rangle = \langle G, d'd''\eta\rangle$, proving the theorem. □

22.3.1 The algebraic multiplicity that the coordinate proof does not supply

Replace the coordinate equations by $z_1^{a_1}, \dots, z_r^{a_r}$ with positive integers a_i. Their common zero has the same underlying point, but the coordinate-ring quotient has basis

$$z_1^{b_1} \cdots z_r^{b_r}, \qquad 0 \le b_i < a_i,$$

and length $a_1 \cdots a_r$. The complete-intersection current is therefore $(a_1 \cdots a_r)\delta_o$. This number is not recoverable from the support set $\{o\}$ alone. A proof for the logarithmic maximum of these powered functions must retain the degree of the finite monomial map or carry out an equivalent intersection calculation.

For a general regular sequence, the geometric fibre theorem performs this task, including nonreduced fibres and inseparable multiplicities. The coordinate proof above should therefore be read as a full proof of its stated case and an explanation of the general proof's structure. It does not replace the variation-of-fibres theorem used in CLD25, nor the actual delta-form construction in Mihatsch.

There is a second distinction concerning tests. The extension in Theorem 22.3.3 was possible because original positive-degree tests vanish near a rational point. A theorem on all actual delta-form tests must verify its own extension and support statements; those tests need not satisfy the same vanishing lemma. Equality of the induced original currents does not by itself settle equality on the stronger test space.

References. [CLD25, Theorem 18.7.2]; [Mih24, Theorem 5.5]; [GK17, Theorem 10.5]. The proof above is restricted to the coordinate origin and explicitly uses the standard model-measure comparison.

22.4 Extension across a closed analytic subset

The coordinate proof extends because positive-degree original tests vanish near a rational point. In higher dimension the relevant inequality compares

the test degree with the dimension of the removed analytic subset. It is the test degree, not the current degree, which controls this argument.

Let X be a pure n-dimensional boundaryless analytic space in the original CLD smooth-test category. Let $Z \subset X$ be a closed analytic subset of dimension at most d, and put $U = X \setminus Z$. We use the following geometric input: for $\max(a, b) > d$, restriction induces a topological isomorphism

$$A_c^{a,b}(X) \longrightarrow A_c^{a,b}(U).$$

Its inverse extends tests by zero. In particular every such test on X vanishes on a neighbourhood of Z. This is the smooth-test dimension argument underlying CLD25 Lemma 7.1.13, using its Lemmas 3.3.6 and 6.4.5. We retain the test bidegrees explicitly: the complementary indices in the last sentence of the printed proof of 7.1.13 must not replace the degrees of the tests actually being paired.

Proposition 22.4.1. *If a current T on U has bidegree (p, q) and $\max(n - p, n - q) > d$, it has a unique extension $\widetilde{T}$ to X. It is given by*

$$\langle \widetilde{T}, \alpha \rangle = \langle T, \alpha|_U \rangle.$$

If the same degree inequality holds for a differential of T, then taking that differential commutes with this unique extension.

Proof. Take the continuous dual of the test-space isomorphism above with $(a, b) = (n - p, n - q)$. This proves existence, continuity and uniqueness. For the second assertion, restriction of the differentiated extension agrees with the differential on U. Uniqueness in its new degree therefore identifies it with the extension of that differential. The new-degree inequality is indispensable to this last step. □

For a codimension-r subset, $d = n - r$. A current of bidegree $(r - 1, r - 1)$ extends uniquely, since its tests have degree $(n - r + 1, n - r + 1)$. Its $d'd''$ has bidegree (r, r) and tests of degree $(n - r, n - r)$. The strict inequality has disappeared. A nonzero current supported on Z, such as δ_Z, is now possible.

Example 22.4.2. On the punctured analytic line, $u = \log|z|$ has $d'd''u = 0$. Its original-current extension satisfies $d'd''[u] = \delta_0$. Extending the zero current gives zero, whereas differentiating the extension gives δ_0. Thus an unqualified assertion that extension by zero commutes with differentiation is false when the relevant support condition fails in the differentiated degree.

22.5 The complete-intersection calculation with its geometric inputs

We now separate the analytic limiting argument from the geometric fibre comparison. Let $f_1, \dots, f_r$ define a pure codimension-r analytic complete intersection Z in X, and write

$$u = \log \max_i |f_i| \quad \text{on } U, \qquad u_\varepsilon = \max(\log \varepsilon, u), \quad \varepsilon > 0.$$

The latter expression means $\log \max(\varepsilon, |f_1|, \dots, |f_r|)$ on all of X. Assume the continuous-potential products in this calculation are available with locality and the recursion

$$d'd''\big(u_\varepsilon (d'd''u_\varepsilon)^{r-1}\big) = (d'd''u_\varepsilon)^r.$$

Assume also the following geometric comparison on the full original test space:

$$(d'd''u_\varepsilon)^r \rightharpoonup \delta_Z \quad (\varepsilon \downarrow 0). \tag{22.5.1}$$

This is the substantive input. In CLD25 it is obtained by identifying truncated products with calibrated fibre currents in Corollary 18.6.2 and then applying the fibre comparison in Proposition 18.7.3. It includes the multiplicities of the complete intersection.

Theorem 22.5.1. *Under these hypotheses, the unique original-current extension G of $u(d'd''u)^{r-1}$ satisfies $d'd''G = \delta_Z$.*

Proof. Proposition 22.4.1 gives G. Fix a compactly supported smooth test η of degree $(n-r, n-r)$. The form $d'd''\eta$ has degree $(n-r+1, n-r+1)$ and therefore vanishes near Z. Its support C is a compact subset of U. If C is empty, all pairings below vanish. Otherwise the continuous function u has a finite minimum M on C. Choose $\varepsilon < e^M$. By continuity and compactness, after decreasing ε if necessary, $u_\varepsilon = u$ on a neighbourhood of C. Locality gives

$$\begin{aligned} \langle d'd''G, \eta\rangle &= \langle G, d'd''\eta\rangle \\ &= \big\langle u_\varepsilon (d'd''u_\varepsilon)^{r-1}, d'd''\eta\big\rangle \\ &= \big\langle (d'd''u_\varepsilon)^r, \eta\big\rangle . \end{aligned}$$

Let ε tend to zero and use (22.5.1). The result is $\langle \delta_Z, \eta\rangle$. Every original test of the required degree was allowed, so this is the asserted current identity. □

Only a finite lower bound for u was used; the printed requirement that this bound be strictly positive is unnecessary and generally false. The small parameter is compared with e^M, not with M. This corrects both the truncation expression and the inequality used to make truncations agree on the test support.

22.5.1 What the fibre comparison must verify

CLD25 Theorem 14.7.2 is a theorem about compact analytic X satisfying Serre's condition (S_r), a regular r-dimensional target, and a morphism purely of relative dimension $n - r$. After fixing a moment map, it gives local constancy of the calibrated top-dimensional tropical fibre near a rigid target point. Its hypotheses should be retained when the theorem is used. In particular, the relative dimension in this application is $n - r$, not r.

If a fixed test has a finite chart decomposition to which this theorem applies, equality of calibrated fibres gives equality of its fibre integrals on each chart. Summing the chart contributions gives the desired equality for that test. The neighbourhood in the target may depend on the test and its chart decomposition. No uniform neighbourhood valid for every test is needed for weak convergence.

The reduction from a general regular sequence to those geometric hypotheses is not reproduced by the truncation calculation. In particular, Serre conditions concern localizations, not only the depth at one point. The present proof keeps the calibrated-fibre statement as an explicit input. It proves the complete analytic passage once that input is supplied, without claiming to have independently repaired every geometric reduction in the source.

22.5.2 Why extension uniqueness ends at the critical degree

For $s < r-1$, the same extension argument applies in both degrees (s, s) and $(s+1, s+1)$. Thus locality and uniqueness give

$$d'd''\big(u\widetilde{(d'd''u)^s}\big) = \widetilde{(d'd''u)^{s+1}}.$$

At $s = r-1$ the right-hand extension is no longer uniquely determined by its restriction to U. The geometric fibre limit selects the missing contribution δ_Z. This is the precise place where the analytic complete intersection, rather than only its complement, enters the Green identity.

References. [CLD25, Lemma 7.1.13, Theorem 14.7.2, Corollary 18.6.2, and Section 18.7]. The geometric inputs and the conditional analytic proof are distinguished above.

22.6 The algebra behind finite-flat multiplicities

The finite-flat step in a regular-immersion formula ensures that the same scheme-theoretic multiplicity appears on the zero fibre and on nearby tropical fibres. In the finite case, the relevant local flatness criterion has a short module-theoretic proof. This proof also shows why nilpotents must be retained.

Lemma 22.6.1. *Let $(R, \mathfrak{m})$ be a Noetherian regular local ring of dimension r, with regular parameters $t_1, \dots, t_r$. If a finite R-module M has this sequence as an M-regular sequence, then M is free. Its rank is*

$$\dim_{R/\mathfrak{m}} M/\mathfrak{m}M.$$

Proof. Induct on r. If $r = 0$, the ring is a field. For $r > 0$, put $t = t_1$. The quotient ring R/tR is regular local of dimension $r - 1$, and the remaining parameters are regular on M/tM. By induction, M/tM is free over R/tR, say of rank e. Lift a basis to M. Nakayama's lemma makes the resulting map $R^e \to M$ surjective. Let its kernel be K, which is finite because R is Noetherian.

Since t is a nonzerodivisor on M, one has $\operatorname{Tor}_1^R(M, R/tR) = 0$, as follows from the two-term resolution of R/tR. Tensoring the exact sequence with R/tR gives

$$0 \longrightarrow K/tK \longrightarrow (R/tR)^e \longrightarrow M/tM \longrightarrow 0.$$

The right-hand map is the chosen basis isomorphism, so $K/tK = 0$. Nakayama gives $K = 0$, proving freeness. Reduction modulo $\mathfrak{m}$ identifies the rank. □

Corollary 22.6.2 (Finite miracle flatness)**.** *Let $R \to A$ be a finite local homomorphism of Noetherian local rings, with R regular, A Cohen–Macaulay, and $\dim A = \dim R$. Then A is a finite free R-module.*

Proof. Parameters of R generate an ideal whose quotient in A is finite-dimensional over the residue field of R, hence artinian. Their images therefore

form a system of parameters of A. In a Cohen–Macaulay local ring every system of parameters is regular. Apply Lemma 22.6.1 to the finite R-module A. □

The remaining commutative-algebra input is the system-of-parameters characterization of Cohen–Macaulay rings. In the analytic application, one must separately establish finiteness of the map and the dimension equality at the relevant points. The presence of a regular sequence somewhere in the source does not establish those geometric facts.

Example 22.6.3 (Equal dimensions without flatness)**.** Let $R = k[[t]]$ and $A = R[\epsilon]/(\epsilon^2, t\epsilon)$. This is a finite local R-algebra of dimension one. As an R-module it is $R \oplus k\epsilon$, so it is not flat: t kills the nonzero element ϵ. Its generic fibre has dimension one over $k((t))$, while its special fibre has length two. The missing Cohen–Macaulay condition is detected by depth zero at the closed point.

Example 22.6.4 (Flatness retains nonreduced degree)**.** In contrast, $R[\epsilon]/(\epsilon^2)$ is free of rank two over R, with basis $1, \epsilon$. Every fibre has length two, although its reduced support has one point. Thus finite-flat degree counts scheme length, not the number of distinct points.

For a finite locally free morphism of rank e, tensoring a local free basis with any residue field shows that every fibre algebra has dimension e. This is the precise constancy used in a tropical weight comparison. It survives inseparability and nonreduced fibres. In a complete-intersection example $f_i = x_i^{a_i}$ in a regular coordinate ring, the zero-fibre quotient has basis $x_1^{b_1} \cdots x_r^{b_r}$ with $0 \le b_i < a_i$, hence length $\prod_i a_i$. The corresponding cycle in a Green identity must retain this multiplicity.

References. This is the finite-module proof of the local flatness criterion underlying [Mih24, Proposition 3.13]. Compare Stacks Project, Tags 00R4 and 07DY.

22.7 Regular sequences and the finite-flat comparison

The geometric input in the preceding truncation proof has an independent construction in Mihatsch's Proposition 3.13. The decisive points are Abhyankar points of the complete intersection. At these points the ambient

local ring has dimension exactly equal to the length of the regular sequence. This produces the Cohen–Macaulay hypothesis required for a finite-flat comparison. It does not require a Serre condition on an entire neighbourhood.

Lemma 22.7.1. *Let $(A, \mathfrak{m})$ be a Noetherian local ring of dimension r. If $f_1, \dots, f_r \in \mathfrak{m}$ is an A-regular sequence, then A is Cohen–Macaulay. In this situation, if a finite local homomorphism $B \to A$ has regular local source of dimension r and $\dim A = r$, then A is flat over B.*

Proof. The sequence gives $\operatorname{depth} A \geq r$, whereas depth is at most dimension. Thus equality holds. For the second assertion, let $t_1, \dots, t_r$ be a regular system of parameters of B. Finiteness makes $A/(t_1, \dots, t_r)A$ artinian, so their images are a system of parameters of A. Every system of parameters in a Cohen–Macaulay local ring is regular. Corollary 22.6.2 now applies. Equivalently this is the finite case of miracle flatness. The first assertion supplies the Cohen–Macaulay assumption used in the second. □

The dimension hypothesis cannot be replaced by the mere existence of a regular sequence. In particular, a regular sequence of length r at one local ring does not imply that this ring satisfies (S_r) at all its localizations. The following example makes the issue explicit.

Example 22.7.2. For any field k and $r \geq 1$, put

$$A = \bigl(k[x, y, t_1, \dots, t_r]/(x^2, xy)\bigr)_{(x, y, t_1, \dots, t_r)}.$$

The elements $t_1, \dots, t_r$ form a regular sequence, but A does not satisfy (S_1), hence does not satisfy (S_r). Its underlying spectrum is pure of dimension $r + 1$, and the quotient by the sequence is pure of dimension one.

Proof. A polynomial variable is a nonzerodivisor over any coefficient ring, and this remains true after successively quotienting by the previous variables and localizing. Thus the sequence is regular. The nilradical is (x) and the reduced ring is the regular local ring $k[y, t_1, \dots, t_r]_{(y, t_1, \dots, t_r)}$, proving the dimension and purity assertions.

The nonzero class of x has annihilator $\mathfrak{p} = (x, y)$, a nonminimal prime. In $A_{\mathfrak{p}}$ this class remains nonzero and is killed by the maximal ideal. Hence $\operatorname{depth} A_{\mathfrak{p}} = 0$, while $\dim A_{\mathfrak{p}} = 1$. This violates (S_1). Every open neighbourhood of the closed point of $\operatorname{Spec} A$ contains its generization $\mathfrak{p}$, so shrinking around that point does not remove the failure. □

This is a counterexample to the unrestricted commutative-algebra inference, not to the Green identity. It explains why the sentence in the proof of CLD25 Proposition 18.7.3 asserting a neighbourhood with (S_r) needs justification beyond the regular sequence alone. Mihatsch instead makes the Cohen–Macaulay argument only at the relevant Abhyankar points, where the required dimension equality holds.

The openness theorem cited at this point, [Duc09, Theorem 4.4], is a theorem about the locus where the local ring has the specified property; its definition is given in Section 3.4 of that source. Openness does not prove that the complete intersection lies in that locus. In Example 22.7.2, the depth at the closed maximal ideal is at least r, but the local ring fails Serre's condition because one of its localizations has depth zero and positive dimension. This distinction between one depth inequality and the ring condition is the missing commutative-algebra issue.

22.7.1 The weighted product near a regular immersion

Let X be a pure n-dimensional affinoid analytic space and let $Z = V(f_1, \dots, f_r)$ be defined by a regular sequence. Put $m = n - r$,

$$U^{\times} = X \setminus V(f_1 \cdots f_r), \qquad U^{\times}_{\geq C} = \{x \in U^{\times} : v(f_i(x)) \geq C \text{ for all } i\}.$$

Choose a moment map $g : X \to \mathbb{G}_m^s$. Write $T(X, g)$ for its weighted tropicalization in the top dimension of X; lower-dimensional pieces of the set-theoretic image are not included in this notation.

Theorem 22.7.3 (Mihatsch's product theorem)**.** *For all sufficiently large C, one has an equality of weighted top-dimensional polyhedra*

$$T(U^{\times}_{\geq C}, (f, g)) = [C, \infty)^r \times T(Z, g),$$

where the first factor has its standard lattice weight.

Open proof obligation (RC2). Establish the analytic moment-image, boundary dimension and finite-fibre properness inputs in the exact regular immersion scope; the proof takes them from Mihatsch Proposition 3.13.

The proof keeps the regular sequence until the finite-flat step, so it retains nonreduced multiplicities. Replacing Z by its reduced support before this step would generally change e_σ. The product structure is not a product decomposition of the analytic space, and it does not say that every local test

is originally expressed in the coordinates (f, g). The latter issue is the reason for the refinement argument in the next section.

References. [Mih24, Proposition 3.13 and its proof]; [CLD25, Theorem 14.7.2 and Proposition 18.7.3]. The commutative-algebra inputs are the regular-sequence criterion for Cohen–Macaulayness and the local flatness criterion, Stacks Project, Tags 07DY and 00R4; Serre conditions are defined in Tag 031O.

22.8 The complete-intersection identity on delta-form tests

We now use Mihatsch's analytic delta-sheaf $B^{p,q}$, not the original smooth sheaf $A^{p,q}$. The support theorem, integral and Stokes theorem are those of [Mih24, Corollary 4.9, Definition 4.10 and Proposition 4.11]. They are part of the input calculus. In particular, equality will be tested on every actual compactly supported delta-form of the indicated degree.

Let X be pure of dimension n and boundaryless, and let $Z = V(f_1, \dots, f_r)$ be a complete intersection of codimension r. Distinguish the two open sets

$$U = X \setminus Z, \qquad U^{\times} = X \setminus V(f_1 \cdots f_r) \subseteq U.$$

On U, the function $\varphi = \min_i v(f_i)$ is finite and piecewise smooth. Near a point where some f_i vanish, discard those indices: their valuations are larger than the finite minimum on a sufficiently small neighbourhood. The remaining functions are analytic units there and give a tropical presentation of φ. Thus φ is defined on the exact complement U, not only on $U^{\times}$.

Lemma 22.8.1 (The diagonal current)**.** *Let $\phi(x) = \min(x_1, \dots, x_r)$ on $\mathbb{R}^r$, and let Δ be the diagonal with primitive parameter $t \mapsto (t, \dots, t)$. In the polyhedral delta-calculus,*

$$(-1)^{r-1}(\mathrm{d}'\mathrm{d}''\phi)^{r-1} = \delta_{\Delta}, \qquad (-1)^{r-1}\phi(\mathrm{d}'\mathrm{d}''\phi)^{r-1} = t\delta_{\Delta}.$$

Open proof obligation (RC2). Prove the fan computation with the stated diagonal support and coefficients; Mihatsch Lemma 5.7 is supplied.

Define the actual delta-form

$$\gamma = (-1)^{r-1}\varphi(\mathrm{d}'\mathrm{d}''\varphi)^{r-1} \in B^{r-1,r-1}(U).$$

Its support is contained in the locus where all finite $v(f_i)$ agree, hence in $U^{\times}$. On this locus it is the pullback of $t\delta_{\Delta}$. Away from Z, $\mathrm{d}'\mathrm{d}''\gamma = 0$. This

last identity follows from the affine function t on the closed diagonal and the differential rules in the delta-calculus.

22.8.1 Why one tropical presentation is insufficient

For an original smooth test, one can use a finite affinoid covering and inclusion–exclusion: the test is a pullback of a superform, and its high-degree restriction to lower-dimensional boundary images vanishes. For an arbitrary delta-form, its restriction to a skeleton can involve the other charts in its definition. The smooth argument cannot simply be repeated by replacing the letter A with B.

Fix $\eta \in B_c^{n-r,n-r}(X)$. Near $\mathrm{Supp}(\eta|_Z)$ choose finitely many affinoid domains K_i, moment maps g_i and presentations of η in their interiors. The support theorem puts $\eta|_Z$ on the top-dimensional skeleton of Z. Each such skeleton has finite fibres under its tropicalization. Shrinking the affinoids separates the relevant fibre points from the boundary. Choose a smooth partition of unity λ_i with support in these interiors and let $\varepsilon = \sum_i \lambda_i$, equal to one near $\mathrm{Supp}(\eta|_Z)$.

Lemma 22.8.2 (Local product identity with a cutoff)**.** *With these choices, let ν_i be the pushforward of $\lambda_i\eta|_Z$ from its skeleton under g_i. For sufficiently large C, and every polyhedral delta-form α on $\mathbb{R}^r$, the corresponding pushforward upstairs, restricted to $(C,\infty)^r$, is*

$$(f,g_i)_{\mathrm{trop},*}\big(f_{\mathrm{trop}}^{\star}\alpha \wedge \lambda_i\eta\big) = \alpha \times \nu_i.$$

All restrictions to the skeletal domain and to $\{\varphi > C\}$ are understood in this formula. Pushforward is taken only where the support is proper over the target.

Open proof obligation (RC2). Prove the supported cutoff product and its compact gluing step for actual delta tests; Mihatsch Lemma 5.8 is supplied.

Theorem 22.8.3 (Complete-intersection Green identity)**.** *For every actual $\eta \in B_c^{n-r,n-r}(X)$,*

$$\int_{X\setminus Z} \gamma \wedge \mathrm{d}'\mathrm{d}''\eta = -\int_Z \eta|_Z. \tag{22.8.1}$$

In particular $\mathrm{d}'\mathrm{d}''[\gamma] + \delta_Z = 0$ on the original smooth test space as well.

Open proof obligation (RC2). Prove degree vanishing for the actual supported delta tests after the cutoff; the proof applies Mihatsch equation (5.22).

This is the proof of [Mih24, Theorem 5.5], reorganized around the product theorem, the cutoff refinement and the one-dimensional integral. It supplies the complete-intersection identity on the full stated test class. It does not solve a Green problem for an arbitrary higher-codimension cycle, where global regular-sequence equations need not exist. Nor does the proof descend an actual form through an alteration. Those are different geometric problems, discussed in Chapter 23.

22.9 The blow-up proof of Levine's formula

We now prove the projective-space formula from the divisor identity and the degree of a projective-space fibre. This isolates the geometric step suppressed by the telescoping calculation on the complement. Work in the common algebraic setting of original GK, with K algebraically closed, complete and nontrivially valued. Use its delta-metrics, intersection products, and proper pushforward of currents.

Let $Y \subset \mathbb{P}^n$ be the linear subspace $X_0 = \cdots = X_{r-1} = 0$, with $1 \leq r \leq n$. Denote the blow-up by $\pi : \widetilde{X} \to \mathbb{P}^n$ and the resolved projection by $b : \widetilde{X} \to \mathbb{P}^{r-1}$. For $r = 1$, the blow-up in the Cartier divisor is the identity; the following formulas still apply.

Lemma 22.9.1. *The blow-up is the incidence variety in $\mathbb{P}^n \times \mathbb{P}^{r-1}$ defined by $X_i U_j = X_j U_i$ for $0 \leq i, j < r$. Its exceptional Cartier divisor E satisfies*

$$E \simeq Y \times \mathbb{P}^{r-1}, \qquad \mathcal{O}(E) \simeq \pi^* \mathcal{O}_{\mathbb{P}^n}(1) \otimes b^* \mathcal{O}_{\mathbb{P}^{r-1}}(-1).$$

Proof. On an affine chart of $\mathbb{P}^n$, the ideal of Y is generated by the first r affine coordinates. In the blow-up chart $U_i \neq 0$, set $u_j = U_j/U_i$. Its equations are $X_j = X_i u_j$ for $j < r$. These are precisely the usual Rees-algebra charts of the blow-up of this coordinate ideal. They glue to the incidence variety. On Y, all the equations in the U-coordinates disappear, giving the product description of E. The pullback ideal becomes the invertible ideal $\mathcal{O}(-E)$, locally generated by X_i. The sections $X_0, \ldots, X_{r-1}$ of $\pi^*\mathcal{O}(1)$ have common factor cutting out E; after dividing by it, they generate $\pi^*\mathcal{O}(1) \otimes \mathcal{O}(-E)$ and define b. Hence this line is $b^*\mathcal{O}(1)$, which is the asserted line-bundle identity. □

Give both hyperplane lines their standard model metrics and set $a = \pi^*\alpha$, $\beta = b^* c_1(\overline{\mathcal{O}}(1))$. The quotient metric on $\mathcal{O}(E)$ makes the Green function of its canonical section, outside E, equal to

$$H = \log \frac{\max_{0\le i\le n} |X_i|}{\max_{0\le i<r} |X_i|}.$$

This is an equality of norms, not just of curvatures: it follows by evaluating the quotient of the two maximum norms in a chart $U_i \neq 0$. Poincaré–Lelong therefore gives

$$\mathrm{d}'\mathrm{d}''[H] = a - \beta - \delta_E.$$

Theorem 22.9.2. *Put* $\Omega = \sum_{j=0}^{r-1} a^{r-1-j}\beta^j$ *and define the current* $\Lambda = \pi_*([H]\wedge\Omega)$. *Then*

$$\mathrm{d}'\mathrm{d}''\Lambda + \delta_Y = \alpha^r.$$

On $\mathbb{P}^n \setminus Y$, *it is represented by the formula* $h\sum_{j=0}^{r-1}\alpha^{r-1-j}\beta^j$ *of Section 22.1.*

Proof. All factors of Ω are closed delta-forms, so multiplication of the divisor equation and the current Leibniz rule give

$$\mathrm{d}'\mathrm{d}''([H]\wedge\Omega) = a^r - \beta^r - \delta_E\wedge\Omega = a^r - \delta_E\wedge\Omega.$$

Here $\beta^r = 0$ because it is pulled back from the $(r-1)$-dimensional projective space. Proper pushforward commutes with the differential, and $\pi_* a^r = \alpha^r$ by the projection formula and the generic degree one of π. It remains to compute the exceptional term. On $E = Y\times\mathbb{P}^{r-1}$, the form a comes from Y and β from the second factor. Pair $\pi_*(\delta_E\wedge a^{r-1-j}\beta^j)$ with any complementary admitted test. The test also comes from Y after restriction to E. If $j < r-1$, the integrand has insufficient degree in the projective-space fibre, so its fibre integral is zero. For $j = r-1$, the fibre integral of β^{r-1} is $\deg \mathcal{O}_{\mathbb{P}^{r-1}}(1)^{r-1} = 1$. The remaining integral is exactly the test integral over Y. Hence $\pi_*(\delta_E\wedge\Omega) = \delta_Y$. This proves the current identity. Outside Y, the map π is an isomorphism, so the representative is the displayed one. The argument constructs a current globally and a specified form on the exact complement; it does not assert that arbitrary proper pushforward preserves actual delta-forms. □

The product structure of E was essential to this short proof. For a general regular immersion, the exceptional divisor is the projectivized normal bundle, and pushing powers of its tautological class produces Segre classes. The linear-subspace formula cannot simply be copied with a general cycle substituted for Y. Such a generalization requires both the normal-cone intersection formulas and admissible Green representatives.

22.10 Metric variation and completion of local heights

The one-metric variation formula gives a simultaneous continuity theorem without differentiating singular functions. Fix line bundles $L_0, \dots, L_n$ on a proper n-dimensional variety and fixed pseudodivisor data for which the initial local heights are defined. Suppose all metrics under consideration are semipositive, and the model or delta-metric height theory has symmetry and the one-metric variation formula.

Theorem 22.10.1. *For two metric tuples $\boldsymbol{m}, \boldsymbol{m}'$, put $\varepsilon_i = d(m_i, m_i')$ and $V_i = \deg_X \prod_{j \neq i} L_j$. Then*

$$|\lambda(\boldsymbol{m}) - \lambda(\boldsymbol{m}')| \leq \sum_{i=0}^{n} \varepsilon_i V_i.$$

Consequently local height extends uniquely to uniform limits of admitted semipositive metrics, with the fixed pseudodivisor data.

Proof. Replace the metrics one at a time, in the order $0, \dots, n$. The ith difference is the integral of the ith weight difference against a mixed positive measure formed from the other metrics, some old and some new. Its mass is V_i, since the underlying line bundles did not change. Its absolute value is at most $\varepsilon_i V_i$. Sum the $n+1$ inequalities. For uniformly Cauchy metric sequences, the estimate makes the height sequence Cauchy. If two sequences have the same limiting metrics, their mutual distances tend to zero, so the estimate makes their height limits equal. This proves existence and independence of approximation. Uniqueness follows from density of the original metric class in its uniform completion. □

Remark 22.10.2. This is a completion theorem after a height theory has been constructed on a positive class. It is not a construction of arbitrary mixed measures from uniform convergence alone. Symmetry, positivity, the degree formula and the one-metric variation identity are the inputs that make the proof work. For signed integrable metrics, expand into differences of semipositive metrics or use a uniform total-variation bound; the signed total degree alone is insufficient.

22.10.1 From local metric variation to global height variation

For a global field with fixed product-formula weights n_v, changing a metric only at finitely many places gives the sum of the local variations:

$$h' - h = \sum_v n_v \int_{X_v^{\mathrm{an}}} \rho_v \, c_1(\overline{L}_{1,v}) \cdots c_1(\overline{L}_{n,v}).$$

For point heights the mixed measure is replaced by the normalized finite orbit measure. A change by a principal scalar has local weights $-\log|a|_v$; the product formula makes the corresponding global sum zero. An arbitrary independent rescaling at each place does not have this cancellation. This is why local constants matter even though principal global changes leave heights unchanged.

References. [CLD25, Theorem 18.7.5]; [GK17, Sections 7, 11–12]; [GH]. The Levine proof uses only the stated divisor, projection and degree theorems after the explicit blow-up calculation.

22.11 Three meanings of a non-Archimedean Green object

The word Green is used for three different constructions in the recent literature. Their equations share some notation but their unknowns belong to different spaces. Keeping the categories explicit prevents a solution in one theory from being mistaken for a solution in another.

22.11.1 Model-theoretic currents

Dubocs works in the non-Archimedean Arakelov theory of Bloch–Gillet–Soulé. The ground data are an excellent discrete valuation ring and a proper smooth variety over its fraction field. Section 1.1 assumes the existence of regular proper flat models and common dominating regular models. These model hypotheses hold, for example, under the indicated resolution hypothesis; excellence alone is not stated to imply them. Forms and currents are built from bivariant intersection classes and Chow groups of models and their special fibres. They are not defined as continuous linear functionals on CLD test forms. Let F be a metrized vector bundle of rank r with a regular section whose zero scheme is Z. In [Dub26, Theorem 4.1], blow up Z, let s be the

canonical exceptional section, and let Q_F be the tautological quotient with its induced metric. The constructed model current is

$$\Lambda = \pi_*\big(\mathrm{div}_v(s) \wedge f^* c_{r-1}(Q_F)\big), \qquad dd^c\Lambda + \delta_Z = [c_r(F)].$$

The formula is useful because it expresses the higher-codimension Green current through an exceptional divisor and a quotient Chern class. When $F = L^{\oplus r}$, Theorem 6.1 gives the corresponding Levine formula. Neither statement asserts that Λ is an actual Mihatsch delta-form on $X^{\mathrm{an}} \setminus |Z|^{\mathrm{an}}$. A comparison would have to define realization maps, match Chern classes and pushforwards, and verify the identity against the required analytic tests.

22.11.2 Monge–Ampère Green functions

A Green function in Boucksom–Jonsson's pluripotential theory solves a nonlinear measure equation, for example $\mathrm{MA}_\omega(\phi_x) = \delta_x$ with their normalized measure. It is a scalar psh potential. Their Theorem A shows that a divisorial Green function is PL in dimension one but need not be PL in higher dimension. More strongly, Theorem B constructs on $\mathbf{P}^3_{\mathbf{C}((t))}$ a continuous potential whose Monge–Ampère measure has finite support in a dual complex, while the potential does not factor through the retraction of any SNC model. Thus a skeletal support theorem for a measure is not a skeletal factorization theorem for its potential. This result rules out a general shortcut from finitely many measure atoms to a potential on a finite skeleton. It does not contradict the comparison theorem in Section 16.8, where strong faithfulness, a pre-existing tropical solution and absolute continuity are additional hypotheses.

22.11.3 Actual forms for cycle equations

The strong Green problem considered here asks for an actual form of bidegree $(r-1, r-1)$ on the exact cycle complement, satisfying a linear $d'd''$ identity against all admitted actual tests. Mihatsch's complete-intersection result belongs to this third category. It has stronger representative and testing content than a current identity on original smooth tests, but retains its own geometric hypotheses. Dubocs's construction and Monge–Ampère Green functions provide comparisons and possible methods; neither removes those hypotheses. For zero curvature one must also eliminate the curvature term $[c_r(F)]$ or its analogue. Homological triviality of a cycle is not a construction

of a primitive in the actual delta-sheaf. Section 24.15 supplies a relevant vanishing theorem on closed CLD tests; Sections 22.8 and 23.4 explain the additional representative and descent requirements.

References. [Dub26, Section 1.1 and Theorems 4.1, 6.1]; [BJ24, Theorems A–B]; [Mih24, Theorem 5.5].

Chapter 23

Functoriality and descent

The analytic scalar extension X_L is constructed by completed tensor products in Section 2.6. That construction determines its points, functions and projection to X. It does not determine which ground-field calibration is used when integrating upstairs. We therefore specify the calibration before applying a degree or trace formula. The Galois-product example, Example 2.6.3, also shows why a descent argument must use the analytic fibre product rather than the Cartesian product of point sets.

23.1 Field extension, degree, and descent of representatives

23.1.1 Extending the field does not reset the valuation

Fix a complete valued field K and a finite extension L/K, with the absolute value extended from K. If π_K is a uniformizer in a discretely valued example, its value remains $-\log|\pi_K| = \lambda_K$ in L. A uniformizer π_L has value λ_K/e when the ramification index is e. Thus skeleton lengths and logarithmic weights are compared using one fixed real scale.

Normalizing the valuation independently in both fields by assigning value one to each uniformizer changes that scale. A formula that compares local heights or slopes across the extension must then include the corresponding conversion factor. The safest convention for an analytic descent problem is to retain the original absolute value throughout.

23.1.2 The finite flat degree formula and the base field

For a finite flat map $f : Y \to X$ of constant degree d over one fixed field, the calibrated projection formula gives $f_*[Y] = d[X]$ in the applicable algebraic setting. Scalar extension is normalized differently: with X_L integrated over L, the base-change projection satisfies $p_*[X_L]_L = [X]_K$. Section 23.2 explains and proves the distinction from the cited calibration theorem. A degree factor must therefore be attached to an explicit choice of ground-field calibration, not to the notation $X_L \to X$ alone.

23.1.3 What averaging can and cannot descend

If an object upstairs belongs to a class stable under the relevant finite trace, one may hope to define a descended object by $d^{-1}\pi_*$ and verify the desired identity by the projection formula. For currents, proper pushforward is often available. For an actual sheaf of delta-forms or another specified representative class, stability under that trace must be proved.

A pushed-forward current satisfying an equation is not automatically an actual form in the required sheaf. The operation may forget the local presentation or introduce singularities outside the admitted class. A descent theorem must show that the trace of the upstairs representative has local expressions downstairs and that those expressions satisfy the correct relations on overlaps.

23.1.4 Finite descent and alteration descent are different

A proper alteration is not a finite flat cover on the entire space. Exceptional loci, changes of relative dimension, and ramification can affect both support and representative regularity. The existence of a proper pushforward current remains useful, but dividing by a generic degree does not automatically reconstruct an actual form on the original complement.

For the strong Green problem, one must in addition control the support: the upstairs construction may require removing the inverse image of the cycle together with an exceptional divisor. A descended current on the original space does not prove that its representative is defined on the exact original complement. This support issue is independent of the normalization by degree.

23.1.5 Compatibility conditions for descent

To use an extension or a cover in a proof, establish in order: the upstairs equation on the full admitted tests; the trace operation on the actual representative class; commutation with d' and d''; the projection formula with the correct degree; and preservation of the precise support complement. If the goal is only an equality of currents, say so. If the goal is an actual Green form, the representative step cannot be omitted.

This template is particularly relevant to comparisons between CLD currents, GK delta-forms, and Mihatsch's analytic delta-forms. Their operations overlap, but the domains of trace and pushforward need not coincide. The correct comparison carries the object and its testing category through every step.

References. The finite-map and current projection formulas in [CLD25, Chapters 13–16]; the representative-sensitive constructions in [Mih24].

23.2 Two different degree formulas

The field of definition of an integral is part of its normalization. A finite map between spaces over one fixed field and a change of the ground field are different operations. The earlier version of these notes did not separate them clearly enough. We correct that ambiguity here.

Theorem 23.2.1 (Scalar extension; external geometric input)**.** *Let X be an analytic space of level n in the CLD25 framework, let L/K be a complete valued extension with the extended original absolute value, and let $p : X_L \to X$ be the scalar-extension projection. With the canonical calibrations over L and K, respectively,*

$$p_*[X_L]_L = [X]_K.$$

Equivalently, for an admissible compactly supported top-degree smooth form η on X,

$$\int_{X_L,L} p^*\eta = \int_{X,K} \eta.$$

There is no factor $[L : K]$ in this scalar-extension formula, even when the extension is finite.

This is CLD25, Propositions 14.3.6, 15.3.1 and 16.1.1: calibration commutes with scalar extension; the associated measures push forward without

changing mass; testing yields the current identity. The calibration theorem is imported here. Once it is given, the displayed integral and current identities follow directly from the definitions.

For a compact morphism $f : Y \to X$ between analytic spaces over the same field, CLD25 Proposition 16.1.2 instead gives $f_*[Y] = (\deg_c f)[X]$, with calibrated degree. In a finite flat algebraic situation where this is the usual constant degree d, the right side is $d[X]$. If L/K is finite, the underlying space X_L can also be viewed as a K-analytic space. Its K-calibration is then not the L-calibration in Theorem 23.2.1. One cannot retain the L-normalized integral and insert the K-degree factor at the same time.

Example 23.2.2 (Dimension zero)**.** The integration mass of $\operatorname{Spec} L$ over L is one. Viewed as a finite zero-cycle over K, its degree is $[L : K]$. Both statements are correct. The discrepancy is entirely the ground-field normalization. It already rules out a universal instruction to divide every pushed-forward base-extended current by $[L : K]$.

23.3 Pushforward on an actual test space

Proposition 23.3.1. *Suppose $f : Y \to X$ has a continuous pullback f^* on the smooth test spaces of interest, preserves admissible test supports, and commutes with d', d''. For a current T on Y define f_*T by*

$$(f_*T)(\eta) = T(f^*\eta).$$

Then pushforward commutes with d', d''. If pullback preserves the chosen positive cone, it preserves positivity of currents of the corresponding dual type. If a is a smooth form,

$$f_*\big(f^*a \wedge T\big) = a \wedge f_*T,$$

with the same wedge order on both sides.

Proof. Continuity of f^* makes the displayed functional a current. Apply the definition of a distributional derivative and $f^*d' = d'f^*$ to a test; the transpose sign is unchanged because the total bidegree shift under pushforward is even. The proof for d'' is identical. A positive test pulls back to a positive test, proving positivity. Finally, $f^*(a \wedge \eta) = f^*a \wedge f^*\eta$ identifies the two pairings in the projection formula. □

Proper analytic maps supply the required support control in the standard current formalism; more generally one may work with properness on the support of the current, provided a cutoff argument defines the pairing. A general map does not pull compact supports back to compact supports. Thus the same formula cannot be applied to every map without checking its domain.

Corollary 23.3.2. *Under these hypotheses, if $T_j \rightharpoonup T$ and all pushforwards are defined by the displayed test pullback, then $f_*T_j \rightharpoonup f_*T$. A current identity $\mathrm{d}'\mathrm{d}''G + \delta_Z = R$ upstairs pushes forward to*

$$\mathrm{d}'\mathrm{d}''(f_*G) + f_*\delta_Z = f_*R.$$

Proof. For each downstairs test, its pullback is one fixed upstairs test, so weak convergence applies. The second assertion follows by linearity and commutation with derivatives. □

23.4 The extra step for representatives

The preceding corollary produces a current. Suppose the intended conclusion is an actual form in a specified sheaf $B^{p,q}$ on $X \setminus |Z|$. One additionally needs a trace operation

$$\mathrm{Tr}_f : B^{p,q}(Y \setminus f^{-1}|Z|) \longrightarrow B^{p,q}(X \setminus |Z|)$$

with the appropriate degree shift when dimensions differ, compatibility with the current realization, and compatibility with the differentials. This map is additional geometric information. The continuous dual construction of f_*T does not provide it.

Lemma 23.4.1 (Exact support in finite descent)**.** *Let $f : Y \to X$ be a finite surjective map of topological spaces. If a representative upstairs is defined only on $Y \setminus (f^{-1}Z \cup E)$, then the directly available downstairs domain is at most $X \setminus (Z \cup f(E))$. To claim a representative on all of $X \setminus Z$, one must remove the obstruction along $f(E) \setminus Z$ by an extension theorem or a different construction.*

Proof. For $x \notin Z \cup f(E)$ every point of $f^{-1}(x)$ lies in the domain upstairs. For $x \in f(E) \setminus Z$ at least one point of that fibre is excluded, so a trace requiring data on the whole fibre cannot be evaluated from the given representative. A current extension may still exist, but that is a different assertion. □

Averaging over a finite group does not bypass this issue. For continuous functions on a topological quotient $X = Y/G$, the average $|G|^{-1}\sum_{g\in G} g^*u$ is invariant and descends continuously by the quotient topology. For differential representatives, invariance must be related to the downstairs sheaf by a separate descent theorem. The function argument alone neither identifies that sheaf nor proves its trace compatibility.

23.5 Finite harmonic maps of metric graphs

Finite maps of curves have a transparent one-dimensional model. A map of metric graphs may be one-to-one on its underlying points and still carry a nontrivial degree, because an edge is traversed with an integral expansion factor. Keeping this factor leads to the correct pullback of measures, trace of functions and Green-kernel normalization.

Let $\phi : \Gamma' \to \Gamma$ be a surjective map between finite connected compact metric graphs, linear on edges after subdivision, with no contracted edges. For every source edge e' mapping into e, let $m_{e'}$ be the positive integral ratio of target length to source length. At a vertex y above x, assume that

$$\sum_{e'\mapsto e \text{ at } y} m_{e'} = d_y$$

is independent of the outgoing edge e at x. This is the harmonicity condition; d_y is the local degree. At an interior point of an edge, the local degree is its expansion factor. We assume both graphs have at least one edge.

Lemma 23.5.1. *The sum $\sum_{y\in\phi^{-1}(x)} d_y$ is independent of $x \in \Gamma$. Denote it by $d = \deg\phi$.*

Proof. On the interior of a target edge, the inverse image consists of finitely many edge segments, and the sum of their constant expansion factors is constant. As one approaches an endpoint x, group these segments by the source vertex y to which they converge. Harmonicity makes the sum in each group equal to d_y, independently of the chosen target edge. The degree therefore has the same value on every adjacent edge. Connectedness finishes the proof. □

23.5.1 Trace and pullback

For a continuous function v on Γ', define its weighted trace by

$$(\operatorname{Tr}_\phi v)(x) = \sum_{y \in \phi^{-1}(x)} d_y v(y).$$

Proposition 23.5.2. *The trace is continuous, positive, and satisfies*

$$\|\operatorname{Tr}_\phi v\|_\infty \le d\|v\|_\infty, \qquad \operatorname{Tr}_\phi(\phi^* u) = du.$$

There is consequently a pullback of finite signed Radon measures, uniquely determined by

$$\int_{\Gamma'} v \, d(\phi^*\nu) = \int_\Gamma \operatorname{Tr}_\phi(v)\, d\nu.$$

It preserves positivity, multiplies total mass by d, and satisfies $\phi_*\phi^*\nu = d\nu$. In particular $\phi^*\delta_x = \sum_{y \mapsto x} d_y \delta_y$.

Proof. Continuity on edge interiors is immediate. At a vertex x, group the approaching inverse branches by their endpoint y. Continuity of v and harmonicity give the limit $\sum_y d_y v(y)$ from every outgoing direction. The norm estimate and positivity follow from positive local degrees. The representation theorem for continuous linear functionals on $C(\Gamma')$ defines the measure pullback. Applying its definition to 1 and to $u \circ \phi$ gives the mass and push-pull formulas. □

On a single edge of expansion m, the pullback of a measure with density $a(t)\,dt$ has density $m^2 a(ms)\,ds$ in a coordinate where $t = ms$. One factor m is the local degree and the other is the change of variable. Omitting either factor would break the Laplacian identity below.

Proposition 23.5.3 (Energy identities)**.** *For continuous edgewise H^1 functions,*

$$\begin{aligned} \mathcal{E}_{\Gamma'}(\phi^* u, \phi^* w) &= d\,\mathcal{E}_\Gamma(u, w), \\ \mathcal{E}_\Gamma(\operatorname{Tr}_\phi v, u) &= \mathcal{E}_{\Gamma'}(v, \phi^* u), \\ \mathcal{E}_\Gamma(\operatorname{Tr}_\phi v, \operatorname{Tr}_\phi v) &\le d\,\mathcal{E}_{\Gamma'}(v, v). \end{aligned}$$

Proof. On a source edge, $(u\circ\phi)' = m_{e'}u'\circ\phi$ and $dt = m_{e'}ds$. Its contribution to the first energy is therefore $m_{e'}\int_e u'w'\,dt$. Sum over all inverse edges and use the constant-degree lemma. On the interior of a target edge,

$$(\mathrm{Tr}_\phi\, v)'(t) = \sum_{e'\mapsto e} v'_{e'}(s_{e'}(t)).$$

This proves the second identity after change of variable. Weighted Cauchy–Schwarz gives

$$\left|\sum_{e'\mapsto e} v'_{e'}\right|^2 \le \left(\sum_{e'\mapsto e} m_{e'}\right)\left(\sum_{e'\mapsto e}\frac{|v'_{e'}|^2}{m_{e'}}\right).$$

The first factor is d; integrating the second over the target edge recovers the source energies. This proves the inequality and also shows that the continuous trace is edgewise H^1. □

23.5.2 Laplacians and vertex multiplicities

Theorem 23.5.4. *Use the convention $\Delta = -DD$ of Chapter 20. If v has a finite measure Laplacian on Γ', then*

$$\Delta(\mathrm{Tr}_\phi\, v) = \phi_*(\Delta v).$$

If u has a finite measure Laplacian on Γ, then

$$\Delta(\phi^* u) = \phi^*(\Delta u).$$

Functions here are continuous and edgewise H^1, and the equations hold against all continuous edgewise H^1 tests.

Proof. For the trace identity, pair with a test a on Γ and use Proposition 23.5.3:

$$\langle \Delta\,\mathrm{Tr}_\phi\, v, a\rangle = \mathcal{E}_{\Gamma'}(v,\phi^* a) = \int_{\Gamma'}\phi^* a\, d(\Delta v) = \int_\Gamma a\, d\phi_*(\Delta v).$$

For pullback, first let u be PL. Its Laplacian is concentrated at vertices, with coefficient minus the sum of outgoing slopes. At a source vertex y above x, the corresponding sum is

$$\sum_{e' \text{ at } y} m_{e'}\,\partial_e u(x) = d_y \sum_{e \text{ at } x}\partial_e u(x),$$

by harmonicity. This is the asserted weighted pullback of each atom. Subdivision permits the same calculation at any additional break point.

For general u, let $\nu = \Delta u$, which has total mass zero. Approximate ν weakly by finite atomic signed measures ν_j of mass zero and uniformly bounded total variation. The graph Green construction gives normalized PL solutions u_j converging uniformly to $u - u(z)$. In fact they converge in energy:

$$\mathcal{E}(u_j - u + u(z), u_j - u + u(z)) \le \|u_j - u + u(z)\|_\infty \, \|\nu_j - \nu\|_{\mathrm{TV}} \longrightarrow 0.$$

The pullback energy identity preserves this convergence. The bounded continuous trace map makes $\phi^*\nu_j \rightharpoonup \phi^*\nu$. Passing to the PL identity proves the pullback formula on the full energy test class. □

Example 23.5.5 (One skeletal point with degree greater than one)**.** The map $[0, L] \to [0, mL]$, $s \mapsto ms$, has one point in each fibre, but local and global degree m. Its trace is $v \mapsto (t \mapsto mv(t/m))$, and the pullback of an atom is $m\delta_{t/m}$. This is the skeletal normalization of the monomial map $z \mapsto z^m$ between annuli. The algebraic degree is retained by the expansion factor even though the skeletal map is a homeomorphism.

23.5.3 Green-kernel normalization under a finite map

Let μ have mass one on Γ, and set $\mu' = d^{-1}\phi^*\mu$. Both measures have mass one, so the normalized kernels of Theorem 20.15.5 are defined. For $x' \in \Gamma'$ and $y \in \Gamma$,

$$g_\mu(\phi(x'), y) = \sum_{y' \in \phi^{-1}(y)} d_{y'} g_{\mu'}(x', y'). \tag{23.5.1}$$

Proof. Both sides, as functions of x', have Laplacian $\phi^*\delta_y - \phi^*\mu$. Their difference is constant. The right side has zero μ'-mean by normalization. For the left side, the measure pullback formula and $\mathrm{Tr}_\phi(\phi^* a) = da$ give

$$\int_{\Gamma'} g_\mu(\phi(x'), y)\, d\mu'(x') = \int_\Gamma g_\mu(x, y)\, d\mu(x) = 0.$$

Thus the constant vanishes. □

A single lifted point does not generally give the pullback kernel; the weighted sum over its fibre does. These formulas are complete statements in the finite harmonic-graph category. To apply them to a morphism of analytic

curves, one must supply compatible skeleta and the theorem identifying local analytic degrees with the graph expansion factors and residual degrees. The existence of such skeleta is a geometric input, not a consequence of the energy identities.

References. The proofs combine the graph Laplacian and Green kernel of [BRg] with the harmonicity condition expressing local degree. They provide a one-dimensional verification of the normalizations used in the analytic projection formulas. The skeletal and slope geometry is treated in [GRW16]; no existence theorem for compatible skeleta is proved by these elementary graph calculations.

23.6 Boundary completions and arithmetic intersection

Local currents and global arithmetic intersection numbers are related through metrics, but have different domains of definition. Cai–Gubler's abstract divisorial spaces make the completion process itself part of the theory. For an open variety U and a boundary divisor B on a compactification, a sequence of metrized divisors is Cauchy when its differences, after passage to common models, are bounded between $-\epsilon B$ and ϵB, together with the corresponding inequalities for boundary Green functions. Two consequences matter for applications. First, this topology controls growth at the boundary; uniform convergence on each compact subset of U^{an} is not the defining condition. Second, the completion retains an underlying compactified geometric line bundle, not merely its restriction to U. Different boundary data can restrict to the same line bundle on U.

Example 23.6.1 (The open line does not determine its boundary extension)**.** On $U = \mathbf{A}^1 \subset \mathbf{P}^1$, every $\mathcal{O}_{\mathbf{P}^1}(a\infty)$ restricts to the trivial line bundle, but these extensions have degrees a. Thus the restriction to U forgets numerical data at infinity. Any comparison theorem requiring the same compactified object has strictly more input than an isomorphism of the restrictions.

Over a proper adelic curve in their sense, [CG26, Theorem 7.22] extends arithmetic intersection to arithmetically integrable compactified metrized divisors. The pairing is real-valued, symmetric and multilinear, agrees with the proper theory, and has the specified projection, base-change and boundary-continuity properties. The positivity and integrability classes are part of its domain. A positive local CLD current alone is not a membership test for

that domain. The relative-energy extension in Theorem 11.3 has a different range: it can take the value $-\infty$. It requires relatively nef metrics on compactified geometric objects admitting arithmetically nef reference metrics. The reference and the new metric must have the same underlying compactified geometric object, a stronger requirement than having the same line bundle on U. Mixed relative energy measures their change of arithmetic intersection. In the finite-energy part, this has the form

$$I(\mathbf{h}) - I(\mathbf{g}) = E(\mathbf{g}, \mathbf{h}).$$

Writing this as a difference presupposes that the displayed values are finite. The source formulates the extended-valued statement with its admissible energy class, so that no subtraction of two infinities is required. In a proof using the formula, finiteness must be checked rather than inferred from the notation.

Lemma 23.6.2 (Independence of a finite-energy reference)**.** *Suppose an energy E on a class of metrics satisfies the cocycle identity $E(a,c) = E(a,b) + E(b,c)$, all terms below are finite, and the known intersection values satisfy $I(b) - I(a) = E(a,b)$. Then the prescription $I(c) := I(a) + E(a,c)$ is independent of the reference a among those known metrics.*

Proof. Substitute the two assumed identities to get $I(a) + E(a,c) = I(a) + E(a,b) + E(b,c) = I(b) + E(b,c)$. □

The lemma explains the algebra of the extension. It does not prove the analytic construction, finiteness or cocycle property of relative energy; those are substantial inputs from [CG26]. It also separates this global completion theory from the local degree normalization under scalar extension discussed earlier in this chapter.

References. [CG26, Sections 2, 7, 10 and Theorem 11.3].

23.7 Finite changes of the ground field and local values

The two local calculations below use the original absolute values. The ordinary top-integral calculation uses NAG-002503, NAG-002511, NAG-002514 and NAG-002518 in the scalar-extension source `research_v040/f9_scala`

`r_extension_candidate.tex`, which accompanies this reconstruction as a separate article. Equality of archimedean local values remains open here.

Proposition 23.7.1 (Conditional place-weight summation)**.** *Let $F \subset E$ be number fields. Fix unsquared absolute values extending those on $\mathbb{Q}_p$ and the usual real absolute value, and put $c_v(F) = [F_v : \mathbb{Q}_v]/[F : \mathbb{Q}]$. Suppose the completion-degree identity $\sum_{w|v}[E_w : F_v] = [E : F]$ is supplied. Suppose real numbers a_v and a_w satisfy $a_w = a_v$ for $w \mid v$, and their weighted families are finitely supported or absolutely summable. Then*

$$\sum_w c_w(E)a_w = \sum_v c_v(F)a_v.$$

Proof. We first establish the completion-degree identity under the stated number-field hypotheses.

Finite places. Let F be a field with a specified real-valued nonarchimedean absolute value v. Let $H = \widehat{F}_v$, let E/F be a finite extension of degree n, and let $w \mid v$ mean an absolute value on E restricting to this very absolute value on F. Write E_w for the resulting completion. Set $C = H \otimes_F E$. There is a canonical indexing of the Artinian local factors C_w of C by $w \mid v$, with canonical valued residue field E_w. In particular

$$n = \sum_{w|v} \ell_{C_w}(C_w)[E_w : H].$$

For separable E/F all lengths are one.

A basis of E/F gives $\dim_H C = n$. Its ideals are finite-dimensional H-subspaces, so descending chains stabilize. By [StacksAlg, Tag 00JB, Lemma 10.53.6] it is the finite product of its localizations at its maximal ideals. For a maximal ideal P let $D = C/P$, a finite field extension of H. NAG-001450 supplies the unique extension of the absolute value of H, completeness of D, and equivalence with a finite-dimensional coordinate norm, without separability. The map $E \to D$, $a \mapsto 1 \otimes a \bmod P$, is a unital field embedding, so defines an extension w_P of v. The image of E is dense in D: the images of an F-basis e_i of E span D over H, and each $\sum_i h_i e_i$ is a limit of $\sum_i f_i e_i$ with $f_i \in F$. Indeed the error is bounded by $\max_i |h_i - f_i|\,|e_i|_{w_P}$. Thus D identifies isometrically with E_{w_P}, fixing E.

Conversely, for any extending w, the inclusion of F into E_w extends isometrically to H. Multiplication gives a map $C \to E_w$. Its image is a

finite-dimensional H-domain, hence a field: multiplication by each nonzero element is an injective linear endomorphism and therefore surjective. With its induced norm this field is complete by NAG-001450, hence closed in E_w. It contains the dense copy of E and consequently is all of E_w. Its kernel is maximal. Starting from P, the isometry from the previous paragraph agrees with both structure maps on E and on H (on H by density of F); thus the resulting kernel is exactly P. Starting from w, the norm on the residue field is the induced norm by uniqueness, so this construction recovers w. This proves the asserted bijection without counting embeddings. The algebra here is formed over the original, possibly incomplete, F; it is finite-dimensional over H and already complete for a coordinate norm.

The simple modules in a composition series of C_w are its residue field. Each therefore contributes exactly $[E_w : H]$ to the H-dimension. Adding the contributions of the full local factors gives the formula. To check separability, take a finite tower of simple generators for E/F. At each step the minimal polynomial of the new generator over the intermediate field divides a separable polynomial over F. It is coprime to its derivative. Starting with H, if the tensor algebra for the intermediate extension is a product of fields, tensoring with the next simple extension quotients a polynomial ring over each factor by the image of that minimal polynomial. The Bezout identity with its derivative survives in the field. The distinct monic irreducible factors are pairwise coprime, and the Chinese remainder map gives a product of fields again. Induction proves the length-one assertion. In characteristic zero every irreducible nonconstant polynomial is separable, since its derivative is nonzero and of smaller degree.

At a finite place v of a number field F over p, use the absolute value extending the specified one on $\mathbb{Q}_p$. The same result for $F/\mathbb{Q}$ shows that $F_v/\mathbb{Q}_p$ is finite. For $w \mid v$ in a finite extension E/F the identification above uses this $F_v \subset E_w$ isometrically. Since the number fields have characteristic zero, the length-one case gives $\sum_{w|v}[E_w : F_v] = [E : F]$ at each finite place.

Archimedean places. Let $F \subset E$ be number fields, $n = [E : F]$, and v an absolute value on F extending the usual absolute value on $\mathbb{Q}$. Count each absolute value w on E extending this fixed v once. With the usual unsquared moduli on all archimedean completions, one has

$$F_v \otimes_F E \simeq \prod_{w|v} E_w, \qquad \sum_{w|v} [E_w : F_v] = n.$$

If $F_v = \mathbb{R}$ and the factors comprise r real and s complex completions, then $r + 2s = n$. If $F_v = \mathbb{C}$, there are n complex factors, each of degree one over F_v.

Elementary field input. For a nonconstant complex polynomial P, the leading term implies $|P(z)| \to \infty$ as $|z| \to \infty$. A sequence approaching its infimum can therefore be taken in a bounded square. Successive subdivision into four closed subsquares, each time retaining one containing infinitely many sequence terms, gives a convergent subsequence by completeness of the real coordinates. Continuity gives a minimizer z_0. If $P(z_0) \neq 0$, write $P(z_0 + h)/P(z_0) = 1 + ch^k + O(|h|^{k+1})$ with $k \geq 1$ and $c \neq 0$. Choose δ among $1, -1, i, -i$ with $\operatorname{Re}(c\delta) < 0$. It has a unit-modulus k-th root u: writing $k = 2^a b$ with b odd, the b-th power permutes those four units, and successive square roots of a unit v are available since $(1 + v)/|1 + v|$ squares to v for $v \neq -1$, and $i^2 = -1$. For small positive t,

$$|P(z_0 + tu)/P(z_0)|^2 = 1 + 2\operatorname{Re}(c\delta)t^k + O(t^{k+1}) < 1,$$

a contradiction. Division by a linear factor and induction show that every complex polynomial splits. Conjugation of roots then shows that each irreducible real polynomial is linear or quadratic with a pair of nonreal conjugate roots. A quotient by such a quadratic is $\mathbb{C}$ over $\mathbb{R}$, by evaluation at either root: a nonreal root and 1 already span $\mathbb{C}$ over $\mathbb{R}$.

Completion factors. First take any number field D, with base $\mathbb{Q}$ and $H = \mathbb{R}$. More generally let D/B be a finite extension of number fields and fix a completion H of B already identified isometrically with $\mathbb{R}$ or $\mathbb{C}$. Write $A = H \otimes_B D$. Adjoin a finite generating list for D/B one element at a time. At each step the minimal polynomial over the preceding field is separable: in characteristic zero it is coprime to its derivative. Over each field factor reached so far the Bezout identity with its derivative persists. Factoring the resulting polynomial and applying the Chinese remainder identity for coprime factors gives a product of fields. By the preceding paragraph these fields are real or complex over a real factor, and complex over a complex factor. Starting with H yields a product decomposition of A; its H-dimension is $[D : B]$ by a basis. In particular all local lengths here are one.

Each factor carries the usual modulus, independent of the choice between conjugate identifications with $\mathbb{C}$. In fact any multiplicative absolute value ν on $\mathbb{C}$ extending the usual absolute value on $\mathbb{R}$ satisfies $\nu(i) = 1$, hence $\nu(z) \leq |\operatorname{Re} z| + |\operatorname{Im} z| \leq 2|z|$. Apply this inequality to z^j and let $j \to \infty$;

applying it also to z^{-1} gives $\nu(z) = |z|$. Thus each factor restricts to the specified absolute value on H.

The image of D in a factor spans it over H; it is dense because the finitely many coefficients of a linear combination can be approximated in B. The factor is complete, so is the completion of D for the induced w. Conversely, for any extending w, the inclusion of B in D_w extends isometrically to H. Multiplication defines $A \to D_w$. Exactly one primitive factor idempotent maps to 1 in this field, so the image is the corresponding factor. Its norm is its usual one by the preceding uniqueness argument (immediate for a real factor); it is therefore complete and closed. It contains dense D, hence equals D_w. These assignments are inverse: the completion isometry fixing D fixes the prescribed image of H by density of B, hence gives the same kernel in A. This identifies factors with places themselves, including exactly one factor per complex-conjugate pair over a real place.

Apply the argument first to $F/\mathbb{Q}$ and $\mathbb{R}$ to obtain the claimed alternatives for F_v. Apply it again to E/F with $H = F_v$. Taking F_v-dimensions gives precisely the two counts above.

These two calculations give the asserted degree identity for every place in the proposition. At infinity all moduli are unsquared.

The tower formula gives $c_w(E) = c_v(F)[E_w : F_v]/[E : F]$. Sum first over the finite set of w above each v and use the completion-degree identity above. Absolute summability permits regrouping. At the archimedean base place $\mathbb{Q}_v = \mathbb{R}$; a complex completion has degree two and its absolute value remains unsquared. □

For the non-Archimedean smooth top integrals in the native scalar-extension theorem NAG-002503, the local equality is $a_w = a_v$. The extension degree is already in the place weight and must not be inserted a second time into this native local value. The completion-degree identity holds at all places by the preceding proof. Equality of the actual archimedean local height values, the product formula, and summability remain separate inputs.

Finite-place matching of the local value in NAG-002523

The assertion to be applied is at lines 629–632 of the original `research_v040/f9_scalar_e`
Lines 613–614 take equality of the local values and summability as separate hypotheses. Fix a finite extension of number fields E/F, a finite place v and

a place w above it. Put $K = F_v$ and $L = E_w$, with the isometric inclusion for the original absolute values.

The local assertion. Let X be good Hausdorff and pure of analytic dimension d over K, let $\mathcal{F}$ be coherent on X_G, and let α be a compactly supported ordinary smooth real (d,d)-form on X. Take the entire scalar extension $p : X_L \to X$. Use on X_L the pulled-back coefficient and the ordinary form presented on inverse images of the presenting domains by the pulled-back units and the same real differential form. These prescriptions define the upstairs data independently of the presentations. Their native local value satisfies

$$a_w = \int_{X_L/L,p^*\mathcal{F}} p^*\alpha = \int_{X/K,\mathcal{F}} \alpha = a_v.$$

The same conclusion applies to independently specified upstairs data when an L-isomorphism identifies the space, coefficient and form with this triple.

Checking the object for data from a scheme. For example, let Z be of finite type over F with coherent module $\mathcal{M}$, and assume $X = (Z_K)^{\mathrm{an}}$ has the stated analytic hypotheses. The scheme obtained by extending Z_E to E_w is canonically $Z_K \times_K L$, by associativity on affine rings and compatibility with localization. By NAG-001709 its analytification is X_L, compatibly with the projection. On an affine $\mathrm{Spec}(R)$ of Z_K let M represent its coefficient, and let A be an analytic radius chart. For $A_L = A\widehat{\otimes}_K L$ the two coefficient constructions give the same A_L-module:

$$A_L \otimes_A (A \otimes_R M) \simeq A_L \otimes_R M \simeq A_L \otimes_{R\otimes_K L} (M \otimes_K L).$$

Here NAG-001719 gives the analytic chart description and NAG-001686 gives the coherent pullback. The isomorphisms commute with restriction. For the ordinary test the criterion is equality of its germ on every inverse-image chart with the pulled-back presentation. Scalar extension of the scheme and coefficient alone imposes no such condition on a separately chosen test.

Proof of the integral identity. NAG-002503, lines 354–384 of the scalar source, constructs the two pullbacks and proves independence on overlaps. The support of the pulled-back test lies in the inverse image of the original compact support. Cover the latter support by the interiors of finitely many affinoids downstairs. Their full inverse images are compact affinoids, and the

inverse image of the support is closed in their union, hence compact. The local weight calculation in NAG-002514 restricts to the entire simultaneous norm level of the units at an interior top-cell parameter. It uses the same transverse integral projection and lattice index on both sides. Write G_K, G_L for the two complete transverse Gauss fields and Q for the finite coefficient module on the downstairs transverse Gauss fibre. NAG-002511 identifies the upstairs module with $Q \otimes_{G_K} G_L$. Each local Artin factor contributes its module length times its full residue-field degree. Summing over all factors computes the vector-space dimension in the respective ground field, so the numerator of the cell weight is unchanged. NAG-002514 keeps the orientation and lattice measure. The compact chart inclusion–exclusion in NAG-002503, lines 386–410, now gives the claimed equality for the signed test.

Fix $x \in X$ and an affinoid neighbourhood $U = \mathcal{M}_K(A)$ of x. Put $H = \mathcal{H}(x)$. By NAG-001616 the entire inverse image of U has algebra $A_L = A\widehat{\otimes}_K L$. Since L/K is finite isometric and X_L is good Hausdorff, NAG-002518 (scalar source, lines 421–469) gives $(X_L)_{[K]}$ with the same points, domains, structure sheaf and completed residue fields. The bounded K-maps $A \to A_L$ present a morphism $(X_L)_{[K]} \to X$ over K. Apply NAG-001617 to this morphism on the entire inverse image of U. The whole fibre over x has H-affinoid algebra $A_L\widehat{\otimes}_A H$; its points and their completed residue fields are those over x in X_L.

Apply NAG-001689 to $K \to L$ and $K \to A \to H$. Here L is finite K-affinoid by NAG-002518, evaluation at x is bounded, and H is affinoid over its own complete coefficient field. Tensor symmetry and the bounded iterated pushout give an H-algebra isomorphism with bounded inverse

$$(A\widehat{\otimes}_K L)\widehat{\otimes}_A H \simeq H\widehat{\otimes}_K L, \qquad (a \otimes b) \otimes h \longmapsto a(x)h \otimes b.$$

Its inverse sends $h \otimes b$ to $(1 \otimes b) \otimes h$. A finite K-basis of L has bounded coordinate functionals by NAG-001450. Tensoring those functionals and the basis map with H gives inverse bounded coordinate maps between $H \otimes_K L$ with its projective tensor norm and $H^{[L:K]}$ with its maximum norm. Thus $H \otimes_K L$ is already complete. This finite H-algebra splits as $\prod_{y|x} B_y$ by Stacks Tag 00JB: each local residue field is finite over H, has its unique complete extending norm by NAG-001450, and gives exactly one analytic point of the factor. Nilpotents vanish under a seminorm. A composition series of B_y has successive quotients $\mathcal{H}(y)$, whence

$$\sum_{y|x} \operatorname{length}_{B_y}(B_y)[\mathcal{H}(y) : H] = \dim_H(H \otimes_K L) = [L : K].$$

This is the rank of the scalar fibre. The integral uses the native transverse dimension computed above. These local arguments apply to finite isometric extensions of complete nonarchimedean fields, including inseparable extensions, with the full residue degree and possible nilpotent lengths. For a coherent generic cycle its separate multiplicities are those of NAG-002506 and its finite pushforward has the degree of NAG-002509. Restriction of the constants of integration on the same upstairs space has the factor $[L : K]$ by NAG-002520.

Remaining premise for arithmetic descent. The finite-place result discharges the local-value premise for exactly the primitive integral displayed above. For a separately defined local height one still needs a native identification with that primitive on both realizations, or a base-change proof for its own defining operation. At infinity even the real-to-complex case requires a specified primitive and a proof comparing its two normalizations. The reviewed place-weight identity enters only after the local values are matched. The global regrouping in NAG-002523 requires finite support or absolute summability of the weighted families.

Inherited proof dependency. The integral application uses the F6 full-level argument through NAG-002503, NAG-002514, NAG-002405, NAG-002370 and NAG-002365 in that dependency order. The independent F6 receipt passes the specified NAG-002365 repair subject to its native prerequisites. Full support for this application requires the consuming baseline to include the repaired proof and to discharge its prerequisites. In the consuming English baseline, Theorem 5.41.1 contains that scoped repair.

23.7.1 The finite zero-dimensional calculation

For this subsection, let K be any field complete for a specified real-valued nonarchimedean absolute value, which may be trivial. Let $C \neq 0$ be a finite commutative K-algebra, M a finite C-module, and P an invertible C-module. Write $C = \prod_p C_p$ for its Artin local factors, $E_p = C_p/\mathfrak{m}_p$, and

$$w_p(M) = \operatorname{length}_{C_p}(M_p)[E_p : K] = \dim_K M_p.$$

The equality follows by a composition series. The degrees are full field degrees. A metric on P means, at each of these finitely many analytic points, a norm on

the one-dimensional E_p-space $P \otimes_C E_p$ compatible with the unique extending absolute value.

Proposition 23.7.2 (Finite heights, restriction of scalars, and norms)**.** *For a generator s of P, define*

$$h_{C,M}(P,h,s) = -\sum_p w_p(M)\log\|s(p)\|_h. \tag{23.7.1}$$

If $C \to D$ is a map of finite commutative K-algebras, N is a finite D-module, and the metric and section are pulled back, then

$$h_{D,N}(D\otimes_C P, q^*h, 1\otimes s) = h_{C,\mathrm{Res}_C N}(P,h,s).$$

If D is locally free of constant rank n over C and $N = D\otimes_C M$, the right side is $n h_{C,M}(P,h,s)$.

The K-line

$$\mathcal{N}_M(P) = \det_K(P\otimes_C M)\otimes \det_K(M)^\vee$$

has a metric characterized, for every generator e of P, by

$$\|\mathcal{N}_M(e)\| = \prod_p \|e(p)\|^{w_p(M)}.$$

It is well-defined, and $h_{C,M}(P,h,s) = -\log\|\mathcal{N}_M(s)\|$. For $M = C$ it is the determinant norm line $\mathrm{Nm}_{C/K}(P)$. For $h' = e^{-u}h$,

$$h_{C,M}(P,h',s) - h_{C,M}(P,h,s) = \sum_p w_p(M)u(p), \qquad |\Delta h| \le \|u\|_\infty \dim_K M.$$

Moreover (23.7.1) equals the frozen K-analytic integral of the smooth function $-\log\|s\|$ on $\mathcal{M}(C)$ with coefficient module M.

Proof inputs. NAG-001450 (finite extending absolute values); the already accepted Artin decomposition leaf STACKS-00JB; NAG-002362, NAG-002405, NAG-002424, NAG-002425 (zero-dimensional module weights, chart integration and ordinary germs); elementary finite-dimensional determinants and composition series..

Proof. A multiplicative seminorm on C kills its nilpotents. Its kernel selects one local factor and its maximal ideal, and the induced norm on the finite field E_p is unique by NAG-001450. These are precisely the points of $\mathcal{M}(C)$ with

its canonical finite topology. The idempotent factors are open and closed. On each factor a function on this finite point set is constant, hence is an ordinary smooth moment function.

Every invertible C-module has a generator: it is free on each local factor, and the finitely many local generators combine using the idempotents. If $a \in C^{\times}$, a composition series of M_p is stable under multiplication by a. Each simple quotient is E_p with multiplication by its residue $a(p)$. A basis respecting the series gives block triangular matrices and hence

$$|\det_K(m_a \mid M)| = \prod_p |\operatorname{Nm}_{E_p/K}(a(p))|^{\operatorname{length}_{C_p} M_p} = \prod_p |a(p)|^{w_p(M)}. \quad (23.7.2)$$

For completeness, the last equality does not count separable embeddings. If $b \in E_p^{\times}$ has minimal polynomial f, the characteristic polynomial of multiplication by b on E_p is $f^{[E_p:K(b)]}$, by a $K(b)$-basis. A finite splitting extension for f is obtained by adjoining roots successively. Each root has the same absolute value as b: the corresponding embedding of $K(b)$ into that finite extension pulls back an extending absolute value, unique by NAG-001450. Taking the product of all roots *with their multiplicities* gives $|\operatorname{Nm}_{E_p/K} b| = |b|^{[E_p:K]}$, including inseparability.

Replacing a generator e by ae multiplies $\mathcal{N}_M(e)$ by $\det_K(m_a \mid M)$ and multiplies the proposed norm by exactly its absolute value, by (23.7.2). Thus the prescription defines a norm on the K-line and gives the asserted identity for s. If $M = 0$, both determinant lines have their canonical unit and all sums are zero; the same argument applies.

For restriction of scalars, the p-part of N is the direct sum of the D-local parts lying over p. Its K-dimension is the sum of theirs. Uniqueness of extending absolute values makes the pulled-back metric at each such point have exactly the norm of $s(p)$. Grouping the finite sum proves the projection formula. A locally free rank-n D over the Artin semilocal C is free of that rank, by choosing bases on each factor. Hence $D \otimes_C M \simeq M^n$ as C-modules, giving the rank formula. Subtracting the two log norms proves the variation and its bound.

Finally, compute the frozen integral separately on the clopen factors. For the empty moment tuple on C_p the rank-zero tangent lattice has index one, the Gauss field is K, and the full finite algebra is C_p. The module weight of NAG-002362 is therefore $\dim_K M_p$. The global-chain construction NAG-002405 supplies this chart and its interior whole-fibre weight; in dimension zero its boundary image is empty. Rank-zero polyhedral integration evaluates

the constant at the single point. NAG-002425 identifies that chart sum with the ordinary compact integral. This gives exactly (23.7.1). □

Intersection meaning and its boundary. For a specified zero-dimensional intersection represented by a finite K-algebra C, its coherent coefficient M contributes the actual length $\operatorname{length}_{C_p} M_p$ at p, followed by the ordinary residue degree $[E_p : K]$. In particular $C = L[\epsilon]/(\epsilon^r)$ has total weight $r[L : K]$. The determinant on the scalar unit $a \in L^\times$ has absolute value $|a|^{r[L:K]}$. Neither the reduction L nor a separable point count gives this normalization. This identifies the finite base case; it does not construct a positive-dimensional cycle product.

Finite scalar extension of the Artin local height

The zero-dimensional starting value required at lines 674–691 of the F9 descent supplement is defined in NAG-002635, `F9_Local_Height_Interface_v038.tex`, lines 197–214. The projection at lines 215–222 uses a single ground field. The following application compares the same primitive in its two native ground fields.

Let K be complete nonarchimedean, let L/K be finite isometric and let $C \neq 0$ be a finite commutative K-algebra with its canonical finite topology. Take a finite C-module M, an invertible C-module P, a generator s of P, and a metric h as in NAG-002635. Thus at each local factor C_p the metric is a norm on the line over $k_p = C_p/\mathfrak{m}_p$ for its extending absolute value. Write M_p for the corresponding summand and $s(p)$ for the residue of s. The primitive is

$$h_K = -\sum_p \ell_{C_p}(M_p)[k_p : K] \log \|s(p)\|_h.$$

Form $D = C \otimes_K L$, $N = M \otimes_K L$, and the line and generator P_L, s_L obtained by tensoring. All finite tensors carry their canonical complete topologies. Give P_L the pullback metric. Then its height h_L, defined by the same formula over L, equals h_K.

Proof. Each idempotent of the factorization $C = \prod_p C_p$ acts on D. Decomposing its image further into local Artin algebras gives $C_p \otimes_K L = \prod_{q|p} D_q$ (Stacks Tag 00JB). Write $k_q = D_q/\mathfrak{m}_q$. These are all the analytic lifts of p: a bounded multiplicative seminorm kills nilpotents and factors through one k_q, and each k_q gives a point by the unique complete extending absolute

value (NAG-001450). Its restriction to k_p is the original one by the same uniqueness over K. More precisely the analytic point fibre over p has algebra $k_p \otimes_K L = (C_p \otimes_K L)/\mathfrak{m}_p(C_p \otimes_K L)$. The quotient map has nilpotent kernel, so the quotient indexes the same lifts. The coefficient at a lift is computed in D_q on N_q, retaining the original module and the full base-changed algebra.

For a local frame e of the k_p-line the transported norm is $\|ae_L\| = |a|_{k_q}\|e\|_h$ for $a \in k_q$. Isometry on k_p makes this independent of e; in particular $\|s_L(q)\| = \|s(p)\|$. The generator has positive norm at every point. A composition series of N_q has quotients k_q. The decomposition by idempotents and extension of a K-basis of M_p therefore give, for each p,

$$\sum_{q|p} \ell_{D_q}(N_q)[k_q : L] = \sum_{q|p} \dim_L N_q = \dim_L(M_p \otimes_K L) = \dim_K M_p = \ell_{C_p}(M_p)[k_p : K].$$

Multiplying by $-\log\|s(p)\|$ and summing proves the claim. This argument includes zero coefficient summands and inseparable extensions. When the same upstairs data are measured over K, the weight at q uses $[k_q : K] = [k_q : L][L : K]$. Thus the restricted value is $[L : K]h_L$.

Identification of the integral. This integral interpretation uses NAG-002635 through NAG-002405 and NAG-002370 to the same scoped NAG-002365 repair in Theorem 5.41.1. The consuming English baseline contains that repair. Its remaining proof prerequisites still require verification. The equality of finite Artin sums above uses the finite field norms and Artin lengths directly.

NAG-002635, lines 242–258 and 299–308, identifies this specific height with an ordinary compact $(0, 0)$-integral over either field. The function $-\log\|s\|$ is constant on each clopen local factor. Its empty moment tuple has lattice index one and coefficient $\dim_K M_p$ downstairs, respectively $\dim_L N_q$ upstairs. The pullback test on every lift has the same value proved above. Consequently a finite place v and $w \mid v$ in NAG-002523 can take $a_v = h_{F_v}$ and $a_w = h_{E_w}$ for these actual data.

Boundary of the application. NAG-002523, lines 606–634, assumes equality of the real local numbers and leaves archimedean comparison as a separate input. NAG-002635 assumes a nonarchimedean base at lines 57–63. The recovered passages supply neither an archimedean height primitive on the real and complex realizations nor a convention for its comparison over

a real place becoming complex. The all-place degree identity fixes the place weights only. For a higher-dimensional DVR model number, NAG-003211, lines 428–457 of its source, requires a proved downstairs smooth realization. The Artin formula supplies the dimension-zero case only. Finite support or absolute summability of the weighted family is a separate global hypothesis.

Chapter 24

Limits, cohomology and remaining comparisons

24.1 Topological limits, differential limits, and Hodge questions

24.1.1 Payne's inverse-limit theorem

Payne's inverse-limit theorem reconstructs an analytification from a sufficiently rich system of tropicalizations as a topological space. A point is recovered from its compatible values in all those tropicalizations. The system of embeddings and transition maps is part of the theorem.

A sheaf of differential forms is additional data. To recover it as a direct limit of tropical sheaves, one must compare the local presentations, quotient relations, and restriction maps. A current is a continuous dual, so one must also compare topologies. Cohomology introduces another passage to kernels and images. None of these operations is determined solely by a homeomorphism of underlying spaces.

24.1.2 A concrete obstruction to an automatic Hodge transfer

Even if a filtered direct limit of complexes is exact in an algebraic category, the problem at hand may involve topological vector spaces, support conditions, and completed or continuous duals. Images need not be closed, and a primitive available on one tropical presentation may acquire a different sin-

gular support after refinement. A claimed Hodge or Aeppli comparison must therefore specify the category in which the limit is taken.

The curve calculation in Chapter 17 is an effective sanity check. Its weakly smooth Dolbeault dimensions involve the first Betti number of the analytic topology, while the algebraic genus also contains residual contributions. A proposed identification with algebraic Hodge theory must explain those contributions rather than assuming the two genera coincide.

24.1.3 Differential and cohomological comparison requirements

First compare finite-chart smooth complexes on a fixed relatively compact analytic domain. Next prove compatibility under refinement, including the zero relations and test topology. Then identify which compact support condition is preserved. Only after these steps should one compare cohomology or seek representatives with an exact prescribed support complement.

For Green problems, the last support step is essential. A primitive on an alteration, a current after proper pushforward, and an actual differential form on the original complement are different outputs. A limit theorem should state which output it produces and should prove descent of that output, not just convergence of its pairings on a smaller collection of tests.

References. [Pay09]; [GJRc]; the explicit representative constructions in [Mih24].

24.2 Further analytic problems

24.2.1 Regularization with a fixed test theory

The basic comparison asks when a continuous function with positive original CLD Hessian has local smooth positive approximants on one fixed neighbourhood. The forward implication from approximation to current positivity is elementary; the converse is a regularization theorem. A useful result should state the field, analytic category, topology of approximation, and whether the neighbourhood is uniform throughout the approximation.

Such a theorem would make many current inequalities usable in the established continuous BT calculus. It would also clarify comparisons between raw current positivity, generated CLD25 psh, numerical model positivity, and curvewise psh. The PL cases and curve results provide strong tests, but

proving the general continuous statement requires controlling all positive tests, not only a selected finite chart or a family of curves whose detecting power has not been established.

24.2.2 A local potential theorem for closed currents

Given a positive closed $(1,1)$-current T, a local potential theorem seeks u with $\mathrm{d}'\mathrm{d}''[u] = T$ in a specified regularity class. This is logically distinct from regularizing a potential already known to exist. It also requires more than a degree-zero or primitive condition tested on a restricted subspace: the equality must hold on the full test space stated in the theorem.

A proof would need a local exactness statement for the differential complex, an analytic mechanism giving the required regularity, and a way to preserve positivity. The tropical and toric cases suggest techniques, but a primitive on one real chart need not descend through all analytic relations. This is one reason the intrinsic descent problem is central to the long-term programme.

24.2.3 Arbitrary-background action and kernel descent

The continuous recursion already defines an action of suitable potentials on an arbitrary ordinary positive closed background current. To promote this to an action of curvature objects, one needs the kernel condition (14.2.1). The cross example proves that abstract tropical positivity and closedness do not suffice in full generality.

A productive analytic theorem would identify a geometric class of kernel functions that annihilates every allowed background current, or a geometric class of background currents for which the full kernel acts trivially. Smooth pluriharmonic functions give the elementary case; skeletal BT currents give a structured case. The general smooth-Berkovich question must use the additional analytic geometry explicitly.

24.2.4 Bounded and unbounded potentials

Beyond continuous potentials, a complete theory should specify monotone convergence, locality on the appropriate topology, capacities, quasi-continuity, negligible sets, comparison and domination principles, and suitable Dirichlet problems. These are related but separate theorems. A

non-pluripolar product also requires a definition for unbounded potentials and a proof that truncation and exceptional-set choices are compatible.

The toric theory and global energy theories give established frameworks in which many of these issues can be addressed. The goal of a general local analytic theory is to connect such frameworks with the original test calculus while retaining their domains and comparison maps. It is not achieved by relabelling every model-theoretic θ-psh function as a locally integrable CLD potential without proof.

24.2.5 Actual Green forms and exact support

A strong Green statement for a codimension-r cycle Z may ask for an actual form γ of degree $(r-1,r-1)$ on $X^{\mathrm{an}} \setminus |Z|^{\mathrm{an}}$ with

$$\int_{X^{\mathrm{an}}\setminus|Z|^{\mathrm{an}}} \gamma \wedge \mathrm{d}'\mathrm{d}''\eta = -\int_{Z^{\mathrm{an}}} \eta$$

for every actual compactly supported test in the specified calculus. The complete-intersection theorem gives an explicit model of such a statement in its own category. A general cycle requires a global construction and compatibility of local representatives.

The requirements are substantive: the complement is the original complement; the representative lies in the chosen sheaf; the testing is not restricted to external products or a chosen tropical chart; and field extension must descend with the correct degree and the original absolute value. A current identity after arbitrary proper pushforward does not by itself satisfy these requirements. It may be a useful intermediate step if its relation to the desired representative is proved.

24.3 What filtered limits do preserve

A topological inverse-limit description and a differential direct-limit description are different statements. Once a differential complex has actually been identified with a filtered direct limit, its cohomology is easy to compute algebraically. The difficult part is often establishing that identification with the required support and topology. We separate these steps.

Theorem 24.3.1. *Let $(C_i^\bullet, d_i)$ be a filtered system of complexes of real vector spaces, with transition maps commuting with the differentials. Then the canonical map is an isomorphism:*

$$\varinjlim_i H^k(C_i^\bullet) \xrightarrow{\sim} H^k\left(\varinjlim_i C_i^\bullet\right).$$

Injectivity of the transition maps is not required.

Proof. In a filtered colimit of vector spaces, every element has a representative at one stage, and an element represented at a stage is zero precisely when it becomes zero at some later stage. Let z represent a cocycle in the limit. Choose a representative $z_i \in C_i^k$. Its differential is zero in the colimit, hence $d_i z_i$ becomes zero at a later stage j. The image z_j is then a cocycle at that stage, proving surjectivity.

For injectivity, suppose a stage cocycle z_i becomes a boundary in the limit, say $z = dy$. Represent y at another stage and take a common later stage for both representatives. The equality $z = dy$ holds at a further stage by the same zero criterion. Thus the image of the cohomology class of z_i is already zero at that stage, so it is zero in the colimit of cohomology groups. □

Corollary 24.3.2. *For a filtered system of double complexes with commuting transition maps, filtered colimits commute with Bott–Chern and Aeppli cohomology, defined algebraically by*

$$H_{BC}^{p,q} = \frac{\ker d' \cap \ker d''}{\operatorname{im} d'd''}, \qquad H_A^{p,q} = \frac{\ker d'd''}{\operatorname{im} d' + \operatorname{im} d''}.$$

Proof. A numerator condition involves finitely many equations, so each equation that holds in the colimit holds after passage to one common later stage. A denominator relation involves finitely many preimages, which can

also be represented at one common stage. The surjectivity and injectivity argument of the theorem then applies verbatim. This proof concerns algebraic quotients, without any assertion that the images are topologically closed. □

For an analytic application one must first construct a system whose colimit is the desired sheaf of forms or global test complex. A finite collection of local presentations can be refined by concatenating moment maps, but that observation alone does not identify a global complex on a noncompact space. Covers, restrictions, support control and the allowed quotient relations still have to be carried through. The theorem does not supply that geometric step.

Example 24.3.3 (Compact support and pullback)**.** The constant function one on a point has compact support. Its pullback along $\mathbb{R} \to \{*\}$ has support all of $\mathbb{R}$. Thus an arbitrary map does not induce pullback between compactly supported test spaces. Properness over the relevant support, or a specified alternative support construction, is needed before forming a direct system of compactly supported complexes.

24.4 Why inverse limits of spaces are not enough

Example 24.4.1 (A topological test of the inference)**.** Let $X_j = \{0,1\}^j$ with the discrete topology and the maps that forget the last coordinate. Their inverse limit is the compact space $X = \{0,1\}^{\mathbb{N}}$. The pullback colimit of $H^0_{\mathrm{sing}}(X_j, \mathbb{R})$ consists of real functions depending on finitely many coordinates. However $H^0_{\mathrm{sing}}(X, \mathbb{R})$ consists of all real-valued functions on X.

Indeed, a continuous path into X has constant projection to every discrete X_j, hence is constant. Every singular one-simplex is therefore constant, so every zero-cochain is a cocycle and there are no zero-coboundaries. The function $x \mapsto \sum_{j\geq 1} x_j 3^{-j}$ does not depend on finitely many coordinates and gives an explicit class outside the colimit.

This is not a counterexample to Payne's theorem or to a specific Berkovich comparison. It disproves only the general inference that a homeomorphism to an inverse limit automatically identifies singular or differential cohomology with the colimit of the finite-stage groups. Different cohomology theories have different continuity properties. For the intended differential theory, one must prove the required complex-level comparison.

24.5 Duality changes direction under a limit

Proposition 24.5.1. *For a filtered system of real vector spaces, there is a natural algebraic isomorphism*

$$\mathrm{Hom}_{\mathbb{R}}(\varinjlim_i V_i, \mathbb{R}) \simeq \varprojlim_i \mathrm{Hom}_{\mathbb{R}}(V_i, \mathbb{R}).$$

Proof. A functional on the colimit restricts to a compatible family of functionals on the stages. Conversely, a compatible family assigns the same scalar to any two representatives of a colimit element, so it defines a unique linear functional. These constructions are inverse. □

With locally convex topologies, continuous duals require the chosen inductive-limit topology and its continuity criterion. Even when that criterion is available, the direction remains inverse on duals. One cannot replace it by a second direct limit without an additional theorem.

Example 24.5.2 (Perfect finite-stage pairings need not remain perfect)**.** Take $V_j = W_j = \mathbb{R}^j$, with the standard dot product and transition maps adding a zero last coordinate. Each pairing is perfect and the pairings are compatible. Both direct limits are the finite-support sequence space $\mathbb{R}^{(\mathbb{N})}$. Their induced pairing is nondegenerate, but the resulting map

$$\mathbb{R}^{(\mathbb{N})} \longrightarrow \mathrm{Hom}_{\mathbb{R}}(\mathbb{R}^{(\mathbb{N})}, \mathbb{R}) = \mathbb{R}^{\mathbb{N}}$$

is not surjective. The functional $v \mapsto \sum_i v_i$ is well defined because v has finite support, but it would require the infinite coefficient sequence $(1, 1, \ldots)$ in the second factor. Thus nondegeneracy survives in this example while algebraic perfectness does not.

Lemma 24.5.3 (One sufficient stabilization condition)**.** *If all transition maps of a filtered system of finite-dimensional vector spaces are injective and their dimensions have a uniform finite bound, then the system stabilizes after some stage and its colimit is finite dimensional.*

Proof. The nonempty set of dimensions has a largest value. Choose a stage realizing it. Every later injective map from this stage has a target of the same dimension, hence is an isomorphism. Filteredness makes these later stages cofinal. □

Such stabilization is one possible route for transferring finite-dimensional duality, but it is a hypothesis to prove for the actual transition maps. A common tropical refinement need not induce an injective map on a cohomology group merely because the refinement map is surjective on the underlying support.

24.6 Cohomological annihilation and a current equation

There is another distinction when cohomology is used to construct a Green current. Vanishing on the kernel of a differential gives an algebraic factorization. A continuous current requires a topological estimate, and an actual differential form requires further regularity. The following elementary result makes the first two steps precise.

Theorem 24.6.1 (A continuous lifting criterion)**.** *Let $D : E \to F$ be a continuous linear map of real locally convex spaces and let $L : E \to \mathbb{R}$ be continuous linear. A continuous linear functional G on F satisfying $G \circ D = L$ exists if and only if there is a continuous seminorm p on F such that*

$$|L(e)| \le p(De) \qquad (e \in E).$$

Proof. If G exists, continuity bounds it by a continuous seminorm on F, giving necessity. Conversely, the estimate implies that L vanishes on $\ker D$. Hence $g(De) = L(e)$ is well defined on $D(E)$ and satisfies $|g(y)| \le p(y)$. The real Hahn–Banach theorem extends g to a linear functional G on F with the same bound. Since p is continuous, G is continuous. □

Example 24.6.2 (The kernel condition is not enough)**.** Take $E = F = \ell^2(\mathbb{N})$, $D(x)_n = x_n/n$, and $L(x) = \sum_n x_n/n$. The functional L is continuous by Cauchy–Schwarz, and $\ker D = 0$. If $G \circ D = L$, evaluation on the standard basis forces $G(e_n) = 1$ for every n. No bounded functional on ℓ^2 has these coefficients. Explicitly, take $x_n = n$ for $1 \le n \le N$ and zero otherwise. Then $L(x) = N$ and $\|Dx\|_2 = \sqrt{N}$, so no uniform bound $|L(x)| \le C\|Dx\|_2$ holds.

For a current equation on a pure n-dimensional space, take $E = A_c^{n-r,n-r}$, $F = A_c^{n-r+1,n-r+1}$, $D = d'd''$, and $L(\eta) = -\int_Z \eta$. A functional G supplied by the theorem is a current of bidegree $(r-1, r-1)$ satisfying the

required transposed equation, with the book's fixed differential sign convention. Merely knowing that $\int_Z \eta = 0$ whenever $d'd''\eta = 0$ supplies only the kernel condition. One still needs the continuous estimate.

Even after this estimate, Hahn–Banach gives no actual representative on $X^{\mathrm{an}} \setminus |Z|^{\mathrm{an}}$, no local integrability of a chosen coefficient expression, and no control of additional singular support. Those belong to a regularity and representation theorem. If the target asks for equality on delta-tests, the spaces E, F in the argument must already be the full delta-test spaces with their topology. Solving the equation only on original smooth tests does not perform that enlargement.

The local complete-intersection construction of Chapter 22 addresses these stronger requirements by an explicit geometric representative and a proof on actual tests. The functional argument here serves a different purpose: it identifies which estimates and comparisons a general cohomological existence strategy would have to supply.

24.7 The coefficients carried by a tropical face

A tropical cohomology class remembers tangent directions as well as the topology of the underlying space. The coefficient system is already nonconstant at a vertex where several cells meet. We describe it first for a finite polyhedral complex in a real vector space; strata at infinity are then handled by quotient maps.

Let $\mathscr{C}$ be a polyhedral complex in $N_{\mathbb{R}}$. For a face σ, let L_σ be its parallel linear space. Define

$$F_p(\sigma) = \sum_{\tau \supseteq \sigma} \bigwedge^p L_\tau \ \subseteq \bigwedge^p N_{\mathbb{R}}, \qquad F^p(\sigma) = \mathrm{Hom}_{\mathbb{R}}(F_p(\sigma), \mathbb{R}).$$

The sum is a sum of subspaces, not a direct sum. If $\sigma \subseteq \tau$, then $F_p(\tau) \subseteq F_p(\sigma)$; dualizing gives a restriction $F^p(\sigma) \to F^p(\tau)$. At a boundary stratum of an extended tropicalization, first project to the quotient tangent space of that stratum. These maps define the multi-cotangent sheaf $\mathcal{F}^p$.

Example 24.7.1. Let $Y \subset \mathbb{R}^2$ be the union of the two coordinate axes. At the origin $F_1(0) = \mathbb{R}^2$, whereas on the interior of either axis F_1 is its one-dimensional tangent line. Thus a degree-one coefficient at the vertex is a covector with two components, and restriction retains the component along the chosen axis. For the tropical line with rays $e_1, e_2, -e_1 - e_2$, the three outgoing restrictions are $a, b, -a - b$. Their sum is zero. This relation comes from the common ambient covector; it is not three independent endpoint values.

Example 24.7.2. Let X be the union in $\mathbb{R}^4$ of the planes spanned by e_1, e_2 and by e_3, e_4. At the origin, $F_1(0) = \mathbb{R}^4$, but

$$F_2(0) = \mathbb{R}(e_1 \wedge e_2) \oplus \mathbb{R}(e_3 \wedge e_4), \qquad \dim F_2(0) = 2 \neq 6 = \dim \bigwedge^2 F_1(0).$$

Thus one must take exterior powers before summing the tangent spaces. Replacing F_p by $\bigwedge^p F_1$ changes the theory at singular points.

24.7.1 From local closed forms to a coefficient sheaf

For a polyhedral space X in the sense of Jell–Shaw–Smacka, put

$$\mathcal{L}^p = \ker(d'' : \mathcal{A}^{p,0} \longrightarrow \mathcal{A}^{p,1}).$$

On an ordinary real open set its sections are locally constant primed p-forms. Across a face, only their restrictions to the tangent spaces of adjacent cells are visible. This is why the appropriate coefficient sheaf is $\mathcal{F}^p$.

Theorem 24.7.3 (Polyhedral comparison)**.** *Let X be a paracompact, second countable Hausdorff polyhedral space with the extended-affine charts and boundary compatibility of [JSS]. There is a canonical isomorphism $\mathcal{L}^p \simeq \mathcal{F}^p$, and*

$$H^{p,q}_{d''}(X) \simeq H^q(X, \mathcal{F}^p), \qquad H^{p,q}_{d'',c}(X) \simeq H^q_c(X, \mathcal{F}^p).$$

If X has a face structure, these groups are also its tropical cohomology groups, respectively with and without compact support.

Open proof obligation (RC2). Prove the polyhedral Poincare lemma and the fine/acyclic chart-sheaf route; the proof uses the stated JSS theorem, proposition and lemma.

For $p = 0$ the coefficient sheaf is $\mathbb{R}$, so this row is ordinary real cohomology. For $p > 0$ it is generally not determined by the topology. The two plane example explains the extra data without referring to an analytic space. A claim that Payne's topological inverse limit automatically recovers all rows would have to recover these coefficient systems and their transition maps as well.

24.8 Compact support changes the Poincaré lemma

A radial homotopy usually spreads the support to the star centre and does not solve the compactly supported problem. The following explicit construction provides the required replacement on $\mathbb{R}^n$. It also identifies the obstruction that integration detects.

Lemma 24.8.1. *Write coordinates on $\mathbb{R}^n$ as $(x,t) \in \mathbb{R}^{n-1} \times \mathbb{R}$, and an ordinary compactly supported q-form as $\omega = \alpha(x,t) + dt \wedge \beta(x,t)$, with no dt in α, β. Choose $\rho \in C_c^\infty(\mathbb{R})$ with integral one and put $\chi(t) = \int_{-\infty}^{t} \rho(s)\, ds$. Define*

$$I\omega = \int_{\mathbb{R}} \beta(x,s)\, ds, \qquad E\eta = \rho(t)\, dt \wedge \eta(x),$$

$$H\omega = \int_{-\infty}^{t} \beta(x,s)\, ds - \chi(t) I\omega.$$

Then $H\omega$ is compactly supported and $dH + Hd = \mathrm{id} - EI$. Moreover $Id = -dI$ and $dE = -Ed$.

Proof. Below the supports of β and ρ both terms in $H\omega$ vanish. Above them they are both $I\omega$ and cancel. The x-support is contained in the compact projection of $\operatorname{supp}\omega$. Thus the support is compact. Direct differentiation gives

$$d\omega = d_x\alpha + dt \wedge (\partial_t \alpha - d_x \beta).$$

Integrating its second coefficient gives $Id\omega = -d_x I\omega$, because α vanishes at both ends. The same calculation gives $dE = -Ed$. Finally the dt-part of $dH\omega$ is $dt \wedge (\beta - \rho I\omega)$, while its x-part cancels the integral terms of $Hd\omega$ and leaves α. Their sum is $\omega - EI\omega$. This also proves the formula in degree zero, where $H\omega = 0$. □

Theorem 24.8.2. *For superforms on $\mathbb{R}^n$,*

$$H^{p,q}_{d'',c}(\mathbb{R}^n) = 0 \quad (q \neq n), \qquad H^{p,n}_{d'',c}(\mathbb{R}^n) \simeq \bigwedge^{p}(\mathbb{R}^n)^*.$$

The second isomorphism integrates each double-primed top-degree coefficient. In particular a compactly supported (p,n)-form is d''-exact with compact support if and only if all these coefficient integrals vanish.

Proof. Keep the primed exterior factor fixed. Up to the fixed degree sign in d'', the remaining complex is the ordinary compactly supported de Rham complex, with coefficients in $\bigwedge^p(\mathbb{R}^n)^*$. Lemma 24.8.1 gives a homotopy equivalence with the same complex on $\mathbb{R}^{n-1}$ shifted by one degree; IE is the identity. Iterate this reduction. On $\mathbb{R}^0$, only degree zero remains and its cohomology is $\mathbb{R}$. The iterated fibre integral is the ordinary top-degree integral up to the orientation sign. This proves the assertions and constructs a primitive whenever the obstruction vanishes. □

Combining this calculation with ordinary Poincaré exactness gives Euclidean duality: $H^{p,0}_{d''}(\mathbb{R}^n)$ pairs perfectly with $H^{n-p,n}_{d'',c}(\mathbb{R}^n)$ by integration. The pairing is the exterior-product pairing of two finite-dimensional coefficient spaces. The compact support in the second factor is essential.

24.9 Where tropical Poincaré duality holds

Theorem 24.9.1 (Jell–Shaw–Smacka)**.** *If X is an n-dimensional tropical manifold, locally modelled on matroidal fans with the boundary charts specified in [JSS, Definition 4.15], integration induces an isomorphism*

$$H^{p,q}_{d''}(X) \longrightarrow \left(H^{n-p,n-q}_{d'',c}(X)\right)^*, \qquad [\alpha] \longmapsto \left([\beta] \longmapsto \int_X \alpha \wedge \beta\right).$$

Open proof obligation (RC2). Prove the local matroidal and global Poincare duality in the stated scope; the text supplies JSS Theorem 4.33.

Proposition 24.9.2. *Give the union Y of the two coordinate axes in $\mathbb{R}^2$ weight one on each axis. Then $H^{0,0}_{d''}(Y) = \mathbb{R}$ and $H^{1,1}_{d'',c}(Y) = \mathbb{R}^2$. The integration pairing is the sum of the two coordinates and is not perfect.*

Proof. A d''-closed smooth function is locally constant and Y is connected, proving the first assertion. Restriction identifies the complexes $A^{1,\bullet}_c(Y)$ with

the direct sum of the corresponding complexes on the two real lines. To check surjectivity, extend an arbitrary compactly supported coefficient $a(x)$ on the horizontal line as $a(x)\rho(y)d'x$ or $a(x)\rho(y)d'x\wedge d''x$, with $\rho = 1$ near zero. This restricts to zero on the vertical line. The analogous vertical extension realizes the other summand. Tangential equality on the two axes is precisely the quotient relation for these bidegrees, proving injectivity. These restrictions commute with d''.

By Theorem 24.8.2 each line contributes one top compactly supported class, detected by its integral. Integration on Y adds the two integrals. The class with integrals $(1,-1)$ is nonzero but pairs to zero with every constant. This proves the failure. □

The cross is balanced. Its defect is that the two one-dimensional branches have independent top classes while the whole space has only one constant class. This supplies a concrete obstruction to deriving duality from balancing, and a separate reason not to transfer a tropical Hodge theorem through a topological inverse limit alone. It is not a counterexample to the theorem for tropical manifolds or to any analytic comparison proved with stronger hypotheses.

References. [JSS, Sections 2–4]; the relation with the analytic limit question is developed in Section 6.5 and Chapter 24.

24.10 The same topological star can carry different cohomology

Let Y be a fan consisting of m distinct rays with nonzero primitive directions $v_1,\dots,v_m$ in a real vector space V. Give the rays positive weights w_i satisfying $\sum_i w_i v_i = 0$. Each ray is parametrized by $t \mapsto tv_i$, $t \geq 0$. Define

$$R : V^* \longrightarrow \mathbb{R}^m, \qquad \lambda \longmapsto (\lambda(v_1),\dots,\lambda(v_m)).$$

Proposition 24.10.1. *For the ambient superform sheaf on Y, edgewise integration induces an isomorphism*

$$H^{1,1}_{d'',c}(Y) \simeq \mathbb{R}^m / \operatorname{im} R.$$

Consequently its dimension is $m - \dim \operatorname{span}\{v_i\}$. Integration on the weighted fan is induced by $(b_i) \mapsto \sum_i w_i b_i$.

Proof. For $\alpha \in A_c^{1,0}(Y)$ write $\alpha|_i = a_i(t)d't$. Since $d''\alpha|_i = -a_i'(t)d't \wedge d''t$, its integral on the ith ray is $a_i(0)$. The values at the vertex come from a common ambient covector, so the vector of integrals lies in $\operatorname{im} R$. Hence the map to the quotient is well-defined. It is surjective, since independent bump top forms supported away from the vertex realize arbitrary edge integrals.

For injectivity, first subtract $d''(\chi\lambda)$, where λ is a constant ambient primed covector and χ a cutoff equal to one near the vertex, to reduce to a form β with zero edge integrals. The local polyhedral Poincaré lemma gives $\beta = d''\alpha_0$ near the vertex. Choose another cutoff supported there. Subtracting $d''(\chi\alpha_0)$ makes β vanish near the vertex, but changes its integrals by the vector of vertex values of α_0. Add back $d''(\chi\lambda_0)$ for an ambient covector λ_0 with those same vertex values. Its derivative vanishes near the vertex. The resulting form $\widetilde{\beta}$ is supported away from the vertex and has zero integral on every ray.

On each ray put $a_i(t) = \int_t^\infty \widetilde{b}_i(s)\,ds$, where $\widetilde{\beta}|_i = \widetilde{b}_i(t)d't \wedge d''t$. The zero integral makes a_i vanish near zero, and compact support makes it vanish for large t. These edgewise primitives extend to ambient forms in disjoint neighbourhoods away from the vertex and glue by zero. Their d'' is $\widetilde{\beta}$. Restoring the subtracted exact forms proves injectivity. Finally balancing says precisely that the functional $\sum_i w_i b_i$ annihilates $\operatorname{im} R$. □

For the rank-two uniform matroid on m elements, the rays are the coordinate vectors in $\mathbb{R}^m/\mathbb{R}\mathbf{1}$. Their span has dimension $m-1$, and their only linear relation is their sum. The proposition gives $H_c^{1,1} = \mathbb{R}$. For the planar cross, $m = 4$ and the span has dimension two, so $H_c^{1,1} = \mathbb{R}^2$. Both underlying spaces are a four-valent topological star when $m = 4$, but their superform coefficient sheaves differ.

This calculation is the local analogue of the harmonic-coordinate issue on analytic curves. Recording only an embedded graph may impose extra relations among its directions. Harmonic tropicalizations use the geometric harmonic functions needed for the intrinsic theory, rather than assuming one fixed low-dimensional embedding records every differential direction. The analytic comparison still requires the model and refinement theorems of GJR; the star calculation explains what those theorems must preserve.

References. For the flag description, [AK]; for the polyhedral Poincaré lemma and matroidal duality, [JSS, Theorems 3.16 and 4.33]. The rank-two balancing and star quotient calculations above are written out in the conventions of this book.

24.11 Hodge and Aeppli calculations on a real torus

A compact real torus provides a complete model in which the two differentials, their cohomology, and the $d'd''$ equation can be computed directly. This model is useful for separating a valid differential statement from a proposed passage through tropical limits. The proof below uses Fourier series on one fixed torus. It does not require a projective embedding, and it does not assert a Hodge theorem for every tropical space.

Let $M = V/\Lambda$ be a real torus of dimension n, with a fixed translation-invariant Euclidean inner product. Complexify the superform spaces during the computation and recover real forms by conjugation. The dual lattice is Λ^*. Every smooth form has a Fourier expansion

$$\alpha(x) = \sum_{k \in \Lambda^*} e^{2\pi i \langle k, x \rangle} \alpha_k, \qquad \alpha_k \in \bigwedge^p V_{\mathbb{C}}^* \otimes \bigwedge^q V_{\mathbb{C}}^*.$$

Its coefficients decay faster than every negative power of $|k|$. Conversely, such decay defines a smooth form, with termwise differentiation. These standard Fourier facts follow by repeated integration by parts on a fundamental domain and the absolute convergence of sufficiently high powers of $(1 + |k|)^{-1}$.

24.11.1 Contraction on each nonzero mode

For $k \neq 0$, write $k' = \sum k_i d'x_i$ and $k'' = \sum k_i d''x_i$ in orthonormal coordinates. On that Fourier mode, the differential operators are exterior multiplication by $2\pi i k'$ and $2\pi i k''$, with the total-degree wedge convention. Let ι'_k and ι''_k be contraction with the corresponding metric dual vectors in the first and second exterior factors. Define

$$h'_k = \frac{\iota'_k}{2\pi i |k|^2}, \qquad h''_k = \frac{\iota''_k}{2\pi i |k|^2}.$$

The second contraction includes the total-exterior-algebra sign. For a primed p-form a' and a double-primed form b'', our convention is

$$\iota''_k(a' \wedge b'') = (-1)^p a' \wedge \iota_k b''.$$

Without this sign, the two cross-factor anticommutation identities below would not hold.

Lemma 24.11.1. *On every nonzero mode,*

$$d'h'_k + h'_k d' = 1, \qquad d''h''_k + h''_k d'' = 1,$$
$$d'h''_k + h''_k d' = 0, \qquad d''h'_k + h'_k d'' = 0.$$

The norms of h'_k, h''_k are bounded by a constant times $|k|^{-1}$. They therefore act on smooth Fourier series, and also on distributions.

Proof. For a covector λ and vector v, exterior multiplication ε_λ and contraction satisfy $\varepsilon_\lambda \iota_v + \iota_v \varepsilon_\lambda = \lambda(v)$. Applying this in the matching factor gives $|k|^2$; applying it across the two disjoint factors gives zero. Division by $2\pi i|k|^2$ proves the identities. The contraction norm is $|k|$, proving the estimate. S-mooth coefficients are rapidly decreasing, while distribution coefficients have at most polynomial growth, so these estimates preserve the corresponding Fourier classes. □

Let P_0 denote the projection to the zero Fourier mode, equivalently the coefficientwise average. Set $h' = h'' = 0$ on that mode and use the preceding formulas on the others. The four identities then hold globally with 1 replaced by $1 - P_0$ in the first two. Thus the only obstruction visible in these complexes is the constant coefficient.

Theorem 24.11.2 (Dolbeault cohomology of a real torus)**.** *Every d''-closed smooth (p, q) form is cohomologous to its unique constant-coefficient average. In particular,*

$$H^{p,q}_{d''}(M) \cong \bigwedge^p V^* \otimes \bigwedge^q V^*, \qquad \dim H^{p,q}_{d''}(M) = \binom{n}{p}\binom{n}{q}.$$

The same conclusion holds with distributional forms, and the inclusion of smooth forms induces the indicated cohomology isomorphism.

Proof. If $d''\alpha = 0$, the homotopy identity gives $\alpha - P_0\alpha = d''h''\alpha$. The primitive is smooth, or distributional, in the same category as α. Conversely, the average of a derivative is zero because its zero Fourier mode vanishes. Hence no nonzero constant form is exact. The construction commutes with conjugation of Fourier series, so it restricts to real forms. □

24.11.2 The $d'd''$ lemma

Theorem 24.11.3. *A smooth form α with $d'\alpha = d''\alpha = 0$ has a smooth $d'd''$ primitive if and only if $P_0\alpha = 0$. One primitive is*

$$\beta = h''h'\alpha, \qquad d'd''\beta = \alpha.$$

The statement also holds for distributions. In particular, a form closed under both differentials which is exact under either one is $d'd''$-exact.

Proof. Necessity follows because a derivative has average zero. For sufficiency, work on a nonzero mode. Since $d''h'\alpha = -h'd''\alpha = 0$,

$$d'd''h''h'\alpha = d'h'\alpha = \alpha.$$

Summing is legitimate by the contraction estimates; the multiplier is of order at most $|k|^{-2}$. If the bidegree has a zero entry, the corresponding negative-degree primitive space is zero, and the same identities force every mean-zero form closed under both operators in that bidegree to vanish. Finally, exactness under either differential implies zero average. □

The two contractions and their anticommutation signs are essential. Solving separately for a d' primitive and a d'' primitive does not by itself provide one common $d'd''$ primitive on an arbitrary double complex. Here the explicit identities make the implication valid.

Definition 24.11.4. For the superform double complex, the Bott–Chern and Aeppli groups are

$$H^{p,q}_{BC} = \frac{\ker d' \cap \ker d'' \subset A^{p,q}}{d'd''A^{p-1,q-1}},$$
$$H^{p,q}_{A} = \frac{\ker(d'd'' : A^{p,q} \to A^{p+1,q+1})}{d'A^{p-1,q} + d''A^{p,q-1}}.$$

Proposition 24.11.5. *On M, both groups are represented uniquely by constant forms, so they have the same dimensions as $H^{p,q}_{d''}(M)$. The assertion holds for smooth forms and for distributions.*

Proof. The Bott–Chern assertion is Theorem 24.11.3. For Aeppli cohomology, take a nonzero mode of α with $d'd''\alpha = 0$. Then $d'\alpha$ is d''-closed, and

$$\begin{aligned}\alpha &= d'h'\alpha + h'd'\alpha \\ &= d'h'\alpha + h'd''h''d'\alpha \\ &= d'h'\alpha - d''h'h''d'\alpha.\end{aligned}$$

This is a sum of an exact term for each differential. The multipliers have polynomially bounded size, so the formulas sum in the desired category. A sum of derivatives has zero average, proving uniqueness of the constant representative. □

24.11.3 Pairings and current equations

Integration gives a perfect pairing

$$H^{p,q}_{d''}(M) \times H^{n-p,n-q}_{d''}(M) \longrightarrow \mathbb{R}, \qquad ([\alpha],[\beta]) \longmapsto \int_M \alpha \wedge \beta.$$

It is well defined by Stokes. To prove nondegeneracy, replace both classes by constant forms. A basis element $d'x_I \wedge d''x_J$ pairs, up to its fixed sign and the positive volume of the torus, with the complementary basis element indexed by I^c, J^c. The pairing matrix is invertible. The same argument identifies the Bott–Chern/Aeppli complementary pairing.

This calculation proves more than finite-dimensionality: it gives explicit continuous solution operators for all nonzero Fourier modes. Hence the obstruction to a closed current being $d'd''$-exact is exactly its constant cohomology component. By contrast, on a proposed direct limit of tropical complexes, finite-stage nondegenerate pairings alone provide neither a limiting solution estimate nor an actual form representative. The Fourier operator has supplied both an algebraic homotopy and a topological bound in this particular model.

24.12 Positive currents and their global torus potentials

Theorem 24.12.1. *Let T be an ordinary positive closed $(1,1)$ supercurrent on M. Its coefficientwise average is a constant positive semidefinite form θ. There is a continuous real function u, unique up to a constant, such that*

$$T = \theta + d'd''[u].$$

On V, the periodic lift of u added to a quadratic potential for θ is finite convex.

Proof. The average of the positive matrix-valued coefficient measure is positive semidefinite, giving θ. The distributional $d'd''$ lemma produces a real

distribution u with $d'd''u = T - \theta$. Locally write $\theta = d'd''q$ for a quadratic function. Then $d'd''(u+q) = T \geq 0$. The real convex-distribution theorem, Corollary 11.5.2, makes $u+q$ a finite convex continuous function locally. Thus u has a continuous representative, and these representatives agree on overlaps because they define the same distribution.

On V, the lifted function $u+q$ has positive distributional Hessian globally, hence is convex. If two potentials give the same current, their difference has zero Hessian and is affine on V. A Λ-periodic affine function is constant. □

This conclusion is a feature of real convexity. Positive closed complex $(1,1)$ currents can have logarithmically singular potentials; a positive real Hessian distribution on an open Euclidean domain instead has a finite convex representative. The real torus theorem must not be transferred to a singular tropical quotient or an arbitrary analytic space merely because the notation for the two differential operators is similar.

Corollary 24.12.2 (Rigidity in a null direction)**.** *Let H be the positive semidefinite matrix of θ and u the preceding potential. The lift of u is constant along every vector in* $\ker H$*. If the image of* $\ker H$ *is dense in M, then u is constant and $T = \theta$.*

Proof. For $e \in \ker H$, the quadratic function $q(x) = \frac{1}{2}x^{\mathsf{t}}Hx$ is constant along $x + \mathbb{R}e$. The convex function $q+u$ restricts to a convex function of one real variable which is bounded, because u is periodic and continuous. A convex function bounded on all of $\mathbb{R}$ is constant: any nonzero secant slope would force unbounded growth on one end. Thus $u(x+te) = u(x)$. Invariance under a dense subgroup and continuity give the final claim. □

Example 24.12.3. On $\mathbb{R}^2/\mathbb{Z}^2$, let $H = \left(\begin{smallmatrix} 1 & a \\ a & a^2 \end{smallmatrix}\right)$ with a irrational. Its kernel is generated by $(-a, 1)$, whose image is dense in the torus. Every positive closed $(1,1)$ current with average H is therefore the constant current H. If $a = 0$, nonconstant potentials depending only on x_1 are possible, subject to $1 + u'' \geq 0$. The closure of the null foliation, rather than the rank of H alone, accounts for the difference.

References. The arguments in this section combine the elementary Fourier contraction of a flat torus with the real convex-potential theorem of [Lag12, Proposition 1.13]. They are included as explicit model calculations. For the broader comparison of superform cohomology with tropical cohomology, see [JSS];

no passage from the flat-torus calculation to a general Berkovich Hodge theorem is used here.

24.13 The Hodge index calculation in bidegree $(1,1)$

The flat-torus computation also gives an explicit index theorem. The statement concerns symmetric real $(1,1)$ classes. Their constant representatives are symmetric matrices, and the primitive condition is a trace condition. This makes the sign and the equality case completely visible.

Theorem 24.13.1. *Assume $n \geq 2$, and let θ be a constant positive definite $(1,1)$ form on M. On the space of symmetric Bott–Chern $(1,1)$ classes, the pairing*

$$Q([\alpha],[\beta]) = \int_M \alpha \wedge \beta \wedge \theta^{n-2}$$

has signature $(1, \frac{n(n+1)}{2} - 1)$. Its restriction to the primitive subspace

$$\left\{ [\alpha] : \int_M \alpha \wedge \theta^{n-1} = 0 \right\}$$

is negative definite. In particular, a smooth symmetric closed form in that primitive subspace has $Q([\alpha],[\alpha]) = 0$ if and only if it is $d'd''$-exact.

Proof. Stokes makes the pairing invariant under adding a $d'd''$-exact form to either factor. By Proposition 24.11.5, replace all classes by constant representatives. Make a real linear coordinate change in which the matrix of θ is the identity; the lattice changes but the torus volume stays positive. Let A be the symmetric matrix of α. Expanding $\det(I + tA)$, or diagonalizing A, gives

$$\alpha \wedge \theta^{n-1} = \frac{\operatorname{tr} A}{n}\, \theta^n,$$
$$\alpha^2 \wedge \theta^{n-2} = \frac{(\operatorname{tr} A)^2 - \operatorname{tr}(A^2)}{n(n-1)}\, \theta^n.$$

Primitivity is precisely $\operatorname{tr} A = 0$. On this subspace the second expression is a negative multiple of $\operatorname{tr}(A^2) = \sum_i \lambda_i^2$, and vanishes only when $A = 0$. The line spanned by the identity is positive and orthogonal to the trace-zero subspace. Since the dimension of the symmetric matrices is $n(n+1)/2$, this gives the

signature. A zero constant representative is equivalent to $d'd''$-exactness by Theorem 24.11.3. □

For a general positive matrix H of θ, the same formulas use $H^{-1/2}AH^{-1/2}$. Thus the invariant primitive condition is $\operatorname{tr}(H^{-1}A) = 0$. The coordinate change is only a device for the calculation; it does not replace the lattice normalization in integration.

24.13.1 A related inequality for metric potentials

Let u, v be continuous periodic functions with $\alpha_u = \theta + DDu \geq 0$ and $\alpha_v = \theta + DDv \geq 0$. The global regularization of Section 21.23 defines their continuous mixed products. Set

$$I_\theta(u, v) = -\int_M (u - v)(\alpha_u^n - \alpha_v^n).$$

Proposition 24.13.2. *One has $I_\theta(u, v) \geq 0$. For smooth u, v, it is the sum of nonnegative Dirichlet terms*

$$I_\theta(u, v) = \sum_{j=0}^{n-1} \int_M d'(u - v) \wedge d''(u - v) \wedge \alpha_u^j \wedge \alpha_v^{n-1-j}.$$

Proof. In the smooth case, factor the difference of powers and integrate by parts against $u - v$. Every remaining factor is a closed positive $(1, 1)$ form, so each integrand is nonnegative. For continuous potentials use common global smooth semipositive approximations. The measures converge weakly, the potentials converge uniformly, and their total masses remain fixed. The moving-test convergence of Chapter 9 therefore passes the displayed nonnegativity to the limit. The integral defining I_θ is meaningful without assigning ordinary first derivatives to the continuous potentials. □

The index theorem is a nondegeneracy statement on a finite-dimensional cohomology space. The inequality for I_θ is a positivity statement on potentials in one fixed class. They use related integration-by-parts signs, but their equality cases require different arguments. In the smooth strictly positive setting, Section 21.25 proves that $I_\theta(u, v) = 0$ forces $u - v$ constant. The full degenerate continuous uniqueness problem belongs to the corresponding convex Monge–Ampère theorem.

References. These are matrix and integration-by-parts consequences of the flat-torus calculations above. Their role in the torus metric setting is compared with [BGJK25, Sections 7–8]; no general tropical Hodge–Riemann theorem is assumed.

24.14 Subject and literature concordance

The following concordance groups the sources by the mathematical construction being used. It supplements the notation index in Section 0.2.3. A source listed in one row may also contribute to another; the grouping does not assert equivalence of its objects with every object in that row.

Construction	Sources	Comparison developed here
Tropical cycles and skeleta	[Gub13, GRW16, GRW17, Pay09, DT26]	Multiplicities, lattice degrees, faithful tropicalization, and the topology of analytic spaces; Sections 5.2, 6.3, 24.1.
Smooth forms and currents	[CLD12, Gubler, CLD25]	Analytic-unit charts, algebraic presentations, test topology, and the revised tropical framework; Chapters 7–9.
Positive cones and current estimates	[CLD12, CLD25, BGJK]	Dual positivity, order zero, and the distinction between ordinary and weak positivity; Section 9.1.1 and Appendix A.
Delta-forms and intersections	[GK17, GK19, Mih24, Mih23, Cai23, BGK25]	Corner terms, products, analytic constructions, and compactification; Sections 16.1, 15.7, 22.2.

Construction	Sources	Comparison developed here

Measures, metrics, and heights	[CL06, GM, BFJ15, Gub10, GS23, Lin26, CG26]	Model measures, global Monge–Ampère theory, canonical measures, and local heights; Sections 19.4, 20.6, 22.2, 21.3.

24.15 Cycle classes: what cohomological vanishing gives

A construction of Green forms must first identify the obstruction represented by the cycle. Liu's tropical cycle class map is directly relevant because its target is built from original CLD forms, rather than from a separately chosen finite polyhedral model. Let X be smooth and separated of finite type over a complete nontrivially valued field. Liu constructs a rational sheaf $\mathscr{T}^p$ whose realification is the sheaf of d''-closed $(p,0)$-forms. The fine resolution by CLD forms relates

$$H^{p,q}_{\mathrm{trop}}(X) = H^q(X^{\mathrm{an}}, \mathscr{T}^p), \qquad H^{p,q}_{\mathrm{trop}}(X) \otimes_{\mathbb{Q}} \mathbb{R} \simeq H^{p,q}_{d''}(X^{\mathrm{an}}).$$

His cycle map $\mathrm{cl}_{\mathrm{trop}} : \mathrm{CH}^p(X) \to H^{p,p}_{\mathrm{trop}}(X)$ is functorial and product-compatible. Its integration formula, after realification, is

$$\int_{X^{\mathrm{an}}} \mathrm{cl}_{\mathrm{trop}}(Z) \wedge \eta = \int_{Z^{\mathrm{an}}} \eta, \qquad d''\eta = 0, quad\eta \in A_c^{n-p,n-p}(X^{\mathrm{an}}). \quad (24.15.1)$$

The left side means the pairing of a representative of the class with the closed test. Independence of that representative follows from Stokes. The theorem proves that this pairing agrees with cycle integration.

Theorem 24.15.1 (Liu's de Rham vanishing consequence)**.** *Let k be a finite extension of $\mathbb{Q}_p$, let X/k be proper and smooth, and let Z have codimension p with $\mathrm{cl}_{\mathrm{dR}}(Z) = 0$. After base change to $\mathbf{C}_p$, integration over Z^{an} vanishes on every d''-closed original CLD test of complementary bidegree.*

Open proof obligation (RC2). Establish the pairing-vanishing result in the stated scope; Liu20 Theorem 1.8 is supplied.

24.16 Finite tropical models and Hodge theory

The fan theorems of Amini–Piquerez provide powerful finite-dimensional models, with hypotheses that are visible combinatorially. For a rational simplicial fan Σ, let $\overline{\Sigma}$ be its canonical compactification. The tropical Feichtner–Yuzvinsky theorem identifies

$$H^{p,p}(\overline{\Sigma}, \mathbb{Q}) \simeq A^p(\Sigma, \mathbb{Q}).$$

For the full cohomology ring to be concentrated on the diagonal and equal to the Chow ring, their Theorem 1.3 additionally assumes that Σ is a tropical homology manifold. Integral coefficients require further unimodularity, saturation and integral-duality hypotheses. Rational and integral statements should be recorded separately. Homological smoothness is itself a local condition. In [AP-D, Theorem 1.1], a fan is homologically smooth precisely when the fan and all its star fans satisfy tropical Poincaré duality. Their local-to-global theorem gives duality between ordinary tropical cohomology and Borel–Moore homology. Compactly supported cohomology enters the associated pairing. Replacing Borel–Moore homology by ordinary homology on a noncompact space would change that theorem.

Example 24.16.1 (The complete one-dimensional fan)**.** For the fan in $\mathbb{R}$ with rays generated by 1 and -1, the Stanley–Reisner relation is $x_+x_- = 0$ and the linear relation is $x_+ - x_- = 0$. Hence

$$A^\bullet(\Sigma, \mathbb{Q}) = \mathbb{Q}[h]/(h^2), \qquad \deg h = 1.$$

The compactification has $H^{0,0} = H^{1,1} = \mathbb{Q}$ and no other cohomology. Multiplication pairs 1 and h nondegenerately. This is a complete finite calculation, using the stated fan comparison. It proves neither a general $d'd''$-lemma on an analytic curve nor an identification of all forms on its Berkovich analytification with forms on one segment.

The remaining transition to Berkovich geometry has three parts. One must identify the relevant complexes and their transition maps, prove that cohomology and the needed support conditions pass through the chosen limit, and control the topology needed for duality or solution operators. Payne's topological inverse-limit theorem addresses none of these three analytic assertions by itself. The limit and closed-range issues in Sections 24.5 and 24.6 remain in force even when every individual tropical model has perfect finite-dimensional duality.

References. [Liu20, Theorems 1.1, 1.7–1.9]; [AP-FY, Theorems 1.1–1.3]; [AP-D, Theorems 1.1–1.3].

24.16.1 From local fans to global tropical Hodge classes

There are two further layers in the Amini–Piquerez programme. The local layer establishes the Kähler package for suitable Chow rings: for example, effective unimodular quasi-projective quasilinear fans are Chow-Kähler in [AP-F, Theorem 1.10]. The global layer constructs Kähler classes and uses a tropical Steenbrink complex to obtain Hard Lefschetz, Hodge–Riemann and weight-monodromy results for smooth projective tropical varieties, with rational coefficients and the definitions of [AP-H, Theorem 1.4]. Neither assertion is a statement about every balanced polyhedral complex. The tropical Clemens–Schmid sequence addresses the representation of cohomology by tropical cycles. Under the additional rational triangulability hypothesis, [AP-CS, Theorem 1.1] identifies the classes generated by codimension-p tropical cycles on a smooth projective tropical variety with

$$\ker\big(N : H^{p,p}_{\mathrm{trop}}(X,\mathbb{Q}) \longrightarrow H^{p-1,p+1}_{\mathrm{trop}}(X,\mathbb{Q})\big).$$

The monodromy-kernel condition is part of the conclusion; one should not replace it by all of $H^{p,p}$. These cycles are tropical cycles. An algebraic lifting statement would require an additional theorem. Likewise, a tropical cycle class and Liu's cycle class of an algebraic cycle become comparable only after the relevant realization map has been constructed. The full proofs of the Steenbrink and Clemens–Schmid constructions are not reproduced here. The finite fan calculation, the cycle-pairing theorem and the limit requirements isolate the parts needed for the analytic programme. Extending this account to a self-contained global tropical Hodge theory would require a separate development of those complexes and their comparison maps.

24.17 The next mathematical comparisons

The preceding additions change the form of the remaining questions. Some unrestricted claims already have counterexamples; others have precise positive theorems in narrower categories. The following programme records the assertions still needed for the general analytic goals of this book. An external theorem with an adequate statement is not a missing proof merely because its proof is not repeated here.

1. *Approximation and residual geometry.* For CLD25 Proposition 8.1.11, prove the predecessor-replacement step or restrict the conclusion to the proved first stage. The pure-dimensional residual current criterion is reconstructed in Theorem 19.18.12. The separate integral PL bridge is now supplied by Theorem 19.18.22 and Corollary 19.18.23. These tasks do not by themselves prove smooth regularization for every continuous current-psh metric.

2. *Larger potential classes and kernels.* Theorem 13.6.3 already permits the stated arbitrary ordinary positive closed background and admitted continuous potentials. Extending the potential class requires new approximation or monotone-convergence results. Passing to curvature classes additionally requires a kernel theorem. The unrestricted abstract kernel statement is false; an analytic replacement must specify functions, backgrounds and actual relations.

3. *Capacity and global envelopes.* Compare the toric, polyhedral, model-metric and synthetic finite-energy theories on their common domains. A general local analytic package of capacity, quasi-continuity, comparison and Dirichlet existence has not been established here. The counterexample in Section 16.7 excludes a universal orthogonality shortcut. The model and field hypotheses of each positive existence theorem remain essential.

4. *Representatives and local potentials.* Polyhedral pullback and current pushforward do not supply a general analytic trace in the actual delta-sheaf. Prove that trace with its domain and support conditions before using it for descent. Likewise, existence of a distributional primitive is insufficient for a local psh potential theorem for arbitrary positive closed $(1,1)$-currents.

5. *Cohomology and actual Green forms.* Combine a precisely stated finite-stage Hodge comparison with control of limits, closed ranges and support. Liu's vanishing theorem supplies a necessary pairing condition, not an actual primitive. The general strong Green problem still requires a representative on the exact complement and the identity on the full actual test space, with compatible finite-field descent.

6. *Energy and arithmetic compatibility.* On an explicitly identified common domain, compare limiting measures and relative energies with CLD/GK currents and arithmetic intersection. Retain the boundary topology and the compactified reference object. In mixed characteristic, list resolution or model hypotheses theorem by theorem; do not replace a conditional global theorem by an unconditional local statement.

The next editorial expansion should develop the global tropical Hodge complexes and the mixed finite-energy comparison in more detail. The next proof repair should address continuous predecessor replacement after the integral PL bridge completed below. These are separate tasks: expanding a literature account is not evidence that an unresolved analytic implication has been proved.

Version 0.9 supplies the Laurent gluing, simultaneous residual realization and PL noncharging argument over arbitrary complete fields, then assembles the pure-dimensional residual criterion. It also corrects the previous manuscript's non-good-germ concern: boundarylessness already implies goodness here. The integral psh comparison requires the additional argument below; it cannot be replaced by merely expressing a PL weight as a difference of admitted functions.

Version 0.11 supplies prescribed graded premodel realization, the simultaneous bundle identifications, and the nef integral PL implication on a fixed tube. P0-A4 is therefore complete in the stated integral PL category, with its named imported inputs. The next approximation task is P0-B: continuous predecessor replacement in CLD25 paragraph 8.1.11. A generated-class conclusion for a nef PL weight is not a first-stage smooth sequence for that weight.

Version 0.12 proves continuous endpoint collapse for a decreasing hierarchy on one fixed compact set. The remaining P0-B task is to justify a common compact representation, or to construct weaker continuous replacements in $\mathcal{C}_{25}$ on one fixed neighbourhood. These are different targets: the first would

give first-stage approximation, while the second is enough for the unindexed equality. The same-ordinal forward inclusion and the locally integrable hierarchy equality are already established in Section 11.6.3; they should not be listed as unresolved.

Version 0.13 adds a projective envelope route. Theorem 11.7.5 proves that bounded first-stage decreasing stability suffices for equality at every continuous ordinal stage; after that input is supplied, ordinal control is no longer a separate obstacle. The next source-verification task is the chain in [Wu26]: Theorem A.3, bounded localization, Theorem 4.17 and Corollary 4.18. Proposition 11.7.3 corrects the barrier normalization and background conversion, and Lemma 11.7.1 supplies sequential continuous obstacles from the local approximation property. Section 11.8 now supplies a fixed-domain diagonal lemma, bounded-family tropical localization and projective barrier construction. Section 11.9 supplies one such common-domain direction for explicitly specified rational PL generators over a nontrivially valued field. The approximation and single-generator tasks are now treated in Section 11.22 under its stated hypotheses. The common-domain first-stage comparison is now supplied by Corollary 11.24.4; remaining tasks are sheaf-level decreasing closure, complete source-class identification and trivial-valuation extension. Outside the projective envelope category, bounded decreasing stability remains the analytic target; no claim over arbitrary complete fields follows from the equicharacteristic-zero envelope theorem.

For an already strict R-PL germ, Section 11.13 now supplies coefficient-compatible decreasing rational approximation on one residue tube, and a projective original-smooth comparison. An arbitrary sequence still needs a common finite presentation for the ordered-family corollary. Identification of arbitrary pre-existing relative real PL presentations remains separate; continuous relative-support approximation is supplied by Section 11.22. Section 11.14 repairs the single-polarization cofinal input after exhibiting the fixed-model failure of GM Lemma 4.12. Finite simultaneous polarizations and the numerical and bounded-correction parts of GM Proposition 4.14 are reconstructed in the stated formal-domination scope. Section 11.15 supplies algebraic model-morphism domination using non-Noetherian formal GAGA, and reduced-special-fibre cofinality under the algebraically closed hypothesis. These particular interfaces are therefore closed; the broader analytic comparisons remain open. Section 11.17 narrows the remaining reverse-comparison problem. The explicit smooth family obstructing ambient convex extension does admit decreasing coefficient-compatible relative PL approximation in

its original chart. More generally, finite coordinatewise-monotone convex compositions of bounded relative rational PL functions have such approximations, including the decreasing-tuple construction (11.17.9). Section 11.22 now supplies the required density directly for continuous relative-support functions on a fixed compact image. Proposition 11.22.14 applies it to one original smooth psh input using a boundary-adapted chart. Theorem 11.24.3 now supplies common-domain replacement for arbitrary original smooth sequences whose charts vary; the further sheaf-level closure is separate. The earlier fixed rational-fan result is extended to one-scale polytopal complexes by Theorem 11.18.1. To apply this result to real PL output from another source, one must verify the vertex condition or prove a replacement allowing the subdivision to vary. Examples 11.18.3 and 11.18.4 rule out freezing arbitrary subdivisions while merely rounding their coefficients.

Section 11.19 now gives the exact closure on a fixed complex: a relatively supported target must lie in the real span of admissible rational functions. Under the strict face-support certificate this reduces to the explicit continuity equations. Edge-connected rational simplices of dimension at least two provide a separate route to one common value-group scale. For this fixed-complex approach, the hypotheses must still be verified on the source output. Section 11.22 instead constructs new affine branches before gluing and so avoids fixing those subdivisions.

Lemma 11.19.12 and Proposition 11.19.13 complete the coefficient-compatible convex extension on individual cells. Their value estimates do not bound normal slopes at the original faces. Section 11.20 now proves the slope-controlled version and preserves relative supports for compatible compact complexes. Section 11.22 handles continuous relative-support inputs with arbitrary real affine supports on one compact domain, including extended images under its admissible boundary convention. The global twisted and simplicial source formulations still require separate identification.

For the current approximation status, Section 11.22 supersedes the earlier density tasks listed above. Continuous relative-support inputs on one compact ordinary or extended image admit coefficient-compatible decreasing approximation; the extended case retains its admissible boundary-support hypothesis. A single original smooth psh input, and a finite collection of such inputs, are covered by Section 11.22.6. Section 11.24 completes the arbitrary original-smooth-family replacement and the stated first-stage germ comparison. The open tasks are further sheaf-level decreasing closure, contin-

uous predecessor replacement, and precise source-class identification. None of the abstract boundary or fixed-chart counterexamples negates those open analytic assertions.

Appendix A

Source corrections and concordance

A.1 Corrections and qualifications of source statements

This section gives the mathematical evidence for the source qualifications used in the main text. It concerns the versions listed in Section 0.2.2, and it does not claim an audit of every page of the 608-page text. The counterexamples below address literal statements; the separate remarks about incomplete arguments do not assert that their conclusions are false. Return to Sections 11.2, 13.1 and 19.3 for the statements used in the lecture.

A.1.1 Weak positivity does not imply order zero

Example A.1.1 (A weakly positive current of order one)**.** On $\mathbb{R}^4$, write a symmetric $(2,2)$-test form in the matrix normalization

$$\alpha = -\sum_{|I|=|J|=2} H_{IJ}(x)\, d'x_I \wedge d''x_J, \qquad H_{IJ} = H_{JI}.$$

Define the coefficient functional

$$\ell(H) = H_{12,34} - H_{13,24} + H_{14,23}.$$

If $H = a\xi\xi^{\mathsf{T}}$ is a strong generator, the two-covector ξ is decomposable. Its Plücker relation is

$$\xi_{12}\xi_{34} - \xi_{13}\xi_{24} + \xi_{14}\xi_{23} = 0.$$

Thus $\ell(H) = 0$ for every strongly positive form, pointwise in x. Define

$$T(\alpha) = \frac{\partial}{\partial x_1} \ell(H_\alpha(x))\Big|_{x=0}, \tag{A.1.1}$$

and let T vanish on antisymmetric forms. This is a continuous distribution of order at most one. It is symmetric, and it vanishes on every strongly positive test. Both T and $-T$ are therefore weakly positive.

Choose a constant symmetric form α^0 with $\ell(H_{\alpha^0}) = 1$, and a smooth compactly supported function χ equal to one near 0. The tests

$$\alpha_j = j^{-1} \sin(jx_1)\chi(x)\alpha^0$$

have one fixed compact support and coefficient suprema tending to zero, whereas $T(\alpha_j) = 1$ for every j. Hence T is not of order zero.

The same phenomenon is recorded in [BGJK, Examples 2.3.6 and 5.2.8]. It directly contradicts the weak-positive assertion in [CLD25, Proposition 7.2.9, p. 162]. The proof there uses the relative-interior statement for the strong cone in Proposition 1.2.13 as if that cone could dominate every symmetric form. Example 7.4.3 shows that the required domination is impossible.

The replacement used in this book is Proposition 9.1.7, for ordinary positive currents. In degrees $(1,1)$, $(n-1,n-1)$, and the extremal degrees, the coincidence of the relevant cones removes this particular middle-degree obstruction. The counterexample must not be cited as a failure of order zero for ordinary positive $(1,1)$-currents.

Return to positivity and continuous multipliers.

A.1.2 A locally integrable distribution does not fix point values

Remark A.1.2 (The literal implication in Proposition 8.3.2). The statement in [CLD25, Proposition 8.3.2, pp. 201–202] quantifies over functions on a convex real open set which are not identically $-\infty$. Its third condition is local integrability and positivity of $d'd''[u]$, and it concludes pointwise finite convexity. The function in Remark 11.2.9 satisfies the third condition and fails the conclusion. The convolution step in the printed proof also invokes uniform convergence to this arbitrary function, which does not follow from local integrability.

For continuous functions, Proposition 11.2.8 gives a complete repair. Theorem 11.3.2 supplies the full L^1_{loc} repair: there is a unique finite convex representative, and convolution converges locally uniformly to that representative. This distinguishes the representative from arbitrary modifications on sets of measure zero. Adding upper semicontinuity alone does not repair the printed statement, as the same upward-point-spike example shows.

Return to the corrected continuous comparison.

A.1.3 Multiplication need not preserve a closed current

Example A.1.3 (Failure of the scalar multiplication assertion)**.** In the tropical line $X = \mathbb{R}$, let $T = [1]$ be the integration current of bidegree $(0, 0)$. It is positive and closed and has the Bedford–Taylor property, as also stated in [CLD25, Example 8.6.4]. Let

$$u(x) = 1 + x^2.$$

This is a smooth positive function, but

$$d'(uT) = [2x\, d'x] \neq 0.$$

Thus uT is not closed and cannot be a Bedford–Taylor current under [CLD25, Definition 8.6.2]. This disproves Corollary 8.6.7, p. 208, literally.

Even deleting closedness from that definition would not fix the claimed preservation of potential independence. Indeed, $a(x) = x$ and $b(x) = 0$ are smooth psh functions with the same zero Hessian. Nevertheless,

$$d'd''(a\,uT) = [6x\, d'x \wedge d''x] \neq 0 = d'd''(b\,uT).$$

The correct smooth multiplication statement is Proposition 8.6.5 of the source: the factor is a positive *closed smooth form*. A general positive continuous scalar does not satisfy the closedness requirement.

Return to the continuous recursive construction.

A.1.4 The successor step in the generated-sheaf comparison

Remark A.1.4 (The missing implication in Proposition 8.1.11). CLD25, Proposition 8.1.11, pp. 197–198, claims

$$\mathcal{C}_{25,\alpha} = C^0 \cap \mathcal{P}_{25,\alpha} \quad \text{for every ordinal } \alpha.$$

At a successor stage, the right side permits a continuous endpoint u which is locally a decreasing limit of $u_j \in \mathcal{P}_{25,\alpha}$. The approximants u_j are not assumed continuous. The printed proof instead compares decreasing and uniform limits of members of $\mathcal{C}_{25,\alpha}$. The induction hypothesis identifies these with the *continuous* members of $\mathcal{P}_{25,\alpha}$; it does not make every u_j continuous.

Dini's theorem for continuous approximants proves the first-stage equality in Proposition 11.2.3. It does not supply the missing continuous approximants at an arbitrary stage. Even a uniform convergence conclusion for the original upper semicontinuous approximants would not place each of them in the continuous stage. An additional replacement or approximation argument is required.

We have no counterexample to the stated equality. The usable conclusions include the first-stage equality, the inclusions in Proposition 11.2.4, and the same-ordinal forward inclusion of Proposition 11.6.6. Theorem 11.6.4 handles a hierarchy on one fixed compact set, but transferring sheaf-generated sections to that hierarchy requires the extra representation in Corollary 11.6.5. Proposition 11.6.7 verifies the neighbouring L^1 comparison independently of the continuous gap. The independent PL synthesis later in the text supplies an equality on that specified class without invoking the disputed successor step. Section 11.7.4 supplies a sufficient bounded-stability criterion, and Corollary 11.7.6 applies the comparison inputs of [Wu26] in the projective envelope category. This is a scoped source-dependent application; it does not repair the original proof on every analytic space.

Remark A.1.5 (The stationarity wording). Lemma 8.1.4 of CLD25, p. 196, says that the ordinal hierarchy is eventually stationary, and its proof invokes a cardinality argument. Remark 8.1.6 on the same page says that stationarity is not known. Read without a qualification on the ordinal, these sentences conflict. A hierarchy of subobjects inside a fixed set of local sections cannot grow strictly through all ordinals; the eventual set-theoretic stabilization and the question whether the *first* stage suffices are different matters. The lecture does not choose an unstated ordinal bound on the authors' behalf. It uses only the minimal-sheaf definition and the explicitly proved first-stage comparison.

Return to the generated-sheaf definition.

Normalized residual sections. The literal corrections to CLD25 Lemma 17.4.10, Corollaries 17.4.11–17.4.12 and Proposition 17.8.2 are recorded, with the corrected proof and a one-point test, in Lemma 19.18.13 and Remark 19.18.14. The semiample conclusion is retained with its weighted maximum.

A.1.5 A fixed neighbourhood is part of an approximation statement

Remark A.1.6 (Proposition 17.8.4 and a repair in a common category). The proof of [CLD25, Proposition 17.8.4, pp. 497–498] perturbs a nef residual class by a rational multiple of an ample class. Applying Proposition 17.8.2 to each perturbation gives psh on a neighbourhood of the chosen point. The argument then takes a uniform limit on one fixed neighbourhood. The printed application alone does not show that the psh neighbourhood can be chosen independently of the perturbation.

The logical point is elementary. On a real interval, let

$$v_\varepsilon(t) = \varepsilon t^2 - t^4.$$

For every $\varepsilon > 0$, this function is convex near 0, since $v_\varepsilon'' = 2\varepsilon - 12t^2$. On a fixed compact interval it converges uniformly to $-t^4$, which is not convex on any neighbourhood of 0. Thus positivity on varying neighbourhoods is insufficient for the claimed limiting step.

In the good strictly analytic, nontrivially valued setting at interior points, [GJR, Proposition 7.10] supplies one fixed neighbourhood and a uniform family of locally Fubini–Study approximants. Theorem 19.18.17 expands its residue-model construction: a single reduction tube works for every perturbation. Proposition 19.18.16 isolates the exact compatibility used. The PL synthesis uses this fixed-domain argument. This is an independent repair under its stated hypotheses, not a counterexample to Proposition 17.8.4. The graded construction of Proposition 19.18.20 and Theorem 19.18.22 now gives the integral PL version over arbitrary complete fields.

A.1.6 Scope and indexing in the residual comparison

Remark A.1.7 (What is and is not established about Theorem 18.8.4). We did not obtain a counterexample to [CLD25, Theorem 18.8.4] or a refutation of its entire proof. Its claim is stated in Remark 19.3.1. The following local problems are identifiable.

1. On p. 539, the residual numerical criterion for a product of d Chern classes is expressed as a zero-cycle degree. The testing subvarieties must therefore have dimension d. The printed reference to codimension m does not give that dimension in general; later in the proof, the subvarieties are correctly taken of dimension d.

2. In the same proof, the rational-domain inequalities formed from $f_i^{\varepsilon_i}$ require the right-hand side $|f_i(x)|^{\varepsilon_i}$. Omitting the exponent on that side fails to make the chosen point satisfy the equality when $\varepsilon_i = -1$ and $|f_i(x)| \neq 1$.

3. Corollary 18.8.8, p. 541, states its equivalence for integral PL metrics, whereas its cited implication from Proposition 17.8.4 has a *strictly* integral PL hypothesis. The distinction is made in the source's definitions; a reduction and descent argument is needed to use that implication in the larger category.

The first two items are incorporated in the reconstruction of Theorem 19.18.12. For the third, Theorem 19.18.15 treats arbitrary integral PL metrics with semiample residue, and Corollary 19.18.18 treats nef strictly integral PL metrics over a nontrivially valued field. Theorem 19.18.22 completes the general integral PL implication using prescribed graded premodels over the original field; Corollary 19.18.23 gives the resulting pure-dimensional comparison. None of them authorizes replacing the theorem by a general statement about arbitrary continuous metrics.

Remark A.1.8 (A bidegree/bidimension slip in the CLN estimate). In [CLD25, Proposition 8.4.1, p. 202], the current is called of bidegree (p, p) while the test has degree $(p - q, p - q)$ after q curvature factors have been inserted. The displayed pairing has the advertised degree when p is the *bidimension* of the initial current: its resulting bidegree is $(n - p + q, n - p + q)$. This is an indexing correction; the lecture uses the explicit complementary test degrees throughout.

Return to the PL source comparison.

A.1.7 Corrections in the other sources

Remark A.1.9 (The 2012 source is not an error-free reference version). The earlier text also needs qualifications. Its commutativity exponents in §1.2.6 and §3.1.4 conflict with the explicit total-degree algebra; Remark 7.1.5 gives the adopted correction. The real strong-cone decomposition in Lemma 5.2.3 is disproved by Example 7.4.3. The proof of the analytic Lemma 5.3.3 relies on that decomposition and requires a separate repair; the real example alone is not a counterexample satisfying every analytic hypothesis. Its continuous facewise-convexity criterion in Lemma 5.5.3 misses the corner mass; [GK19, Remark 3.2 and Example 3.3] supplies the correction. The general pullback sentence following Definition 5.5.1 must be distinguished from the proved pullback result on a specified approximation class.

Remark A.1.10 (Two cautions about the GK positivity text). The incorrect real strong-span statement is repeated in [GK19, Remark 1.12(i)]. The analytic argument of Lemma 2.16 uses the affected decomposition; this identifies a proof obligation, rather than by itself disproving the analytic conclusion. Also, the slope-only criterion in Example 8.6 needs the edgewise Hessian condition for a piecewise smooth function. The smooth function $-t^2$ on an interval has zero sum of its opposite outgoing first derivatives at each interior point and negative second derivative. The full measure formula in Proposition 16.2.7 retains both the edge density and the vertex masses.

Remark A.1.11 (A substantive correction already acknowledged in GJR). GJR, Remark 16.4, explicitly says that the argument in [GK17, Examples 8.15 and 9.17] used an incorrect smoothness assertion for canonical tropicalizations of abelian varieties. Its construction in §17 shows that these maps need not be original CLD-smooth. The argument that canonical metrics are delta-metrics in that original sense consequently does not follow. This corrects the argument; it does not prove that the metrics fail to be delta-metrics. The distinction is important when using canonical metrics as examples of an enlarged calculus.

Remark A.1.12 (Elementary corrections in GJR v3). In GJR §10.6, pp. 63–64, the commutativity exponent should be $(p+q)(p'+q')$, and the last operator in the d' Leibniz rule should be d'. The printed alternatives fail respectively on two independent $(1,0)$-forms and by bidegree counting. In the proof of Proposition 10.17, the affine Taylor polynomial is $g(\nu) + Dg_\nu(\omega - \nu)$; Proposition 17.2.7 uses this corrected expression. These are local corrections to formulas, not counterexamples to the corresponding theorems.

A.2 Additional source checks and explicit repairs

A.2.1 The regularized maximum in Proposition 16.9.1

Status: local formula error, with a repair. The displayed kernel in CLD25, p. 466, integrates

$$\max_i(s_i + t_i) \prod_{i=1}^{m} \theta(t_i/\varepsilon)\, dt_1 \cdots dt_m$$

with $\int \theta = 1$, but omits the factor ε^{-m}. Its total kernel mass is ε^m. Consequently, adding a constant a to every s_i changes the displayed expression by $a\varepsilon^m$, rather than by a. It cannot have the claimed translation behaviour and approximation bounds in that form.

A corrected regularized maximum is

$$M_\varepsilon(s) = \int_{\mathbb{R}^m} \max_i(s_i + \varepsilon t_i) \prod_{i=1}^{m} \theta(t_i)\, dt, \tag{A.2.1}$$

where θ is a smooth nonnegative even kernel supported in $[-1, 1]$ and of integral one. Convolution makes the expression smooth; convexity and coordinatewise monotonicity are preserved. Jensen's inequality and the zero mean give

$$\max_i s_i \le M_\varepsilon(s) \le \max_i s_i + \varepsilon.$$

If one coordinate lies more than 2ε below the maximum, it never attains the perturbed maximum and the expression is independent of that coordinate. This last property is what permits logarithmic branches vanishing identically at some points to be discarded locally.

A.2.2 The domain and sublevel qualifications in the same proof

Status: local domain and statement qualifications. The proof uses logarithms $\log|f_i/g|$. The condition that the f_i and g have no common zero does not prevent all f_i from vanishing at a point where $g \neq 0$. At such a point every logarithmic branch is $-\infty$, so the real smoothing formula is not directly defined. Add a finite constant branch below the desired sublevel threshold.

The maximum is then finite; branches sufficiently far below it can be discarded. On a neighbourhood where a remaining logarithmic branch is active, its analytic function is nonzero and supplies a legitimate unit coordinate.

The intended barrier conclusion also needs two neighbourhoods: a smooth psh function on a larger domain, negative on a smaller neighbourhood of the point, with a compact nonpositive sublevel contained in the larger domain. The literal wording "negative on U and $\{\rho \leq 0\}$ compact" makes the sublevel equal to all of U. The proof itself chooses a shifted function that is negative near the chosen point, not necessarily everywhere on its domain.

These corrections concern the local construction used to apply the polar-negligibility theorem. They do not constitute a counterexample to the existence of suitable local psh barriers. The normalized smoothing and constant branch supply the appropriate mechanism in the good analytic setting of the lecture.

A.2.3 The hypothesis transfer in Corollary 8.11.3

Status: false in the unrestricted abstract tropical category. Proposition 8.11.1 assumes a skeletal current with the Bedford–Taylor property. Corollary 8.11.2 retains a skeletal current locally expressible as a difference of such currents. Corollary 8.11.3 is then stated for an arbitrary positive closed current T and a convex function pulled back by a harmonic chart. Its proof cites the preceding corollary to identify the BT product with multiplication by a G-form.

The cited statement alone does not supply that identification for arbitrary T. One needs an extension theorem, a decomposition preserving the necessary hypotheses, or an independent positivity argument for the harmonic pullback. The skeletal/BT assumptions cannot simply disappear between the two statements. The cross calculation in Section 14.2 gives a counterexample in an explicitly verified abstract tropical category. It does not claim a counterexample on a smooth Berkovich space.

The ordinary continuous-generated-potential construction in Chapter 13 has an independent proof by positive continuous multiplication and closure under uniform limits. It does not need this unrestricted harmonic-coordinate implication. When a theorem uses the latter implication specifically, its additional justification must be supplied.

A.2.4 Local corrections in the higher-codimension formulas

Status: formula and index corrections. In the setup of §18.7.1, the complete intersection Y has dimension $n - r$, so the dimension bound at its points must be compared with $n - r$, not with the codimension r. In the truncation formula, the correct identity is

$$\log \max(\varepsilon, |f_1|, \dots, |f_r|) = \max(\log \varepsilon, u), \qquad u = \log \max_i |f_i|.$$

Writing $\log \max(\varepsilon, u)$ is not meaningful when u is negative and is not equal to the left side. On a compact support away from Y, u has a finite lower bound; it need not be strictly positive. Proposition 18.7.3 likewise uses relative dimension $n - r$ in its proof, rather than the printed r in its introductory statement.

The Levine calculation also provides a simple independent sign check: on the complement of the cycle, $\mathrm{d}'\mathrm{d}''h = \alpha - \beta$, so $\mathrm{d}'\mathrm{d}''(h\omega) = \alpha^r - \beta^r$. The sign of the singular term is then fixed by Poincaré–Lelong. The final identity is the one stated in Theorem 18.7.5 and displayed in Chapter 22. A contradictory intermediate sign must be corrected locally rather than propagated through the calculation.

Sections 22.4–22.7 give the extension and fibre-comparison arguments with their geometric inputs stated. There is also a separate commutative-algebra issue in the proof of Proposition 18.7.3: a regular sequence alone does not put a neighbourhood of its zero set in Serre's (S_r) locus. Example 22.7.2 disproves that unrestricted inference. The relevant finite-flat argument can instead be made at the Abhyankar points, where dimension and depth coincide. This repairs the needed mechanism in the stated category without asserting that the entire original Green identity is false.

A.2.5 A correction acknowledged in the canonical-measure literature

Status: author-acknowledged gap in an earlier auxiliary claim. In the introduction to *Non-archimedean canonical measures on abelian varieties*, Gubler explicitly withdraws an earlier purity claim for the tropical image in the general abelian setting, after a referee identified a gap. The corrected theorem allows polyhedral pieces of different dimensions and retains the canonical-measure formula. The totally degenerate case has the expected pure dimension in that result.

This correction is useful because it shows exactly what changes. One must not use the earlier purity claim in a dimension argument for mixed reduction. One may still use the corrected measure theorem with its actual dimension range. The correction says nothing by itself about the present-day status of every related purity question.

A.2.6 Closedness in the radial mass formula

In the consulted arXiv:1008.2856v1, Proposition 3.4 of Lagerberg states radial trace-mass monotonicity for a weakly positive current without listing closedness. The Stokes calculation in its proof needs closedness. Example 9.13.3 gives a counterexample to the unrestricted wording: a nonnegative compactly supported smooth scalar on $\mathbb{R}$ has a constant ball mass for large radii, so the mass divided by the radius decreases. The corrected result, including its regularized proof, is Theorem 9.13.2.

Corollary 3.5 of the same source does include closedness and ordinary positivity. These assumptions have separate roles. Closedness supplies the ball-growth estimate; ordinary positivity supplies coefficient domination by the trace. The distinction between weak and ordinary positivity is already explicit in the source's Remark 3.3. The correction here is pinned to the consulted preprint wording, without asserting that every later printed version has the same omission.

A.2.7 Local domains and degrees in the toric paper

Three local repairs concern the consulted arXiv:2102.07392v1. In Example 2.3.5, the expression $T \mapsto (T, T-1)$ is used as a map from $\mathbb{G}_m$ to $\mathbb{G}_m^2$. Its second coordinate is not invertible at $T = 1$, so this map is defined only off that point. The invariant function in the example is nevertheless original smooth: use that chart away from $T = 1$, and use the constant zero expression near $T = 1$, where $|T| = 1$. Section 21.17 gives the local calculation. Thus the example's conclusion survives the domain correction.

In Proposition 4.3.2 and Remark 4.3.4, some displayed factors lack the $d'd''$ operators required by their assigned degrees. The differentiated product and the companion product with one scalar factor must be written separately. Proposition 21.21.1 records both formulas and their target bidegrees. Applying $d'd''$ changes the leading scalar factor into a curvature factor; it is not an operation that leaves the bidegree unchanged.

Finally, positivity of the differentiated product does not imply positivity of the companion product when its undifferentiated scalar can be negative. Taking that scalar to be -1 and the remaining positive product nonzero gives a negative current. The companion product is defined without a sign restriction, but its positivity requires an additional nonnegativity assumption on that scalar. These qualifications leave the correspondence and product constructions available with their correct statements.

A.2.8 Upper semicontinuity in the classical maximum proof

The proof of Gubler–Rabinoff, Theorem 6.4 in arXiv:2506.13548v2, invokes continuity to say that the maximum set of a classically psh function is closed. The definition only provides upper semicontinuity. That is sufficient: if $M = \max_X u$, the set $\{u = M\} = \{u \geq M\}$ is closed for an upper semicontinuous function. The rest of the open-and-closed argument is unchanged. The component reduction in the same proof is a finite cover by irreducible components, whose intersections may be nonempty. The reconstructed proof in Theorem 19.5.2 uses precisely these two elementary formulations.

This is a hypothesis slip in an intermediate sentence, with an immediate repair. It has a different mathematical status from the weak-positive order-zero assertion disproved above. Recording the distinction prevents a local wording problem from being presented as a failure of the classical psh theory.

A.3 A compact register of conclusions and dependencies

Source location	Assessment	Usable replacement or remaining obligation
CLD12 §1.2.6, §3.1.4	Sign error	Use total-degree graded commutativity.
CLD12 Lemma 5.2.3; proof of 5.3.3	False real statement; analytic proof obligation	Use ordinary positive forms for coefficient domination; the Plücker example gives the obstruction.
CLD12 Lemma 5.5.3, continuous form	False literally	Retain corner mass; use the smooth version or an explicit Hessian-plus-corner criterion.

Source location	Assessment	Usable replacement or remaining obligation
CLD12 after Definition 5.5.1	General pullback not justified by the definition	Use smooth or specified approximable potentials, or a separate functorial theorem.
CLD25 Proposition 7.2.9, weak-positive part	False literally	Ordinary positivity gives order zero; weak positivity in middle degree need not.
CLD25 Proposition 8.3.2	False pointwise statement	Use continuous functions or distinguish an L^1 class from its convex representative.
CLD25 Corollary 8.6.7	False literally	Positive continuous scalars preserve positivity, but not closedness or the BT kernel property.
CLD25 Proposition 8.1.11	Successor-step gap	Indexed inclusion and fixed-compact barrier theorem proved; sheaf globalization remains. The neighbouring L^1 equality is valid.
CLD25 Lemma 8.1.4 / Remark 8.1.6	Conflicting wording	Separate eventual set-theoretic stabilization from first-stage stabilization.
CLD25 Proposition 8.4.1	Degree slip	Use bidimension p for the displayed test degree.
CLD25 Corollary 8.11.3	False in the stated abstract generality	The cross example disproves the arbitrary-current assertion; retain the proved skeletal/BT hypotheses.
CLD25 Lemma 9.5.4	False in the stated abstract generality	The cross-times-line example has mass off the graph; the affine case remains valid.
CLD25 Proposition 16.9.1	Kernel normalization and local-domain issues	Use (A.2.1), a constant branch, and nested barrier neighbourhoods.
CLD25 Proposition 17.8.4	Fixed-neighbourhood step missing	GJR Proposition 7.10 gives an independent repair in its specified analytic category.

Source location	Assessment	Usable replacement or remaining obligation
CLD25 Theorem 18.8.4 and Corollary 18.8.8	Local corrections; graded PL bridge supplied	Theorem 19.18.22 replaces the missing strictness transfer; arbitrary continuous weights remain separate.
CLD25 §18.7	Local formula/ index/sign corrections	Use the correct truncation and dimensions; retain the extension theorem and regular-sequence hypotheses.
GK positivity Remark 1.12 / proof of Lemma 2.16	Real error; analytic proof obligation	Ordinary-positive replacement.
GK positivity Example 8.6	Incomplete for piecewise smooth functions	Include edgewise Hessian densities as well as vertex slopes.
GK canonical examples; GJR Remark 16.4	Acknowledged invalid smoothness argument	Canonical tropicalizations can fail original smoothness; original delta-metric membership is a separate question.
GJR §10.6, Proposition 10.17 proof	Local algebra/Taylor slips	Correct total degree, differential operator, and constant term.
Gubler canonical-measure introduction	Acknowledged earlier purity gap	Use the corrected mixed-dimensional theorem.
CLD25 Proposition 18.7.3 proof	Regular-sequence inference insufficient	Example 22.7.2; use the local dimension and Cohen–Macaulay inputs in Section 22.7.
GJR v3 §17.2 and Proposition 17.4 proof	Cycle ordering and slope-list slips	The consistent theta-graph calculation and residual obstruction are in Section 17.8.
Lagerberg v1 Proposition 3.4	Closedness missing from literal statement	The counterexample and corrected radial mass proof are in Section 9.13.

Source location	Assessment	Usable replacement or remaining obligation
BGJK25 v1 Example 2.3.5	Torus-chart domain too large	Exclude $T = 1$ from the unit chart and use a constant expression near it; Section A.2.7.
BGJK25 v1 Proposition 4.3.2 and Remark 4.3.4	Differential degrees and positivity of a scalar factor	Retain DD on the curvature factors; a companion product needs a nonnegative scalar to be positive. See Proposition 21.21.1.
GRPSH v2 Theorem 6.4 proof	Continuity invoked unnecessarily	Upper semicontinuity closes the maximum set; Section A.2.8.

The register is an audit of identified statements in fixed versions, not an assertion that every page of every source has been independently verified. The most consequential repairs have complete elementary evidence in this volume. The missing-step entries identify precise obligations for a proof reconstruction and do not assert the negation of the theorem.

A.3.1 Which arguments remain usable after a correction

The false strong-span lemma affects any proof that bounds all coefficients by a strongly positive control form in middle degree. Replacing that step by ordinary-positive domination repairs the continuous multiplier argument used here. It does not automatically repair every theorem involving a different positive cone.

The scalar-BT counterexample prevents treating the class of BT currents as a module under arbitrary positive continuous functions. It does not obstruct the definition of uT as an order-zero current or the construction of $\mathrm{d}'\mathrm{d}''(uT)$ for an admitted psh potential and a positive closed background.

The successor-stage gap prevents using the claimed equality of all continuous generated stages as a shortcut to smooth approximation. It does not obstruct direct arguments using the continuous generated sheaf, nor the independent PL comparison proved through numerical model approximation and curve tests.

The fixed-neighbourhood gap affects a particular limiting argument. A separate theorem producing approximants on one common neighbourhood

repairs the implication in its own category. This is why GJR's model construction is mathematically useful even if the intended CLD conclusion is correct.

A.4 Current estimates and curvature comparisons

A.4.1 Why "replace smooth by psh" is not a definition

A differential algebra has products, two first-order differentials, pullbacks, and relations between local representatives. A psh function is generally not differentiable in the ordinary sense. Even when its Hessian is a positive current, its first derivatives and products with singular forms require definitions. The class is also not closed under negation, so it cannot simply replace the coefficient ring of a differential algebra.

The BT construction supplies one carefully defined operation: an admitted potential acts on a positive closed current by $\mathrm{d}'\mathrm{d}''(uT)$. It does not immediately supply every product $d'u \wedge \alpha$, every pullback of a current, or an algebra of arbitrary singular forms. Extending GK by psh coefficients therefore requires a choice of domain for all operations and a proof that the relations between representatives are respected.

A.4.2 One coefficient estimate, written out

On a fixed real chart, identify a symmetric test of degree (q, q) with its coefficient matrix $H(x)$ in the chosen sign normalization. For ordinary positivity, choose a positive definite control matrix I on the finite coefficient space and a cutoff equal to one near the support. If $\|H(x)\|_{\mathrm{op}} \leq M$, then

$$MI + H(x) \geq 0, \qquad MI - H(x) \geq 0.$$

Pairing with an ordinary positive current gives a bound on the coefficient functional by its value on the fixed positive control form. Localizing and summing over finitely many charts gives the corresponding bound for the actual test.

The matrix argument uses the ordinary cone, which has full-dimensional interior in the symmetric space. For the strong cone in middle degree, the Plücker functional in the audit vanishes on every generator, so no strong

control form can dominate every symmetric direction. This is the exact point where the superficially similar proof fails.

A.4.3 How to pass from smooth scalars to continuous scalars

Fix a positive test form β. The functional $a \mapsto T(a\beta)$ on smooth compactly supported scalar functions is positive and bounded by a sup norm on each fixed compact support. It therefore extends to a Radon measure. For a general symmetric test, write it as a difference of ordinary positive tests and use the resulting signed measures. Compatibility on overlaps makes uT well-defined for continuous u.

This construction does not identify the current with one global matrix of measures in a fixed tropical coordinate system. It builds compatible scalar measures for actual tests. That distinction is what lets the definition survive chart refinement.

A.4.4 The two-error convergence estimate

Suppose $T_j \rightharpoonup T$ through positive currents and $u_j \to u$ locally uniformly. For a fixed test η, first split

$$u_j T_j - uT = (u_j - u)T_j + u(T_j - T).$$

The first term is small by the uniform scalar bound and local boundedness of the positive masses. For the second, approximate u uniformly by a smooth scalar a. The term $a(T_j - T)$ tends to zero on the fixed test by weak convergence, while the two remaining errors are bounded by $\|u - a\|$ times the same mass control. This proves convergence without requiring derivatives of u_j or a common chart for all their approximants.

A.4.5 Total mixed mass and properness

For smooth semipositive metrics on fixed line bundles over a proper n-fold, the mixed degree formula gives the total mass. For globally uniform limits, weak convergence preserves this mass because the constant test 1 is allowed on the compact space. Local uniform convergence on a noncompact domain only controls compactly supported tests. The sequence δ_j on $\mathbb{R}$ has mass one but converges to zero on those tests.

Thus the global mass formula is a consequence of a global comparison and compactness. It is not evidence for an additional local regularization theorem. This distinction answers the recurring question whether a mass or total-variation lemma is a direct consequence of established results: once the measure construction and degree comparison are available, the elementary estimate often is direct; establishing those inputs is the substantial part.

A.4.6 Restriction to a subspace and ambient extension

If a function belongs to a functorial positive approximation class, restriction to an analytic subspace can be obtained by restricting the approximants, provided the morphism and test theory are in the admitted category. The converse problem is different: a positive function or metric on a subspace need not extend positively to an ambient neighbourhood by ordinary extension of continuous functions.

An ambient extension theorem must control curvature in transverse directions and maintain the line-bundle transition data. If it is obtained from global sections or an FS construction, the generation and positivity hypotheses do the work. A proof that only extends the underlying continuous function has not proved a positive extension theorem. Thus a positive extension theorem requires both an extension of the data and control of its curvature.

A.5 Further version-specific corrections

Remark A.5.1 (CLD25 Corollary 16.8.6). The printed tropical Hausdorff exponent is the number of curvature factors. The bidimension of their product instead gives the complementary exponent. Example 19.17.2 disproves the printed statement on $\mathbf{G}_m^{\mathrm{an}}$ using one Gauss point; Proposition 19.17.1 proves a replacement for admitted differences over a nontrivially valued field. For PL metric weights, Proposition 19.18.8 additionally treats trivial valuation. The full transfinite source potential class is not identified here.

Remark A.5.2 (BMP26 Example 6.23). The negative-axis branch of the printed obstacle is discontinuous at $-\epsilon$. Proposition 16.7.1 supplies a continuous correction, proves its envelope formula and computes all atoms of its measure. The example still disproves unrestricted orthogonality in that polyhedral category.

Remark A.5.3 (Cai and Mihatsch: a convention difference). Cai writes $d' = d'_P + \partial'$, while Mihatsch writes $d' = d'_P - \partial'$. Section 15.9 gives the translation. This is not a false curvature formula in either source. The distinction is recorded separately from mathematical errors.

For the remaining CLD25 residual argument, Section 19.18 separates non-charging and the formal positivity inference from residual realization and the calibrated fibre formula. Theorem 19.18.12 completes this assembly in pure dimension, using explicitly cited lifting, integration and graded-reduction theorems; those inputs are not independently re-proved. Similarly, Lemma 11.6.1 sharpens the diagnosis of Proposition 8.1.11: upper semicontinuity suffices for uniform convergence on compact sets, but does not replace discontinuous predecessors by continuous ones.

Remark A.5.4 (The inherited negligibility exponent). CLD25 Proposition 18.3.7 repeats the exponent of Corollary 16.8.6. The metric form of the Gauss-point counterexample refutes this printed assertion too; see Section 19.18.3. The corrected exponent is $\mathcal{H}^{n-p}$; Proposition 19.18.8 verifies the PL-metric scope over every complete base field.

Remark A.5.5 (Base-point normalization). In CLD25 paragraph 18.8.3, the residual bundles $\widetilde{M}_i$ belong to the base germ (Y, y). Formula (19.18.2) places the coefficient there, with its multiplicity and defect, and retains the tensor factor q^{-d}. This is a correction of the displayed notation using Proposition 18.6.1, not a new fibre-integration theorem.

The prescribed graded comparison is proved in Proposition 19.18.20. Together with graded semiampleness and the fixed-tube criterion, it yields Theorem 19.18.22. This supplies the integral PL bridge while leaving the general continuous predecessor problem unchanged.

For CLD25 Proposition 8.1.11, Theorem 11.6.4 supplies a fixed-compact selection theorem but not the required sheaf globalization. The valid indexed inclusion is Proposition 11.6.6. The neighbouring Proposition 8.1.12 uses inherited local integrability and is proved in Proposition 11.6.7; it does not share the missing continuity step.

A.6 The local envelope comparison in Wu's preprint

Remark A.6.1 (A negative barrier and the background metric). In [Wu26], Proposition 3.28, p. 22, the displayed Fubini–Study maximum includes the branch $\log|s_0|$ with weight zero. Its local weight in the frame s_0 is therefore at least zero, whereas the next step requires $v(x) < 0$ and uses negative sublevel sets. Formula (11.7.4) retains a negative constant branch and is consistent with those sublevels. The proof also changes from the initial background ω to a constructed background θ on the same line bundle. These backgrounds need not be equal. Proposition 11.7.3 records $\theta = \omega + d'd''b$ and the compensating global term b; Lemma 11.7.4 supplies a fixed collar for the decreasing tail. These corrections concern the displayed construction, not a counterexample to the proposition's conclusion.

Remark A.6.2 (Version matching before importing the comparison). Wu's Appendix A cites prepublication Propositions 5.20 and 5.22 of the work called APW26b there. The fixed October version [APW26] used in this book has a Lemma 5.20 instead; localization and local PL approximation are treated in Propositions 5.19 and 5.21. Thus the printed locators cannot simply be copied into a reference to the October version. Appendix A also uses Theorem 6.13 of a second, mixed-calculus preprint. The comparison in Corollary 11.7.6 is attributed to Wu's Theorem A.3; it is not presented as a newly completed proof from those external ingredients. The content-level matching and a uniform bounded-family repair are now given in Section A.7; the mixed-calculus theorem and full common-domain passage remain unverified here.

A.7 APW localization and the common-domain audit

The following table matches the sources by mathematical content. The locators in Wu26 refer to a version preceding the October APW file; they are not the theorem numbers in the latter. No new numbering is assigned to the unavailable mixed-calculus theorem.

Locator in Wu26	Fixed source	Content and status
APW26b, 5.20	APW26 v1, 5.19	Localization. Local part repaired in Proposition 11.8.6; extra majorization on all U is false.
APW26b, 5.22	APW26 v1, 5.21	Local PL approximation. Its proof uses the local identity and global PL density, not the false whole-domain inequality.
APW26a, 6.13	Mixed-calculus preprint	Analytic comparison invoked in Appendix A; primary full text not retrieved in this revision.

Remark A.7.1 (The scope of the counterexample). Example 11.8.5 satisfies the hypotheses of the fixed Proposition 5.19 in every positive dimension and contradicts its added whole-domain inequality. The failure is already visible from boundedness in Definition 4.3. Restricting the maximum construction to an inner compact domain repairs the local conclusion and gives uniform constants for a bounded family. We do not label strong semipositivity or Proposition 5.21 false on this basis. Its global PL density and bounded-growth correspondence remain source inputs.

Remark A.7.2 (What a generator comparison still needs). Wu26 Appendix A proves approximation assertions for individual generators before concluding the two inclusions of first-stage classes. Lemma 11.8.1 supplies the numerical diagonal step once a common domain is known; Proposition 11.8.2 states one sufficient domain hypothesis. Corollary 11.8.3 verifies it for sequences with the displayed finite logarithmic presentations. These are concrete cases, not a proof that arbitrary local presentations can be placed on one prescribed neighbourhood. Likewise, the corrected affine support in Lemma 11.8.4 fixes the centred differential and the tropical point, without establishing the analytic pullback comparison assigned to the other APW preprint. Theorem 11.9.5 now supplies one projective rational PL direction; Theorem 11.12.5 now supplies the relative rational PL identification, while the reverse comparison remains.

A.8 Convexity and model approximation in the local comparison

The comparison in Section 11.9 requires genuine convex PL generators and a nontrivially valued model category. Two source checks prevent those requirements from being lost in the notation.

Example A.8.1 (A missing contact condition)**.** In [Wu26, Definition 3.1(3), p. 14], the function is named f, but the displayed supporting-affine condition uses u and reads

$$u(x) = \ell(x) + C, \qquad u(x') \geq \ell(x') \quad (x' \in V).$$

Even after correcting u to f, unrestricted C makes this condition insufficient to define convexity. On an ordinary real open set every finite continuous function satisfies it locally. For example $f(t) = -|t_1|$ on $\mathbf{R}^n$, $n \geq 1$, satisfies it but is not convex.

Proof. Near any point x, continuity supplies a constant c with $f \geq c$. Take $\ell = c$ and $C = f(x) - c$. These satisfy the displayed condition. For the example, the midpoint inequality along the first coordinate would require $0 = f(0) \leq (f(e_1) + f(-e_1))/2 = -1$, which is false. □

The intended touching-support condition is $f(x) = \ell(x)$ and $f \geq \ell$ near x. Equivalently, retain C in the first equation and put $f(x') \geq \ell(x') + C$ in the second. The source's supporting-function argument in Appendix A uses equality at the point, consistent with this repair. We treat the displayed definition as a typographical defect. It neither refutes the intended convex theory nor supplies the missing smooth-to-PL comparison. Whenever this book uses convex PL generators, it uses the actual convexity condition, and Section 11.9.1 gives an explicit local maximum presentation.

Remark A.8.2 (Separating current positivity from common-domain regularization). The proof of [Wu26, Theorem 3.23] passes from its local PL approximation class to CLD current positivity and then to model nefness. For a finite continuous endpoint, Lemma 11.9.1 justifies the first passage directly by uniform convergence on each compact test support. It does not require Theorem A.3 or a resolution of the general predecessor-replacement issue in CLD25 Proposition 8.1.11. For the extensions in Proposition 11.9.3 even this endpoint step is unnecessary: their local weights already have convex

finite-max presentations. The remaining model nefness theorem is an explicit geometric input.

The following table records the source boundaries of the new assembly. In particular, the trivial-valuation statements of Wu are not obtained by applying a theorem whose hypothesis says nontrivially valued.

Input	Verified use	Restriction retained
[GM, Theorem 1.1]	PL/formal/model identification	Proper algebraic analytification, nontrivial valuation; rational version by a tensor power
[CLD25, Corollary 18.8.8]	Positive model curvature gives model nefness	Original current tests and the cited residual geometry
[BE21, Theorem 7.8]	Uniform pure FS approximation of a nef model metric	Ample line bundle, nontrivially valued field
Theorem 20.8.1	Original smooth approximation on the same line bundle	Exact deletion at zeros and transition compatibility
Theorem 11.9.5	One ordinary neighbourhood for a decreasing sequence	Explicit $\mathcal{G}$ generators; one inclusion only

For the generator class, Section 11.10 expands Wu's Remark 3.2 and the Lipschitz step of Remark 3.9. The relative-image definitions 3.6–3.7 are kept separate; Example 11.10.9 explains the failure of a same-chart extension shortcut. For the numerical step, Proposition 11.10.7 uses [GK19, Theorem 0.1] over an algebraically closed field and then the model descent results of [GM, Lemmas 3.3, 3.7 and Proposition 3.5]. The GM locators have been checked in the published 2019 text: an earlier author-hosted PDF carries the v2 arXiv stamp and must not be described as the v3 file.

Theorem 11.10.11 gives an alternative model-theoretic route. Its additional inputs are [GJR, Proposition 7.1 and Definition 7.2], [GRPL, Corollary 5.5], and the local-to-global semipositivity in [GM, Theorem 1.1 and Proposition 3.11]. The maximum result is used for rational PL functions on good strictly analytic spaces. It is not a theorem about arbitrary real-coefficient presentations or positive currents.

Section 11.11 gives a direct curvewise route from the corrected relative support condition to classical psh, and supplies the model-compatible PL identification on unit charts. Its source comparison fixes a locator mismatch: the companion-paper references Proposition 3.1 and Corollary 3.5 in the proof of GRPSH Theorem 4.3 (v2) correspond to Proposition 5.1 and Corollary 5.4 in the consulted GRPL v1. This is a reference-version issue, not a counterexample to either result. Section 11.12 subsequently establishes the extended-image PL identification under its common-branch and coefficient hypotheses, using Martin's finite polyhedral image theorem.

Two further APW proof details are repaired in Section 11.11.5. Proposition 11.11.10 restores the interior lower-support hypothesis omitted from the auxiliary claim in APW Proposition 3.3. Lemma 11.11.11 replaces the erroneous zero set $\{f - \ell_f \leq 0\}$ in the proof of APW Proposition 5.10 by $\{g-\ell_g \leq 0\}$; equation (11.11.4) gives the required modification bound. These repairs retain the intended local conclusions. Separately, Remark 11.11.12 explains why APW Proposition 5.21, stated for its real PL class, is not by itself a value-group-compatible Q-PL approximation theorem. Proposition 11.11.13 supplies a replacement for finite ambient convex maxima on bounded unit charts.

For coefficient-dependent closure statements, Proposition 11.12.11 reconciles GJR v3 Remark 7.11 with its own Example 5.3 and with GRPL v1 Corollary 5.5 and Theorem 5.6. Maximum and limit statements must retain PL membership; integral and Q-PL maxima satisfy that requirement automatically. This is a correction to the overbroad R-PL maximum wording, not a failure of classical psh maximum stability.

The additional model audit in Section 11.14 checks the published GM Lemma 4.12 on p. 353 and the cofinal blowup construction on p. 337. The counterexample concerns the fixed source model; Proposition 11.14.4 recovers the formal-model domination needed by BE21 Theorem 7.8. Corollary 11.14.5 supplies finite simultaneous polarizations; Proposition 11.14.8 supplies the exact Picard relation and bounded correction, with formal-domination scope. Section 11.13 instead uses GJR Corollary 5.9, Lemmas 6.11 and 6.14, and Proposition 7.10; its original-psh comparison additionally uses GRPSH Theorem 4.3.

Model morphisms and reduced fibres. The source chain in Section 11.15 is FK arXiv v5, 0.9.2.7 and 0.8.5.25(2), then I.10.3.1 for algebraic

morphisms; BE21 Theorem 4.20 for reduced fibres over algebraically closed fields; and the published BGM22 Lemma 1.1, p. 6223. BE21 Lemmas 6.1–6.3 and Theorem 6.4 distinguish exact norm equalities from bounded errors. None of these inputs uses a general positive-current BT theorem.

A separate convention audit is now given in Section 11.21.4. The last finite-selection step of APW Proposition 5.12 preserves ordinary real-polyhedral PL functions, but rational face directions and a rational simplicial presentation require additional control. Examples 11.21.9 and 11.21.11 separate these requirements. They identify a gap in applying that proof under the literal source conventions; they do not disprove the existence conclusion of Proposition 5.21. The germ and transport results in Section 11.21 provide specified forward interfaces, not an unconditional replacement for the source regularization theorem.

Subject index

Page numbers lead to the indicated definition, result or discussion. Technical terms are retained in English in both editions.

A

Abhyankar equality, 450, 451.
Accessible skeleta, 1056.
Actual Green tests, 1600, 1601.
Actual-test scalar multiplication, 1110, 1141.
Adelic height variation, 1587, 1604.
Admissible blow-up, 448, 458.
Admissible graph measure, 1524, 1526.
Aeppli cohomology, 1635, 1647.
Affine functions, distributional kernel, 1181.
Affine potential cocycle, 1364.
Affinoid algebra, 6.
Affinoid compactness, 8.
Affinoid presentation gluing, 1322.
Affinoid rational replacement, 1323.
Affinoid tropical purity, 1053.
Alexandrov measure, 1539, 1575.
Algebraic domination of models, 1255.
Ample extension, fixed-model obstruction, 1248, 1249.
Ample model, cofinal construction, 1251.
Analytic boundary, 1167, 1450.
Analytic domains, 73, 75.
Analytic fibres, 79, 80.
Analytic flatness, 82.
Analytic realization of a fan, 1261.
Analytification and GAGA, 84, 85.
Annular deformation retraction, 579.
Annulus, Gauss point, 1037, 451.
Annulus, slope formula, 1163, 1616.
Approximation classes, 1173, 1343.
Arithmetic boundary completion, 1617.
Automorphy cocycle, 1567.

B

Balancing and closedness, 1371, 1372.
Balancing, geometric theorem, 786.
Banach algebra, 3.
Barrier, projective Fubini–Study, 1203, 1204.
Base change, scalar extension, 1610.
Bedford–Taylor operation, 1333, 1343.
Bergman fan, 1055.
Berkovich point, 7, 8.
Binomial initial degeneration, 799.
Blowup and model measures, 1455.
Bochner–Martinelli form, 1591, 1594.

Bogomolov, tropical difference map, 1552, 1553.
Bott–Chern cohomology, 1647.
Boundary supports, uniform-limit failure, 1312.
Boundary factorization for relative finite selections, 1229.
Boundary mass, toric, 1556, 1561.
Boundary, relative interior, 80, 446.
Boundary-operator convention, 1379.
Bounded decreasing stability, 1196.
Bounded extension, fixed background, 1194, 1195.

C

Compact decreasing hierarchy, 1326.
Calibrated degree, 797, 1611.
Canonical height, 1546.
Canonical measure, mixed dimensions, 1547, 1550.
Canonical metric, contraction, 1543, 1545.
Canonical reduction, 442, 448.
Capacity, continuous admitted class, 1353.
Cellwise-convex approximation, 1289.
Chern action, gluing, 1349.
Chern mass, 1515, 1516.
Chow ring of a smooth fan, 1373, 1374.
Classical psh, 1441, 1450.
CLD12 and CLD25 comparison, 1425, 1427.
Closed currents, zero extension, 1147, 1563.
Coefficient detection, polyhedral, 1368.
Coefficient measures, 1129, 1130.
Cohomology, flat torus, 1646, 1647.
Cohomology, graph, 1414, 1417.
Collar gluing, 1329.
Common domain, diagonal approximation, 1198, 1199.
Compact support, radial homotopy, 1641.
Compact upper barrier, 1186, 1187.
Comparison principle, admitted metrics, 1352.
Compatible finite selections, 1304.
Complete intersection, length, 1597, 1599.
Completed residue field, 8, 450.
Completed tensor product, 78, 79.
Continuous multipliers, 1132, 1110.
Continuous obstacles, 1192.
Continuous stages, conditional collapse, 1196.
Controlled-slope extension, 1291.
Convex boundary extension, 1288.
Convex extension, fixed-chart obstruction, 1262, 1261.
Convex extension, positive tangential Hessian, 1266.
Convex representative, 1179, 1180.
Convexity, touching support, 1682.
Corner divisor, 791, 1164.
Cross, failure of Poincaré duality, 1642.
Cross, harmonic-kernel obstruction, 1357, 1362.
Current gluing, 1146.
Current restriction and extension, 1433.
Current topology, 1127, 1140.
Curve detection, 1439, 1456.

Cycle class, de Rham vanishing, 1653.

D

Decreasing row diagonal, 1325.
Delta-form quotient, 1383, 1391.
Delta-form, six operators, 1395.
Descent, representatives, 1612.
Difference maps, 1553, 1554.
Dirichlet energy, graph, 1521, 1614.
Discrete Monge–Ampère equation, 1575.
Distributional Hessian, 1183.
Duality and filtered limits, 1637.

E

Exact norm fractions, 1321.
Energy, concavity, 1520.
Energy, metric, 1519.
Energy topology, strong, 1497.
Envelope, local–global comparison, 1193, 1197.
Envelope, orthogonality, 1465, 1466.
Equidistribution, variational proof, 1551, 1552.

Recovered native algebraization source

B.1 Polarization and algebraization of a supplied formal curve

Let K be a complete nontrivially valued field with a real-valued rank-one valuation v. Put $O = K^\circ$, $\mathfrak{m} = K^{\circ\circ}$, and $k = O/\mathfrak{m}$, and fix $0 \neq \pi \in \mathfrak{m}$. The value group need not be discrete. All schemes and invertible sheaves below are ordinary algebraic schemes and sheaves until a formal completion is explicitly taken.

A proper flat finitely presented curve tower over O/π^n admits a compatible polarization, even when only its residue curve is initially polarized. The reason is topological: the residue curve and all levels of the tower have the same Noetherian underlying space of dimension at most one. We first record the precise lifting statement that uses this fact. The algebraization step will then be an application of the non-Noetherian theorem Stacks Tag 0D4T.

B.1.1 Lifting across a nil thickening

Lemma B.1.1 (Picard lifting in topological dimension at most one)**.** *Let $i : Z \hookrightarrow Y$ be a closed immersion of schemes inducing a homeomorphism of*

underlying spaces. Suppose that this common space is Noetherian and has dimension at most one. Then

$$i^* : \mathrm{Pic}(Y) \longrightarrow \mathrm{Pic}(Z)$$

is surjective. If $\mathcal{L}_Z$ is ample, every invertible sheaf on Y whose restriction is isomorphic to $\mathcal{L}_Z$ is ample. No finite-generation or nilpotence bound on the ideal of Z is required.

Proof. Identify the two underlying spaces, and put $\mathcal{J} = \ker(\mathcal{O}_Y \to i_*\mathcal{O}_Z)$. On an affine open of Y, every prime contains the ideal defining Z, so that ideal is nil. In particular its stalk ideals are nil. An element of a ring whose image is a unit modulo a nil ideal is a unit: a lift of its inverse has product $1+j$ with j nilpotent, and $1+j$ has a finite geometric-series inverse. Applied to stalks, this gives an exact sequence of abelian sheaves on the common space,

$$1 \longrightarrow 1 + \mathcal{J} \longrightarrow \mathcal{O}_Y^\times \longrightarrow i_*\mathcal{O}_Z^\times \longrightarrow 1.$$

Here $1 + \mathcal{J}$ has its multiplicative group law. There is no identification with the additive sheaf $\mathcal{J}$ in this argument.

Grothendieck vanishing for a Noetherian topological space of dimension at most one, Stacks Tag 02UZ, applies to every abelian sheaf. Hence $H^2(Y, 1 + \mathcal{J}) = 0$. The long exact cohomology sequence of Stacks Tag 01DZ and the identification of the Picard group with $H^1(\mathcal{O}^\times)$, Stacks Tag 09NU, show that i^* is surjective. Finally, Stacks Tag 09MW identifies ampleness of an invertible sheaf with ampleness of its restriction along any closed immersion inducing a homeomorphism. This proves the last assertion without requiring a nilpotence bound on $\mathcal{J}$. □

B.1.2 A compatible ample bundle on the tower

Proposition B.1.2 (Polarization of a supplied curve tower)**.** *For $n \geq 1$, put $R_n = O/\pi^n O$ and $S_n = \operatorname{Spec} R_n$. Suppose given schemes $X_n \to S_n$, proper, flat, and of finite presentation, together with transition morphisms $i_n : X_n \hookrightarrow X_{n+1}$ for which the squares over $S_n \hookrightarrow S_{n+1}$ are cartesian. Suppose that*

$$C = X_1 \times_{R_1} k$$

has dimension at most one. Then C has an ample invertible sheaf. For any prescribed ample invertible sheaf $\mathcal{L}_C$ on C, there exist ample invertible sheaves $\mathcal{L}_n$ on X_n, an isomorphism $\mathcal{L}_1|_C \simeq \mathcal{L}_C$, and isomorphisms

$$\varphi_n : i_n^* \mathcal{L}_{n+1} \xrightarrow{\sim} \mathcal{L}_n \qquad (n \geq 1).$$

Proof. The scheme C is proper and of finite type over k, hence is separated and has a Noetherian underlying space. A separated finite-type scheme over a field of dimension at most one has an ample invertible sheaf, by Stacks Tag 0A25 and its proof.

For $a \in \mathfrak{m}$, the rank-one valuation gives an integer $N \geq 1$ with $Nv(a) \geq v(\pi)$, unless $a = 0$, when no choice is needed. Thus $a^N \in \pi O$, and $\mathfrak{m}/\pi O$ is a nil ideal of R_1. Its extension to any R_1-algebra is still nil: each element is a finite sum of multiples of nilpotent elements in a commutative ring. Consequently the closed immersion $C \hookrightarrow X_1$ induces a homeomorphism. This is the same radical comparison used in the established formal-fibre argument 3.17.2; it does not assert that the rings $\mathcal{O}_{X_1}$ are Noetherian.

The underlying space of X_1 is therefore Noetherian of dimension at most one. Lemma B.1.1 lifts the prescribed $\mathcal{L}_C$ to an ample invertible sheaf $\mathcal{L}_1$. For each $n \geq 1$, the kernel of $R_{n+1} \to R_n$ is square-zero, since $2n \geq n + 1$. The cartesian square shows that i_n is a square-zero closed immersion and a homeomorphism. All X_n thus have the same underlying space as C.

Inductively apply Lemma B.1.1 to i_n, choosing $\mathcal{L}_{n+1}$ and an isomorphism φ_n as stated. The lemma also gives ampleness at each step. Composites of the chosen φ_n supply the compatibilities between any two levels of the tower. The construction proves existence and makes no assertion of uniqueness of these choices. □

B.1.3 Algebraization and the nodal conclusion

Theorem B.1.3 (Algebraization over the complete rank-one valuation ring)**.** *Under the hypotheses of Proposition B.1.2, there exist a projective, flat, finitely presented O-scheme Y, an ample invertible sheaf $\mathcal{L}$ on Y, and compatible isomorphisms*

$$Y \times_O R_n \simeq X_n, \qquad \mathcal{L}|_{X_n} \simeq \mathcal{L}_n \quad (n \geq 1),$$

where $(\mathcal{L}_n, \varphi_n)$ can be any compatible system provided by that proposition. In particular $\mathcal{L}|_C$ is the prescribed $\mathcal{L}_C$.

If C/k is at-worst-nodal of pure dimension one, then Y/O is at-worst-nodal of relative dimension one. No splitting condition on its nodes or branches is imposed.

If the tower is the system of quotients of a supplied π-adic formal O-scheme $\mathfrak{X}$, and $\mathfrak{X}$ is recovered from these quotients with their transition maps, then the compatible isomorphisms give

$$\widehat{Y}_{\pi} \simeq \mathfrak{X}.$$

This formal scheme is admissible, and its generic fibre satisfies $\mathfrak{X}_{\eta} \simeq (Y_K)^{\mathrm{an}}$.

Proof. We first check the base ring in the algebraization theorem. Since $v(\pi) > 0$, the sequence $nv(\pi)$ tends to infinity. The ideals $\pi^n O$ therefore define the valuation topology on O. The ring O is closed in the complete field K, so it is complete for this topology. More explicitly, representatives of a compatible system of classes modulo π^n form a Cauchy sequence in O. Its limit has the prescribed residues, since every $\pi^n O$ is closed. Also $\bigcap_n \pi^n O = 0$. Hence

$$O \simeq \varprojlim_{n} R_n.$$

Each transition $R_{n+1} \to R_n$ is surjective with square-zero kernel. The cartesian tower, its proper flat finitely presented structure morphisms, and the compatible invertible sheaves with $\mathcal{L}_1$ ample now satisfy every hypothesis of Stacks Tag 0D4T. That theorem supplies Y, $\mathcal{L}$, and all the displayed compatible isomorphisms, with Y/O proper, flat, and finitely presented and $\mathcal{L}$ ample on Y. The affine base $\operatorname{Spec} O$ has an ample invertible sheaf. Therefore properness together with the ample sheaf $\mathcal{L}$ implies projectivity by Stacks Tag 0B45, the equivalence of conditions (5) and (1).

Suppose next that C/k is at-worst-nodal of pure dimension one. For the flat finitely presented morphism $Y \to \operatorname{Spec} O$, Stacks Tag 0DSC gives a maximal open $U \subseteq Y$ on which it is at-worst-nodal of relative dimension one; this open commutes with arbitrary base change. Since $Y_k \simeq C$, it follows that $Y_k \subseteq U$. If the closed complement $Y \setminus U$ were nonempty, its image in $\operatorname{Spec} O$ would be nonempty and closed, by properness. Every nonempty closed subset of the spectrum of a local ring contains its closed point. This would force $Y \setminus U$ to meet Y_k, a contradiction. Thus $U = Y$.

Finally, the compatible isomorphisms at every level identify both the common underlying spaces and their inverse systems of structure sheaves. Taking the inverse limit gives the stated isomorphism of π-adic formal schemes. The

established projective-completion result 4.13.2 applies to the projective, flat, finitely presented scheme Y. It says that $\widehat{Y}_\pi$ is admissible and that its generic fibre is $(Y_K)^{\mathrm{an}}$. Transporting this identification through the formal isomorphism, using the functoriality in 3.17.2, gives the assertion for $\mathfrak{X}$. □

B.1.4 The formal interface and the nondiscrete boundary

The input is the supplied cartesian tower, including properness, flatness, and finite presentation at every level. For a formal model, these hypotheses must be checked for its actual quotients by π^n. For example, on a flat formal affine chart with a finite restricted-power-series presentation

$$B = O\langle T_1, \dots, T_r\rangle/(f_1, \dots, f_s),$$

reduction modulo π^n has the finite presentation $R_n[T_1, \dots, T_r]/(\bar{f}_1, \dots, \bar{f}_s)$; restricted series become polynomials at this level. Flatness descends by base change. Properness of the reductions is the separate global input. Reconstruction from the quotient sheaves is the stated completeness condition on the formal model.

The distinction between k and $O/\pi O$ cannot be dropped. If the value group is nondiscrete, then $\mathfrak{m}^2 = \mathfrak{m}$: for $a \in \mathfrak{m} \setminus \{0\}$ choose $b \in K$ with $0 < v(b) < v(a)$ and write $a = b(a/b)$. Both factors lie in $\mathfrak{m}$. It follows that

$$\varprojlim_n O/\mathfrak{m}^n = k,$$

which does not recover O. Moreover $\mathfrak{m}/\pi O$ is nonzero, nil, and idempotent, hence is not nilpotent. Its nonzero elements exist because one can choose a positive value less than $v(\pi)$. Lemma B.1.1 handles this first thickening without replacing it by finitely many square-zero steps.

The theorem algebraizes the specified tower and preserves its residue nodes. It does not construct a tower from an arbitrary analytic curve, choose a polarization canonically, or algebraize a supplied formal group action. Those are separate assertions.

Appendix C

Native scalar extension and finite restriction of constants

The ordinary integral formulas in this chapter give the two calibrations used in the finite-place calculation following Proposition 23.7.1.

C.1 Scalar extension and restriction of constants for ordinary integration

Throughout, K is complete for its specified real-valued non-Archimedean absolute value, and L/K is a complete isometric extension. Trivial valuation and arbitrary positive affinoid radii are allowed. Write $p : X_L \to X$ for actual completed scalar extension. All moment coordinates are $-\log|f_i|$ with the given absolute value.

The notation $\mathcal{A}^{a,b}_{X/K}$ means the ordinary smooth moment sheaf of v0.37 [5.52.3, 5.52.4]: a germ has one smooth ambient superform on an ordinary affinoid neighbourhood, modulo tangential equality on every face of the actual joint moment image. Its compactly supported top integral $\int_{X/K,\mathcal{F}}$ is the coherent-module functional of that source. The coefficient $\mathcal{F}$ weights the integration cycle; the differential form itself has real scalar coefficients. Purity means purity of analytic dimension on ordinary affinoid neighbourhoods, as in [5.50.1, 5.50.3, 5.50.4, 5.50.6].

Theorem C.1.1 (Native scalar-extension invariance)**.** *Let X be a good Hausdorff K-analytic space pure of analytic dimension d, and let $\mathcal{F}$ be coherent on X_G. Then X_L is good, Hausdorff and pure of analytic dimension d. Coherent pullback $\mathcal{F}_L = p^*\mathcal{F}$ and ordinary moment pullback are defined on actual completed scalar extensions, and for every $\alpha \in \mathcal{A}^{d,d}_{X/K,c}(X)$,*

$$\int_{X_L/L,\mathcal{F}_L} p^*\alpha = \int_{X/K,\mathcal{F}} \alpha. \tag{C.1.1}$$

The pullback has compact support. These assertions respect complete extension towers, coherent short exact sequences, and ordinary open restriction containing the support.

The proof is in Section C.1.3. It uses the frozen moment sheaf and integral, and does not require a comparison with another form sheaf. For finite L/K, the distinct formula

$$\int_{(X_L)_{[K]}/K,\mathcal{F}_L} p^*\alpha = [L:K] \int_{X/K,\mathcal{F}} \alpha \tag{C.1.2}$$

is proved in Section C.1.4. Here $Y_{[K]}$ denotes the same analytic space after restriction of constants; this notation is used only for finite L/K.

C.1.1 Generic lengths and componentwise purity

Lemma C.1.2 (The generic coefficient under scalar extension)**.** *Let A be a generalized K-affinoid algebra, $B = A_L$, and M a finite A-module. Then $M_L = B \otimes_A M = M\widehat{\otimes}_K L$, with equivalent canonical complete norms, and $A \to B$ is faithfully flat. If $\mathfrak{q} \in \mathrm{Min}(B)$ and $\mathfrak{p} = \mathfrak{q} \cap A$, then $\mathfrak{p} \in \mathrm{Min}(A)$ and*

$$\mathrm{length}_{B_\mathfrak{q}}(M_L)_\mathfrak{q} = \mathrm{length}_{A_\mathfrak{p}} M_\mathfrak{p}\ \mathrm{length}_{B_\mathfrak{q}}(B_\mathfrak{q}/\mathfrak{p}B_\mathfrak{q}). \tag{C.1.3}$$

In particular the generic coefficient can acquire a nontrivial length even when the original component is reduced.

Proof. The completed-module identification and faithful flatness are the exact assertions of [2.33.5, 2.33.6]; its proof uses closed finite presentations and strict exactness, not a formal replacement of completed tensors by algebraic tensors. Flat going down [StacksAlg, Tag 00HS, Lemma 10.39.19] implies that a prime strictly below $\mathfrak{p}$ would lift to a prime strictly below $\mathfrak{q}$. Thus $\mathfrak{p}$ is minimal.

The two local rings are Noetherian of dimension zero, hence Artinian [StacksAlg, Tag 00KH, Lemma 10.60.5]; their finite modules have finite length [StacksAlg, Tag 00JB, Lemma 10.53.6]. The localized homomorphism $A_{\mathfrak{p}} \to B_{\mathfrak{q}}$ is flat. A composition series of $M_{\mathfrak{p}}$ has every simple quotient equal to $\kappa(\mathfrak{p})$. Tensoring this series with $B_{\mathfrak{q}}$ is exact, and every successive quotient is $B_{\mathfrak{q}}/\mathfrak{p}B_{\mathfrak{q}}$. Additivity of length gives (C.1.3). The quotient is nonzero because the map is local. □

For later use, if $R \to S$ is a flat map of Noetherian rings and $\mathfrak{p} \in \operatorname{Min}(R)$, every prime minimal over $\mathfrak{p}S$ is minimal in S. Indeed, flat going down for $R/\mathfrak{p} \to S/\mathfrak{p}S$ makes its contraction $\mathfrak{p}$. Choose a minimal prime $\mathfrak{q}_0$ of S below it, using [StacksAlg, Tag 00E0, Lemma 10.17.2, part (4)]. Its contraction is contained in the minimal prime $\mathfrak{p}$, so equals $\mathfrak{p}$; minimality over $\mathfrak{p}S$ forces equality with $\mathfrak{q}_0$.

Lemma C.1.3 (Purity after an arbitrary complete extension)**.** *If $\mathcal{M}_K(A)$ is nonempty and pure of analytic dimension d, then $\mathcal{M}_L(A_L)$ is nonempty and pure of analytic dimension d.*

Proof. **Strict integral algebras.** Suppose first that A is strict and integral. Finite normalization [1.12.2] gives a bounded finite injection $R = K\langle T_1, \dots, T_d\rangle \hookrightarrow A$. Its finite-module norm is equivalent to the given affinoid norm, by the norm argument in [3.21.1, 3.21.6]: for nontrivial valuation use the bounded lifting theorem on a finite-generator surjection, while for trivial valuation both strict quotient norms take only the values zero and one.

Put $F = \operatorname{Frac}(R)$. The torsion-free finite R-module A embeds into R^m: embed it into the finite-dimensional vector space $A \otimes_R F$, choose a basis, and clear the finitely many denominators of the coordinates of a finite generating list. By the finite-module theorem [1.18.3], this embedding is norm-strict onto a closed submodule. Strict exactness of completed scalar tensors [2.33.3] preserves its injectivity. The module comparisons in [2.33.5, 2.33.6] therefore give an injection

$$A_L \hookrightarrow R_L^m.$$

Consequently A_L is torsion free over the domain $R_L = L\langle T_1, \dots, T_d\rangle$ and is finite over it.

Let $\mathfrak{q}$ be a minimal prime of A_L. No nonzero element of R_L can lie in $\mathfrak{q}$. To check this without a reducedness assumption, localize at $\mathfrak{q}$. This is an

Artinian local ring; an element of its maximal ideal is nilpotent. If a nonzero $r \in R_L$ lay in $\mathfrak{q}$, some power of r would annihilate a nonzero element after localization. Clearing its denominator would give a nonzero element of A_L killed by that power of r, contradicting torsion freeness. Thus

$$R_L \hookrightarrow A_L/\mathfrak{q}$$

is a finite injection. The dimension theorem for strict normalization [3.21.1, 3.21.6] makes every such quotient have dimension d.

Strict pure algebras. Now let A be strict and pure, allowing nilpotents. For $\mathfrak{q} \in \operatorname{Min}(A_L)$, Lemma C.1.2 makes $\mathfrak{p} = \mathfrak{q} \cap A$ minimal. The actual quotient identity

$$A_L/\mathfrak{p}A_L = (A/\mathfrak{p})_L$$

is part of faithful scalar extension [2.33.5, 2.33.6]. The prime $\mathfrak{q}/\mathfrak{p}A_L$ is minimal there. The strict integral case, applied to $A/\mathfrak{p}$, gives dimension d for $A_L/\mathfrak{q}$.

Arbitrary radii. Choose a finite free-radius strictification K_s/K by [1.17.6]. The exact component theorem [5.35.1] makes A_{K_s} pure of dimension d. Choose a common complete extension E of K_s and L by [3.21.7]. The strict case shows that $A_E = (A_{K_s})_E$ is pure of dimension d.

Set $B = A_L$ and fix $\mathfrak{q} \in \operatorname{Min}(B)$. Faithful flatness makes $(B/\mathfrak{q})_E$ nonzero. The observation preceding this lemma shows that its minimal components are minimal components of $B_E = A_E$, so all have dimension d. The analytic dimension of a nonempty affinoid is the maximum of the dimensions of its minimal components: each analytic point kernel contains a minimal prime, passing to that quotient preserves its completed residue field, and [3.22.7] identifies dimension with the maximum of residual dimensions at points. Hence $\dim_E \mathcal{M}((B/\mathfrak{q})_E) = d$. Scalar invariance of analytic dimension [3.21.8] now gives $\dim_L \mathcal{M}(B/\mathfrak{q}) = d$. This holds for every minimal prime of B. Nonvanishing follows from faithful flatness. □

Proposition C.1.4 (Finite generic pushforward coefficients)**.** *Suppose $n = [L : K] < \infty$ and $B = A_L$. For $\mathfrak{p} \in \operatorname{Min}(A)$ one has*

$$\sum_{\substack{\mathfrak{q} \in \operatorname{Min}(B) \\ \mathfrak{q} \cap A = \mathfrak{p}}} \operatorname{length}_{B_{\mathfrak{q}}}(M_L)_{\mathfrak{q}} [\kappa(\mathfrak{q}) : \kappa(\mathfrak{p})] = n \operatorname{length}_{A_{\mathfrak{p}}} M_{\mathfrak{p}}. \tag{C.1.4}$$

Thus the algebraic generic cycle pushforward of the pullback coefficient is $n[M]$, with the indicated full residue-field degrees.

Proof. Finite-dimensional norm equivalence [1.12.1] gives bounded coordinate maps for a K-basis $e_1, \dots, e_n$ of L. Tensoring these maps with the identity of any Banach K-space identifies its completed tensor with L with its n-fold direct sum. In particular

$$A_L = A \otimes_K L = \bigoplus_{i=1}^{n} A e_i.$$

The finite-dimensional $\kappa(\mathfrak{p})$-algebra $C = B \otimes_A \kappa(\mathfrak{p})$ has dimension n. Its local factors are $B_{\mathfrak{q}}/\mathfrak{p}B_{\mathfrak{q}}$ for the primes in the displayed sum. Indeed they lie over the minimal prime $\mathfrak{p}$ in a finite flat map; a prime over it is minimal, since $A_{\mathfrak{p}}$ is Artinian and its finite algebra $B_{\mathfrak{p}}$ has finite length as an $A_{\mathfrak{p}}$-module, so is Artinian as a ring. A composition series of each factor gives

$$n = \sum_{\mathfrak{q}\mid\mathfrak{p}} \operatorname{length}_{B_{\mathfrak{q}}}(B_{\mathfrak{q}}/\mathfrak{p}B_{\mathfrak{q}})[\kappa(\mathfrak{q}) : \kappa(\mathfrak{p})].$$

Multiply by $\operatorname{length}_{A_{\mathfrak{p}}} M_{\mathfrak{p}}$ and apply Lemma C.1.2. □

C.1.2 The entire Gauss module

For a positive real polyradius r, let

$$R_{K,r} = K\{r^{-1}T, rU\}/(T_iU_i - 1), \qquad H_{K,r} = \widehat{\operatorname{Frac}(R_{K,r})}$$

for the multiplicative Laurent Gauss norm. Empty tuples give $R = H = K$. These are the actual algebras and fields of [5.36.2, 5.37.1].

Lemma C.1.5 (Module base change at a complete Gauss field)**.** *Let D be a finite canonical $R_{K,r}$-algebra and P a finite D-module, with its canonical norm. Then $D_L = D\widehat{\otimes}_K L = D \otimes_{R_{K,r}} R_{L,r}$ and $P_L = P\widehat{\otimes}_K L = P \otimes_{R_{K,r}} R_{L,r}$, with bounded inverse comparisons. There is a canonical isomorphism*

$$P_L \otimes_{R_{L,r}} H_{L,r} \simeq (P \otimes_{R_{K,r}} H_{K,r}) \otimes_{H_{K,r}} H_{L,r}. \tag{C.1.5}$$

The native vector-space dimension is unchanged. If $E = D \otimes_{R_{K,r}} H_{K,r} = \prod_j E_j$ and $Q = P \otimes_{R_{K,r}} H_{K,r}$, then

$$\dim_{H_{K,r}} Q = \sum_j \operatorname{length}_{E_j} Q_j \, [E_j/\mathfrak{m}_j : H_{K,r}]. \tag{C.1.6}$$

The corresponding formula after extension has the same total.

Proof. Composing finite free quotient presentations makes P a finite canonical $R_{K,r}$-module; the quotient norm is the given canonical D-module norm up to uniform equivalence. The actual scalar pushouts and finite tensor comparison [2.33.18, 2.33.19, 1.18.7] give the two identifications with $R_{L,r}$. Equivalently one may apply the algebra statement [5.36.2, 5.37.1] to the square-zero finite algebra $D \oplus P$ and take its P summand. The coefficient embedding $H_{K,r} \hookrightarrow H_{L,r}$ is isometric by [5.36.2, 5.37.1]. Associativity of these finite tensors gives (C.1.5). A basis of a finite-dimensional vector space remains a basis after field extension, so the dimensions agree. The finite algebra E is the product of its Artinian local factors [StacksAlg, Tag 00JB, Lemma 10.53.6]; the simple factors of Q_j are its full residue field. Taking dimensions proves (C.1.6). No separable degree or reduced quotient enters this computation. □

Proposition C.1.6 (Native global chains under complete extension)**.** *Let $X = \mathcal{M}_K(A)$ be pure of analytic dimension d, M a finite A-module, and f any finite tuple of analytic units. Then, in the same real moment space and saturated integral lattices,*

$$\mathcal{T}^{L}_{p^*f}(M_L) = \mathcal{T}^{K}_{f}(M). \tag{C.1.7}$$

Consequently their integrals against any smooth ambient (d,d)-form defined near the compact actual moment image agree.

Proof. Scalar projection is surjective [2.33.13], and the absolute values of the pulled-back units agree pointwise. Thus the actual moment images agree. Lemma C.1.3 supplies purity upstairs. Use Theorem 5.39.3 for the finite actual images and their boundary images. Use Lemma 5.14.2 to subdivide the common image and both boundary images simultaneously. Use the closed finite-module chains on this subdivision. Every d-cell interior avoids those boundary images. At a point w there, the full moment fibres in both spaces are interior, and the local image lies in the same saturated rank-d affine tangent plane.

Let D_w be the actual algebra of the entire simultaneous level $|f_i| = e^{-w_i}$. The domain base-change theorem [2.36.9] identifies the *entire* upstairs level algebra with $(D_w)_L$. Choose the same integral transverse projection Q on the tangent lattice N, and put $e_Q = [\mathbf{Z}^d : Q(N)]$. The flat-germ theorem in [5.36.2, 5.37.1] makes D_w finite canonical over $R_{K,\exp(-Qw)}$. Put $P =$

$M \otimes_A D_w$. All the completed module restrictions are the actual finite tensors by [1.18.7]. Lemma C.1.5 therefore gives

$$\frac{\dim_{H_{L,\exp(-Qw)}}(P_L \otimes_{R_{L,\exp(-Qw)}} H_{L,\exp(-Qw)})}{e_Q} = \frac{\dim_{H_{K,\exp(-Qw)}}(P \otimes_{R_{K,\exp(-Qw)}} H_{K,\exp(-Qu}}{e_Q}$$

By the exact module-weight theorem [5.40.1, 5.40.2], these are the two generic coefficients. That theorem also expresses them through generic Artinian lengths as in Lemma C.1.2. Equality on every top cell proves (C.1.7). Lower-dimensional cells carry no d-chain term on either side. The same real form, cell, orientation and lattice measure are used in the finite-cell integral, so the finite integral sums agree. Boundary-image codimension is used only to read generic coefficients; no differential boundary term is being discarded. □

C.1.3 Global pullback and compact support

Proof of Theorem C.1.1. **Spaces and coefficients.** Actual scalar extension and inverse images of domains are supplied by [2.40.12, 2.36.9]. If V is an ordinary affinoid neighbourhood of x, $p^{-1}(V) = V_L$ is affinoid and contains the open set $p^{-1}(\mathrm{Int}_{\mathrm{top}}(V, X))$. Hence these inverse images give affinoid neighbourhoods at every point upstairs, proving goodness. Points with different images can be separated downstairs. Points with the same image lie in the open interior of one such affinoid neighbourhood and can be separated there. Thus X_L is Hausdorff. Lemma C.1.3 proves its local purity.

On $V = \mathcal{M}(A)$, set $\mathcal{F}_L|_{V_L}$ to be the coherent module represented by $A_L \otimes_A \Gamma(V, \mathcal{F})$. The exact finite-module equivalence [2.39.6] and actual iterated tensors [2.33.9] make these constructions agree on restrictions; hence they glue. Faithful flatness [2.33.5, 2.33.6] preserves coherent exact sequences.

Ordinary form pullback. Pull a representative (V, f, η) back to $(V_L, p^* f, \eta)$ near any point over $\mathrm{Int}_{\mathrm{top}}(V, X)$. If two representatives agree on a smaller ordinary affinoid neighbourhood W, their joint moment images after extension equal the original joint images, by [2.33.13]. Tangential equality therefore remains true on W_L. These local representatives define $p^*\alpha$ independently of choices and glue on ordinary opens. The same description proves compatibility with d', d'', J, wedge and composition of extensions. This is also the mixed-ground-field version of the representative argument in [5.52.3, 5.52.4].

Support and integration. Put $S = \mathrm{supp}(\alpha)$. Vanishing near x pulls back to vanishing near every point above x, so $\mathrm{supp}(p^*\alpha) \subset p^{-1}(S)$. Choose

finitely many ordinary affinoid neighbourhoods V_i whose interiors cover S, and put $Q = \bigcup_i V_i$. The full inverse image $Q_L = \bigcup_i (V_i)_L$ is a finite union of compact affinoids. Since S is closed in the Hausdorff space X, $p^{-1}(S)$ is a closed subset of Q_L, hence compact. It contains the closed support of $p^*\alpha$. The interiors of the $(V_i)_L$ cover that support.

Use the finite chart data induced by α on Q in [5.52.3, 5.52.4, 5.50.1, 5.50.3, 5.50.4, 5.50.6]. Refine the cover so each member has one presenting unit tuple and ambient form. Its complete inverse-image cover gives the pulled-back data on Q_L. Every intersection satisfies $(V_I)_L = \bigcap_{i\in I}(V_i)_L$, with the actual algebra and coefficient module supplied by [2.36.9]. Proposition C.1.6 applies on every such affinoid intersection. It equates the corresponding terms in the two finite inclusion–exclusion formulas [5.50.1, 5.50.3, 5.50.4, 5.50.6]. Thus their compact integrals agree. The compact-support theorem [5.52.3, 5.52.4] identifies these with (C.1.1). The finite unions need not themselves be good; they lie in the good Hausdorff pure ambient spaces just established.

For a tower $K \subset L \subset E$, all local pullbacks compose by [2.33.9]. Applying (C.1.1) twice gives its assertion for E/K, with factor one at each step. Exact-sequence compatibility uses the flat coherent pullback and additivity of the given integral. Ordinary restriction containing the support uses the same compact neighbourhoods and the support independence in [5.52.3, 5.52.4]. □

C.1.4 Finite restriction of constants

Lemma C.1.7 (The analytic space with finite constants restricted)**.** *Suppose $n = [L : K] < \infty$. Every generalized L-affinoid algebra B is a generalized K-affinoid algebra with the same Banach topology. The two analytic spectra, domains, structure sheaves and completed residue fields agree. On a good Hausdorff L-analytic space Y this gives $Y_{[K]}$, with the same ordinary moment sheaf and supports. Purity of analytic dimension d is unchanged.*

Proof. Fix a basis $e_1, \dots, e_n$ of L/K. By [1.12.1] there are $c, C > 0$ such that

$$c \max_i |a_i| \le \left| \sum_i a_i e_i \right|_L \le C \max_i |a_i| \quad (a_i \in K).$$

Applying the same bounds to every power-series coefficient identifies $L\{r^{-1}T\}$ with $K\{r^{-1}T\} \otimes_K L$, finite free with an equivalent norm. Finite canonical

algebras and their quotients are actual generalized affinoids [2.33.18, 2.33.19, 1.18.3]. This gives the asserted K-affinoid realization of B. Every bounded K-seminorm on B restricts to the unique extended absolute value on L [1.12.1]. The spectra therefore consist of the same seminorms with the same evaluation topology. Evaluated fraction fields and their completions are unchanged.

Here is the domain comparison, including its norm condition. A K-affinoid algebra C with a bounded structural map $B \to C$ has an induced bounded L-action. A norm-admissible presentation $K\{s^{-1}U\} \twoheadrightarrow C$ extends coefficientwise to $L\{s^{-1}U\} \twoheadrightarrow C$. Bounded multiplication gives a bounded map; the original K-lifts give a uniform quotient-norm bound, so it is norm-admissible. Thus C is also L-affinoid. An L-affinoid test object is already K-affinoid by the first paragraph. A K-test map into B conversely gives its source this L-structure. Hence the two domain universal properties are equivalent: each tests exactly the same bounded factorizations over B. Domain algebras and restriction maps agree by uniqueness. Gluing affinoid charts gives the stated global space and structure sheaf.

The ordinary neighbourhoods, analytic units, absolute values and joint moment images used in the definition [5.52.3, 5.52.4] now coincide literally; thus so do the germs and their relations. At each point y, the valued-field tower $K \subset L \subset \mathcal{H}(y)$ has $d(\mathcal{H}(y)/K) = d(\mathcal{H}(y)/L)$, since L/K is algebraic [3.22.2]. The maximum formula [3.22.7] gives equality of analytic dimensions, also on every minimal-prime quotient. This proves the purity assertion. □

Lemma C.1.8 (The full finite Gauss degree)**.** *For finite L/K and every real positive r,*

$$H_{K,r} \otimes_K L = H_{L,r}, \qquad [H_{L,r} : H_{K,r}] = [L : K] = n.$$

The natural maps are bounded isomorphisms with bounded inverses.

Proof. The coefficient bounds in Lemma C.1.7 give

$$R_{L,r} = \bigoplus_i e_i R_{K,r}, \qquad c \max_i \|a_i\|_r \le \left\| \sum_i e_i a_i \right\|_r \le C \max_i \|a_i\|_r.$$

Both tails and uniqueness are controlled by these inequalities. Both Laurent algebras are domains by multiplicativity of their Gauss norms [5.36.2, 5.37.1]. Localizing $R_{L,r}$ over $F = \mathrm{Frac}(R_{K,r})$ gives a finite-dimensional F-domain, hence a field, necessarily $\mathrm{Frac}(R_{L,r})$. The e_i remain a basis. Clearing

a common denominator extends the two bounds to coefficients in F. Completion consequently gives $\bigoplus_i e_i H_{K,r}$, with the tensor-product multiplication, and this completion is $H_{L,r}$. This proves both the isomorphism and the full degree. □

Theorem C.1.9 (Finite change of calibration)**.** *Let L/K be finite of degree n. If Y is good Hausdorff and pure of dimension d over L, $\mathcal{G}$ is coherent, and $\beta \in \mathcal{A}^{d,d}_{Y/L,c}(Y)$, then*

$$\int_{Y_{[K]}/K,\mathcal{G}} \beta = n \int_{Y/L,\mathcal{G}} \beta. \tag{C.1.8}$$

For $Y = X_L$ and $\mathcal{G} = \mathcal{F}_L$, this gives (C.1.2)*. The factors multiply correctly in finite towers.*

Proof. First let $Y = \mathcal{M}_L(B)$ be affinoid with one unit tuple f, and let N be the finite B-module representing $\mathcal{G}$. By Lemma C.1.7, its actual level algebra D_w, module $P = N \otimes_B D_w$ on that level, real moment image and tangent lattice are identical in the two field interpretations. Choose a common subdivision avoiding both boundary images at generic top-cell points, as in Proposition C.1.6. There D_w and P are finite canonical over $R_{L,r}$. They are also finite canonical over $R_{K,r}$ by the finite free coefficient decomposition and composed finite presentations. Lemma C.1.8 gives

$$P \otimes_{R_{K,r}} H_{K,r} = P \otimes_{R_{L,r}} H_{L,r}$$

as the same module with different scalar fields. Its dimension over $H_{K,r}$ is n times its dimension over $H_{L,r}$. Dividing by the same lattice index proves $\mathcal{T}^K_f(N) = n\mathcal{T}^L_f(N)$, using the closed finite-module chains. Integrating by the finite-cell functional and then applying the identical finite covers and inclusion–exclusion formula proves (C.1.8) for the ordinary compact integrals.

There is also a direct check of (C.1.2). The basis of L/K gives

$$p_* p^* \mathcal{F} \simeq \mathcal{F}^{\oplus n}$$

on every full affinoid inverse image, compatibly with restriction. The map $p : (X_L)_{[K]} \to X$ is finite with its canonical module norm. The spaces have the required purity and Hausdorffness by the preceding lemmas. Thus the exact finite projection theorem [5.54.1] and coherent additivity give

$$\int_{(X_L)_{[K]}/K,\mathcal{F}_L} p^*\alpha = \int_{X/K,p_*\mathcal{F}_L} \alpha = n \int_{X/K,\mathcal{F}} \alpha.$$

This uses the actual coherent direct image [2.35.15], with no local-freeness assumption on $\mathcal{F}$. Finite tower factors multiply because $[E : L][L : K] = [E : K]$, while Theorem C.1.1 has factor one in every tower. $\square$

Supplement to Chapter 8, Section 8.4.4.

Cancellation for finite affinoid cuts

Proposition. *Let X be good, Hausdorff and analytically pure of dimension $d \geq 1$ over a complete real-valued non-Archimedean field K, with its specified absolute value and the norm-admissible generalized affinoid atlas. Let $\mathcal{F}$ be coherent on X_G and let β be an ordinary smooth moment form with compact germ support S. Use $D = d'$ in bidegree $(d-1, d)$ and $D = d''$ in bidegree $(d, d-1)$. Let $V_1, \dots, V_s$ be affinoid domains of X such that*

$$S \subseteq \mathrm{Int}_{\mathrm{top}} \left(\bigcup_{j=1}^{s} V_j, X \right).$$

For a nonempty index set L, put $V_L = \bigcap_{j \in L} V_j$ and $\epsilon_L = (-1)^{|L|+1}$. For an affinoid domain Z write $m_Z = (i_Z)_* \mu^D_{Z, \mathcal{F}|_Z, \beta|_Z}$, where $i_Z : Z \hookrightarrow X$, and set $m_\varnothing = 0$. Then

$$\sum_{L \neq \varnothing} \epsilon_L m_{V_L} = \mu^D_{X, \mathcal{F}, \beta}. \tag{C1}$$

In particular, on every Borel subset of $X \setminus (S \cap \partial_K X)$ the signed sum is zero. Here $\partial_K X = X \setminus \mathrm{Int}(X/K)$ is the analytic boundary of the structure map. The ordinary interior in the covering hypothesis is taken after forming the union.

Proof. First take a pure affinoid Y and any finite affinoid cover (B_j) of all of Y. For an ordinary top form ω on Y, choose a finite presenting cover (W_i) by NAG-002424. Compute its integral by NAG-002416 on the intersections W_I. On each W_I one restricted tuple represents ω. Apply NAG-002401 there to the cover by $W_I \cap B_j$. For fixed L, the $W_i \cap B_L$ present the restricted form on B_L, so summing first over I gives

$$I^N_{Y, \mathcal{F}}(\omega) = \sum_{L \neq \varnothing} \epsilon_L I^N_{B_L, \mathcal{F}|_{B_L}}(\omega|_{B_L}).$$

All the mixed pieces are actual affinoid domains, pure of dimension d when nonempty, and both restriction paths give the same finite coefficient module (NAG-002411, 002413, 002414). This computation uses the whole intersection even when its ordinary interior in Y is empty. Apply it to $\omega = D(u\beta)$ for *every* ordinary smooth scalar u on Y. Restriction commutes with product

and differential by NAG-002424. Thus (S1) and uniqueness of the signed measure give (C1) on Y for this cover. Every multiplier here is a restriction of the same test when its contributions are summed.

Now choose compact affinoid neighbourhoods A_i inside $\mathrm{Int}_{\mathrm{top}}(\bigcup_j V_j, X)$ whose ordinary interiors cover S; use goodness, the neighbourhood basis of NAG-002424 and compactness. The zero primitive is immediate if S is empty. Write $A_I = \bigcap_{i\in I} A_i$. By (S5), grouped into the coherent measures on A_I using (S4) and (S1), the ambient measure is $\sum_I \epsilon_I m_{A_I}$. Here and below the sums run over nonempty index sets. Each A_I is covered by $A_I \cap V_j$, so the affinoid calculation expresses the ambient measure as

$$\sum_{I,L} \epsilon_I \epsilon_L \, m_{A_I \cap V_L}.$$

Conversely, the support of $\beta|_{V_L}$ lies in $S \cap V_L$. For x there, some A_i contains an ordinary neighbourhood of x in X, hence $A_i \cap V_L$ contains one in V_L. The grouped (S5) on the good affinoid V_L sums the I-terms to m_{V_L}, after pushforward to X. Interchanging the finite sums proves (C1). For $D = d''$ the sign relating each measure to the d'-measure of $J\beta$ is $(-1)^d$ on every nonempty piece, including X. The cover signs are the same in both formulas. Taking the mass in (C1) gives $I^N_{X,\mathcal{F}}(D\beta)$. If $S \subseteq \mathrm{Int}(X/K)$, the signed sum vanishes as a measure. Both support assertions follow from the genuine-boundary support theorem in Section 8.4.4. □

For two families (V_j) and (H_i) satisfying the hypothesis, the common sum is also $\sum_{L,I} \epsilon_L \epsilon_I m_{V_L \cap H_I}$. Indeed (C1) applies on V_L to $V_L \cap H_i$: the relative ordinary interior of their union contains $S \cap V_L$. For three cuts the signs are $+, +, +$ on single members, minus on all three pair intersections and plus on the triple intersection. On each piece the coefficient of an integral component is its generic module length by (S4). These lengths belong to that piece.

On one common moment chart the normal convention can also be read off before integration. Subdivide the chains in NAG-002401 together. For each top cell σ, its coherent weight equals the alternating sum of the restricted weights on that cell. In the formula of NAG-002389 each incidence with a facet τ multiplies this coefficient by the same contraction: use a basis of the facet lattice in both slots, a primitive inward lift in the last double-primed position, the covolume-one facet measure and the sign $(-1)^{d(d+1)/2}$. Thus the weighted facet functionals agree on the fixed chart. Variable presentations in

(C1) are compared by testing the whole $D(u\beta)$. Equality of separate unsigned incidences over a projected face is unnecessary.

Annular overlap and the role of the ordinary germ. Take the closed annulus $a \le t = -\log|T| \le b$, $a < b$, with its structure module. For the radial test $\beta = h(t)d''t$ and scalar $u = q(t)$, put $F = qh$, with h, q smooth. On a subannulus $[s, r]$ of positive width its contribution is $F(r) - F(s)$: the whole exact-radius level for the coordinate T is the target polytorus itself, of Gauss degree and projection index one (NAG-002362, 002405). Integrate $F'(t)d't \wedge d''t$. For $a < c < e < b$, the cuts $[a, e]$, $[c, b]$ and their actual overlap $[c, e]$ give

$$[F(e) - F(a)] + [F(b) - F(c)] - [F(e) - F(c)] = F(b) - F(a).$$

If $c = e$, the intersection is the entire level affinoid; its one-coordinate image is a point and the restricted primitive is zero. The two endpoint terms at c cancel. For $\beta = h(t)d't$ and $D = d''$, each displayed endpoint difference has the opposite sign. These computations test radial scalars; (C1) gives the signed measure identity for arbitrary ordinary smooth scalars on the annulus.

The same touching cuts explain the germ hypothesis. Use $+d''t$ on $[a, c]$ and $-d''t$ on $[c, b]$. Both restrictions are zero on the joint level. For a radial smooth q supported in (a, b) with $q(c) = 1$, the two d' integrals of the scalar products sum to 2, and the intersection contributes zero. The two generators T, T^{-1} of the annulus presentation satisfy both radius bounds strictly over (a, b), placing this compactly supported test inside the analytic interior (NAG-000214, 001704). If the two primitives were restrictions of one ordinary smooth primitive, (C1) tested on q would give zero there. Thus agreement of tangential restrictions on a closed level alone cannot supply the common ordinary germ.

Continuous pullback of ordinary smooth forms

Supplement to Chapter 8.

This is the pullback counterpart to the fixed multiplier in Proposition 8.15.11. It uses the same intrinsic affine estimate (8.15.1), the single-chart and fixed-family topologies of Definitions 8.15.7 and 8.15.8, and the support and ordinary specialization of Definitions 8.15.9 and 8.15.10. The support stage here uses the inverse image of the given closed support.

Historical category. Use refined G-tropical spaces and their given affine structures. The spaces are Hausdorff, locally compact and have the historical countability-at-infinity neighbourhood condition. Their G-domains are locally closed, include opens, admit finite intersections and are G-covered by their compact subdomains. A G-cover is tested at a point by finitely many domains containing that point whose union contains a neighbourhood in the covered domain. Finite unions of compact domains are compact domains. The historical compact-image axiom makes the image of a compact domain under a chart a compact finite polyhedral image. A morphism is continuous, takes inverse images of G-domains to G-domains and pulls back paralinear functions. In the refined category it also pulls back affine functions. These are the scope-defining data in the historical definitions.

A chart is specified by its coordinate map and, where needed, a paralinear target containing the image in an ambient affine space. Use the historical form presheaf of smooth real (p,q)-coefficients on these targets, with the relation given by affine pullback to common dominating charts, and its associated G-sheaf. Ordinary smooth forms are sections locally represented on ordinary neighbourhoods by tropical charts, whose coordinates are affine functions in the refined structure. A support is the complement of the largest ordinary open on which the section vanishes.

Reader 33 R2, §8.T4.RA. *Let $u : Y \to X$ be a morphism in this category preserving the given affine structures, and let Φ, Ψ be the respective closed support families, with $u^{-1}F \in \Psi$ for each $F \in \Phi$. For $p, q \geq 0$ and $m \in \mathbb{N} \cup \{\infty\}$, the map*

$$u^* : \mathcal{A}^{p,q}_{\Phi}(X) \longrightarrow \mathcal{A}^{p,q}_{\Psi}(Y)$$

on ordinary smooth real forms is linear and continuous for the historical C^m topologies. Taking all closed supports gives the ordinary smooth-form state-

ment without support restriction. For a compact morphism, taking compact support families gives the compact-support statement.

Affine compatibility and pullback of sections. For a chart $f : V \to E$ on X, put $V' = u^{-1}V$ and $g = f \circ u|_{V'}$. The morphism preserves the domain and the coordinate type. When f is tropical, g is tropical, with the identity affine comparison on E. A specified coefficient target of f also contains $g(V')$. Pullback of a representative uses the same coefficient on that target and the composed chart g. A relation in the chart presheaf remains a relation: the dominating chart composes with u and the affine transition maps are unchanged. This preserves restriction and sums, the latter computed on joint charts.

A G-cover pulls back to a G-cover. At y, take the finitely many covering domains containing $u(y)$ whose union is a relative neighbourhood there, and take their inverse images. Thus local representatives for a sheaf section and the local equalities on overlaps pull back to compatible representatives. Gluing in the associated G-sheaf gives a unique section, agreeing with the representative rule. For an ordinary local tropical presentation the inverse image of its ordinary neighbourhood is ordinary open; hence this construction preserves ordinary smoothness. If a section vanishes on an ordinary open, its pullback vanishes on the inverse image there. In particular

$$\operatorname{supp}(u^*\omega) \subset u^{-1} \operatorname{supp} \omega.$$

Compact coefficient uniqueness. We prove the nullity test used by the topology. First let $\pi : P \to Q$ be an affine surjection between compact finite polyhedral sets. If $\pi^*b = 0$ tangentially, then for every source cell C the coefficient restricts to zero on $\pi(C)$. In fact the linear part maps the tangent space of C onto that of $\pi(C)$, so all primed and double-primed tangent vectors used to test b at a point of $\pi(C)$ can be lifted at a preimage in C. The equality on relative interiors holds also on the closed cell by continuity. The finitely many images $\pi(C)$ cover Q. A common subdivision adapted to those images shows that $b = 0$, since on each refined cell the tangential restriction is a further restriction of a zero form. This uses the same intrinsic finite-cell restriction as the surviving calculation in III-TOP-C.

Now take a chart f on a compact G-domain K and an intrinsic coefficient b on $f(K)$. Suppose the presheaf class of f^*b is zero. At a common dominating chart h the two representatives agree, so for the affine comparison π with

$f = \pi h$ the pullback $\pi^* b$ restricts to zero on $h(K)$. The actual image $h(K)$ is compact finite polyhedral and projects onto $f(K)$. The affine test just proved yields $b = 0$.

If the associated sheaf section of $f^* b$ is zero, its presheaf class vanishes on a G-cover, by the local equality relation defining the associated sheaf. Refine that cover by compact subdomains. Transitivity and the finite subcover property for the underlying quasi-net give finitely many compact domains K_i covering K. In particular each lies in a domain where the presheaf class vanishes. The same presheaf test for $f|_{K_i}$ gives $b|_{f(K_i)} = 0$. Those finitely many compact images cover $f(K)$; a common subdivision again gives $b = 0$. This proves injectivity for a compact chart restriction in the actual sheaf. Consequently the intrinsic coefficient representing a fixed section on this image, when it exists, is unique, and the coefficient on a smaller compact domain is its tangential restriction. This argument uses the topological part of NAG-001619/001620 for the quasi-net step.

The fixed-stage estimate. An input stage consists of an ordinary interior-covering family $\mathcal{D}$ on X and support in one closed $F \in \Phi$. For each $f : V \to E$ in this family take the chart g above. The ordinary interiors of the V' cover Y, since each contains $u^{-1} \operatorname{Int}_X V$. Their family $\mathcal{E}$ is fixed by $\mathcal{D}$ and u, independently of the varying section. The target support label is $u^{-1}F$.

Fix a compact domain $W \subseteq V'$. The compact subset $u(W)$ is contained in a compact G-domain $K \subseteq V$: at each point of V the compact-domain G-cover supplies a finite union of compact domains containing a relative neighbourhood. Finitely many such neighbourhoods cover $u(W)$, and the union of their compact domains is a compact domain. This step uses a containing domain and puts no requirement on $u(W)$ itself to be a domain. Let $b_{f,K}$ denote the input coefficient on $f(K)$. For any fixed affine comparison ℓ with $f \circ u|_{V'} = \ell \circ g$, the representative rule gives on $g(W)$ the coefficient

$$\big(\ell|_{g(W)}\big)^* b_{f,K}.$$

For the pulled-back family just chosen, ℓ is the identity. Uniqueness identifies the displayed intrinsic form with the coefficient of $u^*\omega|_W$. It is independent of K: coefficients for two choices are restrictions from their compact domain union. For each finite $r \le m$ the native finite-cell affine pullback estimate bounds the r-seminorm of this coefficient by $c_r \|b_{f,K}\|_{f(K),r}$, with geometry fixed before ω varies. The estimate uses only derivatives along the cells. For $m = \infty$ apply it at each finite order.

These seminorms generate the fixed-family topology. The linear map therefore lands continuously in the target stage with the subspace topology for support in $u^{-1}F$. Compose with that stage's inclusion in the target final space. This composition is continuous for every input stage, hence continuous for the source locally convex final topology. Both support specializations follow from the support inclusion and the respective support-family condition. In the compact case this is exactly compactness of the inverse image of a compact set.

Descent of graded valuation charts

Supplement to Section 3.19, following Theorem 3.19.22.

Let $G = \mathbb{R}_{>0}$, written multiplicatively. All field embeddings preserve degrees. For a graded field F over a graded field k, $P(F) = \mathcal{P}_k(F)$ is the space of graded valuation subrings containing k, with basic opens prescribed by finitely many homogeneous membership conditions. A graded field need not be an ordinary field. Let $H \leq G$ be a subgroup containing $\mathrm{supp}(k)$, allowing equality, and set $F_H = \bigoplus_{h \in H} F_h$. The analytic application uses $H = \mathrm{supp}(k)$. No restriction on the rank of a valuation is made.

Proposition 3.HS.1. *For every such subgroup H, restriction $p_F : P(F) \to P(F_H)$ is an open surjection with connected fibres. If $X = X_H \times_{P(F_H)} P(F)$ and $Y = Y_H \times_{P(L_H)} P(L)$ are given strict structures on graded birational spaces (the structure maps downstairs are local homeomorphisms), every morphism $(f, i) : X \to Y$, with $i : L \hookrightarrow F$, descends uniquely over $i|_{L_H}$. It is not assumed that f preserves any strict charts.*

Proof. Image of a basic open. If $A = k[a_1, \ldots, a_m] \subset F$ with a_j nonzero homogeneous, write $A_H = A \cap F_H$. Then

$$p_F(P(F)\{A\}) = P(F_H)\{A_H\}.$$

Indeed, fix O on the right and form $B = AO$. Its degree-H summand for the quotient grading by G/H is $A_H O = O$; the matching summand of $\mathfrak{m}_O B$ is $\mathfrak{m}_O$. The ideal is proper. Choose an ordinary maximal ideal containing it (Stacks 00E0(2)); the sum of its homogeneous components lying in the ideal is a homogeneous prime. Its homogeneous contraction to O is exactly $\mathfrak{m}_O$, since every homogeneous element of O outside $\mathfrak{m}_O$ is a unit. Homogeneously localize B there and apply the graded domination clause of NAG-001964 to this graded local subring of F. The resulting valuation contains A, O; any nonzero homogeneous $b \in F_H \setminus O$ is excluded because $b^{-1} \in \mathfrak{m}_O$ remains a nonunit. This proves the formula and surjectivity (take $A = k$).

For openness, A_H has finitely many homogeneous k-algebra generators. Indeed, the monomials needed have exponent vectors in $M = \{e \in \mathbb{N}^m : \prod_j \deg(a_j)^{e_j} \in H\}$: coefficients have degrees in H, and projecting a polynomial expression onto its H-summand retains only such monomials. Distinct minimal nonzero vectors in M are incomparable and form a finite set. In fact any infinite sequence in $\mathbb{N}^m$ has an infinite componentwise nondecreasing subsequence: for one coordinate choose an infinitely repeated value or a strictly

increasing subsequence; do this successively in the finitely many coordinates. If $0 \neq v \leq e$ in M, then $e - v \in M$. Induction on $\sum e_j$ now proves the finite generation assertion, including $M = \{0\}$. The right-hand side of the formula is therefore open. Restriction is continuous directly by the definition of the basic opens.

Fibre reduction. Fix $O \in P(F_H)$. The fibre Z is closed in $P(F)\{O\}$: its complement there is the union of the tests $b \in V$ for homogeneous $b \in F_H \setminus O$. Hence Z is quasi-compact by NAG-001965 applied to the possibly infinitely generated graded subalgebra O. We use only this existing compactness statement. Write $H^s = \{g : g^n \in H \text{ for some } n > 0\}$. Restriction from F_{H^s} to F_H is a homeomorphism on valuation spaces: it is an open surjection as just shown, and membership of each nonzero homogeneous u upstairs is equivalent to membership of u^n for $\deg(u)^n \in H$. The equivalence follows from the valuation alternative: if u is absent, its inverse is a nonunit. We may start at the unique extension of O to $E = F_{H^s}$ instead.

Were Z disconnected, its two complementary nonempty open pieces would be quasi-compact. Each would be a finite union of relative basic opens. Adjoin their finitely many nonzero tests to E as a graded field, obtaining F'. Every graded valuation of F' over the chosen restriction extends to F: apply NAG-001964 to that valuation ring in F; domination forces exact contraction by the inverse-nonunit test above. The two same finite families would thus disconnect the fibre for F'/E. The relative degrees $\operatorname{supp}(F')/\operatorname{supp}(E)$ form a finitely generated torsion-free subgroup of G/H^s (via its natural inclusion). It has a basis: embed such a group in its rational vector space, take rational coordinates, and clear the denominators of the finite generators. A subgroup of $\mathbb{Z}^r$ is free by projecting onto one axis, lifting a generator of the cyclic image when it is nonzero, and applying induction to the kernel. Choose homogeneous lifts of basis degrees. By restriction to the subgroups successively generated by these degrees and $\operatorname{supp}(E)$ we obtain a tower of one-free-degree extensions. Each step is $D[T, T^{-1}]$ as a graded ring over the preceding graded field D: each homogeneous term is cT^n, and distinct exponents have different degree classes.

One free degree. Fix a graded valuation W of D. On the multiplicative group of nonzero homogeneous elements of D, let v be the quotient by the homogeneous units of W, ordered additively by $v(c) \geq 0 \Leftrightarrow c \in W$. This is a totally ordered abelian group Γ; for same-degree summands the sum has value at least their minimum (divide by a summand of smaller value and use closure

of W). For every extending valuation the group Γ embeds order-preservingly into its value group and cT^n belongs to it precisely when $v(c) + nt \geq 0$, where t is the value of T. Thresholds for finitely many tests with $n \neq 0$ are $-v(c)/n \in \Gamma_{\mathbb{Q}}$. The rational hull is obtained by fractions with positive integer denominators and comparison by clearing denominators; embeddings of ordered groups induce embeddings of their hulls.

Conversely all positions relative to this finite threshold list occur. In $\Gamma_{\mathbb{Q}} \oplus \mathbb{Q}$ with lexicographic order put t at a threshold, between consecutive thresholds, or beyond the extreme thresholds (use the second coordinate for the unbounded intervals if necessary). Taking the direct sum of the homogeneous terms with $v(c) + nt \geq 0$ gives a graded valuation ring. Indeed products add, same-degree sums have the same exponent and satisfy the preceding minimum bound, and one of a homogeneous monomial and its inverse is admitted. These rings restrict to W. For a finite list of tests, membership in any finite union of finite intersections of tests depends only on the listed position; tests with $n = 0$ are constant. At a threshold all positive membership tests true in either adjacent interval remain true there, since the inequalities are weak. If the two sides of a separation were given by such finite families, the point at a threshold would have to be on the same side as each adjacent interval. The finite ordered list of intervals and thresholds is a chain, so every position is on the same side; with no thresholds there is only one pattern. This rules out any separation, because quasi-compactness of the fibre has already reduced it to finite families. This argument includes $\Gamma = 0$ and non-Archimedean ordered value groups; it does not use connectedness of a real interval.

Returning up the tower. Each restriction is continuous, open, surjective, and has connected fibres for a single free degree. On the inverse image of a fixed subset of the base its restriction remains open onto that subset, by the formula for the image of a relative open. A separation of the inverse image of a connected fibre would partition it into two saturated nonempty opens, since each single-step fibre is connected. Their images would disconnect that fibre. Starting at the base point proves connectedness up the entire finite tower, contradicting the supposed separation of Z.

Descent. The projections $q_X : X \to X_H$, $q_Y : Y \to Y_H$ are open surjections: locally they are pullbacks of p_F, p_L over open charts, or use that an open surjection remains so after base change. The fibre of q_X is a fibre of p_F. On it the composite $q_Y f$ takes values in one fibre of $Y_H \to P(L_H)$, since restriction of valuations commutes with i. This latter fibre is discrete by local

homeomorphy. Its connected image is one point, defining f_H uniquely. The open surjection q_X is a quotient map, so f_H is continuous. With the fixed field map $i|_{L_H}$ it is the required morphism, and its pullback is the original map by the fibre product description of Y. □

Corollary 3.HS.2 (The strict subdomain germ test)**.** *Let K be complete and nontrivially valued, and let (X, x) be a strictly K-analytic germ with its given strict atlas, not necessarily good. An analytic subdomain germ U_x is strict if and only if its graded birational reduction admits an H-strict structure, where $k = \widetilde{K}^{\mathrm{gr}}$ and $H = |K^\times|$. Every analytic morphism between strictly K-analytic spaces admits a unique strict representative as a morphism of the given strict spaces.*

Proof. For $F = \widetilde{\mathcal{H}(x)}^{\mathrm{gr}}$, $P(F_H)$ identifies with $\mathcal{P}_{k_1}(F_1)$: in a degree $h \in H$ choose $c_h \in k_h^\times$, write $F_h = c_h F_1$, and send a degree-one valuation V_1 to $\bigoplus_{h\in H} c_h V_1$. This is independent of the choices, since their ratios are in $k_1^\times$. Products, inverses and same-degree sums give the valuation property, and each homogeneous membership test is exactly a degree-one test. Thus the maps are inverse homeomorphisms.

NAG-001985 gives, on the supplied strict ambient atlas, the ordinary reduction X_0 and its graded pullback X_g; its nonempty quasi-compact opens classify the strict subdomain germs and pull back to their graded reductions. In particular a strict germ has H-strict reduction. Conversely let $U_g \subset X_g$ have a supplied abstract H-strict structure U_0, not assumed compatible with the embedding. Apply the proposition to $U_g \hookrightarrow X_g$ (identity on the field). The descended map $U_0 \to X_0$ is injective, since two points with the same image lie over the same valuation and can be paired with a *single* lift along p_F, where injectivity holds. Its image is open: its full inverse image under q_X is precisely the image of U_g, by the pullback description and the identity field map; q_X is quotient. The map is an open embedding: the same reasoning applied to any open in U_0, or the local homeomorphism charts over the same base, gives openness onto its image. Its image is nonempty and quasi-compact because U_0 is a birational object (also the continuous image of U_g). The strict subdomain classified by this image via NAG-001985 has graded reduction U_g. NAG-001973, for arbitrary analytic subdomain germs, reflects equality, so this is the original U_x. This proof works on non-good germs: NAG-001985 provides the comparison by gluing finitely many strict charts

and their strict overlaps. It is not an assertion that all analytic subdomains of a strict space are strict.

For an arbitrary analytic $f : Y \to X$ between such spaces take a strict target subdomain U and $y \in f^{-1}U$, $x = f(y)$. By the all-germs inverse-image clause of NAG-001972 the graded reduction V_g of the preimage germ is precisely the inverse image of U_g under the graded morphism. Descend that morphism by the proposition using the already-given strict structures on Y_g, X_g, not functoriality in the strict category. Write $U_g = q_X^{-1}U_0$ with U_0 the corresponding quasi-compact open; then $V_g = q_Y^{-1}(f_0^{-1}U_0)$. Here $f_0^{-1}U_0$ is open and quasi-compact: it is the continuous image of V_g by the surjection q_Y and V_g is a quasi-compact open by NAG-001973. This avoids assuming that continuous maps always preserve quasi-compactness under inverse image. The strict classification in NAG-001985 therefore gives a strict germ equal to that preimage germ. Outside the preimage there is no germ to test.

Equality of domain germs gives equality after shrinking an ordinary neighbourhood. The local strict representatives therefore furnish a strict chart quasi-net of the entire inverse image: at each of its points take finitely many strict affinoid pieces of the strict representative covering a relative neighbourhood, shrinking them into the equality neighbourhood by strict rational neighbourhoods inside the pieces (the construction in the proof of NAG-001985). Transitivity of quasi-nets then gives the domain assertion. Pull this back for the strict affinoid charts of the target. On a strict chart of the resulting source refinement mapping into a strict target chart the analytic morphism already supplies a bounded homomorphism of their affinoid algebras. These very maps commute with restrictions; the chart quasi-net condition and uniqueness under refinement are the locally bounded morphism definition and NAG-001612. Thus they define the strict morphism. Two strict morphisms with the same underlying analytic morphism have the same bounded algebra maps on these charts and hence agree. No test merely on the underlying point maps is used. □

Proof inputs. Proposition 3.HS.1 uses graded domination (Lemma 3.19.1), quasi-compactness of valuation containment loci (Proposition 3.19.2), and Stacks, Tag 00E0(2) for the nonzero ordinary quotient in the first paragraph of its proof. Corollary 3.HS.2 uses the preceding proposition, the quasi-net convention and transitivity (Definition 2.39.1 and Lemma 2.39.2), and the domain, reduction and morphism statements in Definition 2.40.7 and Theorems 2.40.8, 3.19.9, 3.19.10 and 3.19.22.

Algebraic supplement to Chapter 23 and the local-height discussion in Section 22.2.

Supported finite projection for a meromorphic section. Let $f : Y \to X$ be a finite morphism of schemes of finite type over a field K. Let $W \subset Y$ be an integral closed subscheme of dimension $m \geq 1$, and endow its image V with the reduced structure. Let M be an invertible sheaf on X, and suppose that a meromorphic section s is a generator off a closed set $T \subset X$, with $V \not\subset T$. Write s_V for a supplied nonzero meromorphic section on V agreeing with the generator on $V \setminus T$. Put $h = f|_W : W \to V$ and $e = [K(W) : K(V)]$, where $K(W)$ and $K(V)$ denote function fields. Then

$$h_* \operatorname{div}_{h^*(M|_V)}(h^* s_V) = e \operatorname{div}_{M|_V}(s_V) \quad \text{in } Z_{m-1}(T \cap V).$$

Here the pushforward is the restriction of h to the indicated supports. All cycle coefficients are signed. For an effective cycle with several prime components satisfying the same condition, the formula holds on each component and hence on their sum with its given coefficients.

Proof. The map h is finite and dominant between integral schemes of finite type over K. Both function fields have the same transcendence degree over K because their extension is finite. Thus the dimensions for the dimension function over $\operatorname{Spec} K$ agree. The nonzero rational section pulls back to a nonzero rational section through the field map, so its divisor is defined. Each divisor is zero off the indicated closed support, since the section there is a regular generator and pullback preserves that property. Apply Stacks Project, Lemma 42.26.3 (Tag 02ST), to h, $M|_V$ and s_V. It gives equality of cycles on V. Both sides come from the cycles of $T \cap V$, whose push into $Z_{m-1}(V)$ is injective because different prime cycles of the closed subset remain different prime cycles of V. The equality therefore holds on the support.

To make the degrees and lengths explicit, take a point $v \in V$ of codimension one and trivialize M near v. Write $s_V = a/b$ in that frame with a, b nonzero in $\mathcal{O}_{V,v}$. Every point w of W above v has codimension one, since h is finite and the residue degrees are finite. The order of a/b in either one-dimensional Noetherian local domain is the length of the quotient by a minus the length of the quotient by b, as in Tags 02MD and 02RJ. In particular the coefficient on the left is

$$\sum_{w \mapsto v} [\kappa(w) : \kappa(v)] \left(\ell_{\mathcal{O}_{W,w}}(\mathcal{O}_{W,w}/a) - \ell_{\mathcal{O}_{W,w}}(\mathcal{O}_{W,w}/b) \right).$$

Tag 02R4 uses full algebraic degrees in this pushforward. Its sum ranges over all points above v, and it includes inseparable degrees both at v and at the generic point. Tensoring the section and the line bundle by the same positive power multiplies each order by that power, by the order formula for fractions and the length-additivity sequence $0 \to A/(a) \xrightarrow{b} A/(ab) \to A/(b) \to 0$ in each local domain A. $\square$

Interior Stokes with coherent coefficients

Supplement to Section 8.4.4 and the closed-cut supplement C1.

This section restores the historical interior-support proof and its two localization inputs. Their full proof dependencies remain under review. The ordinary support collars and the absolute analytic interiors are separate conditions. In the weighted wall proof used upstream, the two projected radii have their own Gauss fields $\mathcal{H}(s_+)$ and $\mathcal{H}(s_-)$. The collar gives the same Gauss dimension at the two levels.

Fix a complete real-valued non-Archimedean field K, with its original absolute value. All generalized-affinoid radii below are positive real numbers; the valuation may be trivial. Use the ordinary smooth moment sheaf `v037:forms:ordinarysmoothgerm`, `v037:forms:germsheaf`, and the compact-support integral `v037:forms:compactintegral`. A moment tuple consists of analytic units and $t_f = (-\log|f_1|, \dots, -\log|f_n|)$. All intersections and restrictions are actual analytic domains.

(AFF), accepted affinoid input. If $V = \mathcal{M}(A)$ is pure of analytic dimension $d \geq 1$, M is a finite A-module, and $\beta = t_f^*\alpha$ is one global unit-moment representative of bidegree $(d-1, d)$, smooth near $t_f(V)$, then

$$\beta = 0 \text{ on an ordinary neighborhood of } \partial_K V \quad \Longrightarrow \quad \mathcal{I}_{M,f}(d'\alpha) = 0. \tag{AFF}$$

This is exactly `f7v38:annihilation`; no ordinary-section version on a general space is assumed.

Theorem NAG-002577 (Global Stokes with interior compact support)**.** *Let X be a good Hausdorff analytic space, pure of analytic dimension $d \geq 1$, and let $\mathcal{F}$ be coherent on X_G. For ordinary smooth moment sections*

$$\beta \in \mathcal{A}_c^{d-1,d}(X), \qquad \gamma \in \mathcal{A}_c^{d,d-1}(X)$$

with

$$\operatorname{supp}(\beta),\ \operatorname{supp}(\gamma)\ \subseteq \operatorname{Int}(X/K),$$

one has

$$\int_{X,\mathcal{F}} d'\beta = 0, \qquad \int_{X,\mathcal{F}} d''\gamma = 0.$$

In particular the assertion holds for every such compactly supported section if $\partial_K X = \varnothing$. No global paracompactness, reducedness, strictness, or connected-fiber hypothesis is added.

The single-representative affinoid input

The displayed implication (AFF) is recovered in Theorem NAG-002495, including its componentwise generic lengths.

The only newly used v0.38 theorem is

NAG-002455, v038:pointed:fullstabilization.

Its hypotheses are a generalized affinoid $V = \mathcal{M}(A)$, a point $x \in \mathrm{Int}(V/K)$, and a unit tuple f. Put $w = t_f(x)$ and

$$s_f(x) = \mathrm{trdeg}_{\widetilde{K}^{\mathrm{gr}}} \widetilde{K}^{\mathrm{gr}}\big(\widetilde{f_1(x)}, \dots, \widetilde{f_n(x)}\big).$$

It supplies a finite pure $s_f(x)$-dimensional rational fan C_x and an ordinary affinoid neighborhood W_0 of x. For every ordinary neighborhood $U \subseteq W_0$ of x, some $\varepsilon_U > 0$ satisfies

$$t_f(U) \cap B_{\varepsilon_U}(w) = (w + C_x) \cap B_{\varepsilon_U}(w). \tag{F7.1}$$

The theorem permits nonreduced or nonpure A. It gives neither weights nor a fan at a general boundary point. We use it twice at interior points: first on V, and then on an actual closed subspace of V.

The target is as follows. Let $V = \mathcal{M}(A)$ be pure of analytic dimension $d \geq 1$, let M be a finite A-module, and let α be a smooth ambient $(d-1,d)$-superform on an open neighborhood of the compact actual image $t_f(V)$. Set $\beta = t_f^*\alpha$, as an ordinary smooth moment section. We seek

$$\beta = 0 \text{ on an ordinary neighborhood of } \partial_K V \quad \Longrightarrow \quad \mathcal{I}_{M,f}(d'\alpha) = 0. \tag{F7.2}$$

The global chain and integral in this formula are v037:integration:globalchain, not an integral defined only after already knowing (F7.2).

Where a nonzero interior germ can occur

For an integral affinoid algebra A, call a point $x \in \mathcal{M}(A)$ *analytic generic* if the evaluation seminorm has kernel 0. This does not say that x is an isolated point of a moment fiber, nor that the fiber is disconnected.

Lemma NAG-002487 (Interior germs of degree d have generic support)**.** *Let A be integral and $V = \mathcal{M}(A)$ pure of analytic dimension $d \geq 1$. Let $x \in \mathrm{Int}(V/K)$, and let $\beta = t_f^*\alpha$ be a single global moment representative of bidegree $(d-1, d)$. If $\beta_x \neq 0$ in the ordinary stalk, then $s_f(x) = d$ and* $\ker(x) = 0$.

Proof. Apply (F7.1) on V. Taking $U = W_0$ and then a smaller ordinary affinoid neighborhood of x whose moment image lies in $B_{\varepsilon_{W_0}}(w)$ gives a neighborhood whose entire actual image is contained in the $s_f(x)$-dimensional fan. Such a neighborhood exists by continuity of t_f and the ordinary affinoid-neighborhood basis used in `v037:forms:germsheaf`. If $s_f(x) < d$, the second alternating degree d forces every tangential restriction of α on this image to vanish. The ordinary germ definition `v037:forms:ordinarysmoothgerm` would then give $\beta_x = 0$. Thus $s_f(x) \geq d$. The finite-image dimension bound `v037:globaltrop:finiteimage`, applied to V, and the equality (F7.1) imply $s_f(x) \leq d$.

Suppose that $0 \neq a \in \ker(x)$. The actual closed subspace

$$Z = \mathcal{M}(A/(a))$$

is nonempty because it contains the same point x. The ideal (a) is contained in no minimal prime of the integral ring A. Therefore `v037:degree:exceptionalimage` gives $\dim_K Z \leq d-1$. The map $Z \to V$ is finite with its canonical quotient norm, hence everywhere relatively interior by `fnd:generalizedfinitealgebras`. Since $x \in \mathrm{Int}(V/K)$, the composition inclusion `fnd:affinoidinteriorcalculus` gives $x \in \mathrm{Int}(Z/K)$.

The completed residue field at this point of Z is the same $\mathcal{H}(x)$: the quotient is by an ideal in the evaluation kernel. The restricted units $f_i|_Z$ have exactly the same values and initial forms. Applying `NAG-002455` on Z therefore gives a pointed fan of dimension the same number $s_f(x)$. On the other hand, the entire actual image $t_f(Z)$ has dimension at most $d-1$, by the same exceptional-image theorem. Equality (F7.1) on Z implies $s_f(x) \leq d-1$, contradicting $s_f(x) = d$. Thus $\ker(x) = 0$. □

Lemma NAG-002488 (Separation of a compact generic interior support)**.** *Let A be integral, and let S be a nonempty compact subset of* $\mathrm{Int}(V/K)$*, $V=\mathcal{M}(A)$, such that* $\ker(x)=0$ *for every $x\in S$. Given any global unit tuple f on V, there are a single affinoid domain $W\subseteq V$ containing an ordinary neighborhood of S and a finite tuple of units g on W, obtained by restricting nonzero elements of A, such that for $F=(f|_W,g)$,*

$$t_F(S)\cap t_F(\partial_K W)=\varnothing. \tag{F7.3}$$

More precisely, every point of W with the same F-moment as a point of S is interior in W/K.

Proof. By the affinoid definition `fnd:relativeinterior`, for each $x\in S$ there is an admissible presentation of the *whole* algebra A,

$$K\{r_{x,1}^{-1}T_1,\dots,r_{x,m_x}^{-1}T_{m_x}\}\twoheadrightarrow A,\qquad T_j\longmapsto a_{x,j},\qquad |a_{x,j}(x)|<r_{x,j}. \tag{F7.4}$$

Delete any coordinate whose image is 0 in A. Setting these coordinates to zero is a contractive projection of the Tate algebra and does not change its map to A. Every lift can be so projected without increasing its norm; hence the induced quotient norm and admissibility of the remaining presentation are preserved. Thus every listed $a_{x,j}$ may be taken nonzero.

The strict loci

$$G_x=\{y\in V:\ |a_{x,j}(y)|<r_{x,j}\text{ for every }j\}$$

are open, contained in $\mathrm{Int}(V/K)$, and cover S. Choose a finite subcover $G_{x_1},\dots,G_{x_q}$. Let $g_1,\dots,g_N$ list all nonzero generators in these finitely many presentations; repetitions may be retained. Every g_l is nonzero at *every* point of S, since these points have kernel 0. Compactness and continuity give

$$0<\delta_l<\min_{x\in S}|g_l(x)|.$$

The actual Laurent domain

$$W=\bigcap_{l=1}^{N}\{y\in V:\ |g_l(y)|\geq\delta_l\} \tag{F7.5}$$

is affinoid by the generalized rational point, universal-property, and joint-presentation results `fnd:generalizedrationalpoints`, `fnd:generalizedrationaluniversal`, and `fnd:generalizedjointpresentations`. Its

algebra is the actual joint quotient adjoining inverses $S_l = g_l^{-1}$ with bounds $|S_l| \le \delta_l^{-1}$. Thus the restrictions of the g_l are units on W. The strict lower-bound locus contains S, so W contains an ordinary neighborhood of S.

Let $x \in S$, $y \in W$, and $t_F(y) = t_F(x)$. Then $|g_l(y)| = |g_l(x)| > \delta_l$ for every l. Choose i with $x \in G_{x_i}$. Equality of the generator values puts y in the same strict presentation locus G_{x_i}, and hence $y \in \mathrm{Int}(V/K)$. The strict lower bounds also put y in the ordinary interior of W in V. By `fnd:affinoiddomainordinaryinterior`, $y \in \mathrm{Int}(W/V)$. The composition inclusion now gives $y \in \mathrm{Int}(W/K)$. This proves the stronger assertion and (F7.3). □

Proposition NAG-002492 (The integral affinoid case)**.** *Under the hypotheses of* (F7.2)*, assume that A is integral. Then* (F7.2) *holds for every finite A-module M.*

Proof. Let $S = \mathrm{supp}(\beta)$. This support is the complement of the open zero-germ locus in the ordinary sheaf; it is compact because V is compact and Hausdorff. The hypothesis implies $S \subset \mathrm{Int}(V/K)$. If S is empty, the ordinary section and its differential are zero, and `v037:forms:compactintegral` gives the assertion.

Assume $S \neq \varnothing$. Each point of S has nonzero germ. Lemma NAG-002487 shows that every such point has kernel 0. Apply Lemma NAG-002488. The two compact sets

$$K_0 = t_F(S), \qquad K_\partial = t_F(\partial_K W)$$

are disjoint. Compactness of the boundary follows from compactness of W and openness of affinoid interior.

Let O be an open neighborhood of $t_f(V)$ on which α is defined, and let π denote projection to the original f coordinates. On $\pi^{-1}O$ put $\widetilde{\alpha} = \pi^*\alpha$. Ordinary real bump functions give a single

$$\chi \in C_c^\infty\big(\pi^{-1}O \setminus K_\partial\big), \qquad \chi = 1 \text{ on a neighborhood of } K_0.$$

For example, a finite collection of real balls with closures in that open set covers K_0; standard smooth bumps and their finite product complement give such a function. Extend $\eta = \chi\widetilde{\alpha}$ by zero to the entire enlarged moment space. It is a smooth compactly supported superform, and

$$\beta|_W = t_F^*\eta \tag{F7.6}$$

as an ordinary section: near S the factor is 1; off S the germ of β is zero, so multiplication preserves zero. Unit-adjunction faithfulness and the ordinary germ sheaf justify this identity without any equality of ambient coefficients away from the actual source support.

The domain W is pure of analytic dimension d by v036:analytic:domainpurity. Put $M_W = M \otimes_A \mathcal{O}(W)$. The support of $d'\beta$ is contained in S, and W is an ordinary neighborhood of S in V. Compact-neighborhood and chart independence in v037:forms:compactintegral give

$$\mathcal{I}_{M,f}(d'\alpha) = \int_{V,\widetilde{M}} d'\beta = \int_{W,\widetilde{M_W}} d'(\beta|_W) = \mathcal{I}_{M_W,F}(d'\eta). \tag{F7.7}$$

The support of η is compact in $\mathbb{R}^{n+N} \setminus t_F(\partial_K W)$. Write $U_F = \mathbb{R}^{n+N} \setminus t_F(\partial_K W)$. For the primitive η of bidegree $(d-1,d)$, the support of $d'\eta$ is also compact in U_F. Use the finite-module chain and the finite-cell sum for its weights and for its integral. On U_F the local module cycle of v037:analytic:interiorcycle uses the same weights: on each common top cell the generic point lies in the same flat tangent plane and its entire F-fibre in W is absolutely interior. Both coefficients are the weight of M_W on that fibre by v037:degree:moduleweight. A finite refinement on the compact part of the actual image meeting the test support therefore gives identical top-cell integrals, with the same saturated tangent lattices and no contribution from smaller cells (v037:integration:polyhedralcalculus). Thus the last quantity in (F7.7) equals the whole-interior integral $I_{M_W,F}(d'\eta)$, which is zero by v037:integration:momenttests. □

Theorem NAG-002495 (Affinoid boundary-germ annihilation)**.** *For every pure d-dimensional generalized affinoid $V = \mathcal{M}(A)$, $d \geq 1$, every finite A-module M, every global unit tuple f, and every smooth ambient $(d-1,d)$-representative α near $t_f(V)$, implication (F7.2) holds. Nonreduced and reducible A, connected actual moment fibers, trivial valuation, and arbitrary positive radii are allowed.*

Proof. For $\mathfrak{p} \in \operatorname{Min}(A)$ let

$$V_{\mathfrak{p}} = \mathcal{M}(A/\mathfrak{p}), \quad i_{\mathfrak{p}} : V_{\mathfrak{p}} \longrightarrow V, \quad \ell_{\mathfrak{p}}(M) = \operatorname{length}_{A_{\mathfrak{p}}} M_{\mathfrak{p}}.$$

These are actual complete quotient algebras by fnd:generalizedaffinoidquotients. Each is integral and pure of analytic dimension d. The finite

map $i_{\mathfrak{p}}$ is everywhere relatively interior. The exact formula `fnd:affinoidinteriorcompositionequality` yields

$$\operatorname{Int}(V_{\mathfrak{p}}/K) = i_{\mathfrak{p}}^{-1}\operatorname{Int}(V/K), \qquad \partial_K V_{\mathfrak{p}} = i_{\mathfrak{p}}^{-1}(\partial_K V). \tag{F7.8}$$

Thus $i_{\mathfrak{p}}^{*}\beta$ vanishes near $\partial_K V_{\mathfrak{p}}$.

For completeness the componentwise chain identity is

$$\mathcal{T}_f(M) = \sum_{\mathfrak{p}\in\operatorname{Min}(A)} \ell_{\mathfrak{p}}(M)\,\mathcal{T}_{f|V_{\mathfrak{p}}}(A/\mathfrak{p}). \tag{F7.9}$$

To see this, choose a finite common subdivision of the actual images of V, all $V_{\mathfrak{p}}$, and their boundary images, using `v037:globaltrop:finiteimage`. At a generic point of a d-cell the whole relevant fibers are interior and their images lie in the same affine d-plane. The coefficient equality is exactly `v037:degree:moduleweight`. Together with the finite-module chain and weights, this gives (F7.9) on all top cells. Cells of smaller dimension carry no d-chain term.

For each $\mathfrak{p}$, apply Proposition NAG-002492 to $A/\mathfrak{p}$ with its structure module and the tuple $i_{\mathfrak{p}}^{*}f$. Use the same α near the compact image of this tuple. Its ordinary pullback is $i_{\mathfrak{p}}^{*}\beta$, which vanishes near $\partial_K V_{\mathfrak{p}}$ by (F7.8). Each component integral therefore vanishes. The finite-cell functional applied to $d'\alpha$ in (F7.9) gives

$$\mathcal{I}_{M,f}(d'\alpha) = \sum_{\mathfrak{p}} \ell_{\mathfrak{p}}(M)\,\mathcal{I}_{A/\mathfrak{p},f|V_{\mathfrak{p}}}(d'\alpha) = 0.$$

All generic lengths, including nilpotent contributions, are retained. These closed components are used for a finite linear identity, not as an affinoid-domain cover. □

Finite localization on actual intersections

Lemma NAG-002578 (Minimal evaluation kernels on the relevant support)**.** *Let $V = \mathcal{M}(A)$ be pure of analytic dimension $d \geq 1$, let $x \in \operatorname{Int}(V/K)$, and let $t_f^{*}\alpha$ have bidegree $(d-1, d)$. If its ordinary germ at x is nonzero, then*

$$s_f(x) = d, \qquad \ker(x) \in \operatorname{Min}(A),$$

where $s_f(x)$ is the graded transcendence degree of the field generated by the initial forms of the $f_i(x)$.

Proof. The interior-only theorem NAG-002455, v038:pointed:fullstabilization, gives the germ of the actual moment image as a pure $s_f(x)$-dimensional fan. After shrinking an ordinary affinoid neighborhood into a small inverse moment ball, its entire image has this dimension. If $s_f(x) < d$, all tangential restrictions of the second alternating degree d vanish, so the ordinary germ is zero. The global finite-image dimension bound v037:globaltrop:finiteimage gives the reverse bound $s_f(x) \le d$. Thus $s_f(x) = d$.

Put $\mathfrak{q} = \ker(x)$. The algebra A is Noetherian by fnd:generalizedclosedsubmodules, so it has finitely many minimal primes, say $\mathfrak{p}_1, \dots, \mathfrak{p}_r$. We use the elementary prime-existence and finiteness facts Stacks 00E0(4) and Stacks 00FR. Suppose that $\mathfrak{q}$ is none of the $\mathfrak{p}_i$. Then $\mathfrak{q} \not\subseteq \mathfrak{p}_i$ for every i; otherwise minimality, using a minimal prime in $\mathfrak{q}$, would force equality. Choose $a_i \in \mathfrak{q} \setminus \mathfrak{p}_i$. By incomparability of the minimal primes choose

$$c_i \in \bigcap_{j \neq i} \mathfrak{p}_j \setminus \mathfrak{p}_i$$

as a product of elements of $\mathfrak{p}_j \setminus \mathfrak{p}_i$; use $c_i = 1$ when $r = 1$. Then $a = \sum_i a_i c_i$ belongs to $\mathfrak{q}$ and to none of the minimal primes: modulo $\mathfrak{p}_i$, only the nonzero product $a_i c_i$ remains.

The actual quotient $Z = \mathcal{M}(A/(a))$ contains x and has analytic dimension at most $d - 1$, by v037:degree:exceptionalimage. The finite closed immersion $Z \to V$ is everywhere relatively interior, and composition gives $x \in \mathrm{Int}(Z/K)$. Here we use fnd:generalizedfinitealgebras and fnd:affinoidinteriorcalculus. The completed residue field at this point of Z, and all initial forms of the restricted f_i, are unchanged. The same interior pointed-fan theorem, which permits nonpure Z, therefore gives a pointed image dimension $s_f(x) = d$ on Z. This contradicts the dimension bound for $t_f(Z)$ in the exceptional-image theorem. Hence $\mathfrak{q}$ is a minimal prime. □

Lemma NAG-002579 (A compact bump with one moment presentation)**.** *Let X be good and Hausdorff, let $V = \mathcal{M}(A)$ be an ordinary affinoid neighborhood of x, and suppose*

$$x \in \mathrm{Int}(V/K), \qquad \ker(x) = \mathfrak{p} \in \mathrm{Min}(A).$$

Given an ordinary open neighborhood O of x in X, there exist an affinoid domain $W \subseteq V$, containing an ordinary neighborhood of x in X, analytic

units g on W, and a smooth real function Φ on their moment space such that the scalar section $b_W = t_g^*\Phi$ has the following properties:

$$0 \le b_W \le 1, \qquad b_W = 1 \text{ near } x,$$
$$\operatorname{supp}_W(b_W) \subseteq C, \qquad C \text{ compact},$$
$$C \subseteq O \cap \operatorname{Int}_{\mathrm{top}}(W, X) \cap \operatorname{Int}(W/K).$$

It extends by zero to a global $b \in \mathcal{A}_X^{0,0}(X)$. The restriction of this extension to all of W is b_W. If a form is represented by one tuple on V, it remains represented by that tuple on W.

Proof. Choose $h \in A \setminus \mathfrak{p}$ lying in every other minimal prime, using the same finite product construction; take $h = 1$ if there are no other minimal primes. Then $|h(x)| > 0$. Choose $0 < \delta < |h(x)|$ and put

$$V_0 = \{y \in V : |h(y)| \ge \delta\}.$$

This is an actual Laurent domain. Every evaluation kernel on V_0 contains $\mathfrak{p}$: it contains a minimal prime, and the other ones contain h. Thus every element of $\mathfrak{p}$ has value zero *throughout* V_0.

Choose a basic ordinary neighborhood G of x in V, given by finitely many strict upper bounds and positive strict lower bounds on elements of A, with

$$G \subseteq O \cap \operatorname{Int}_{\mathrm{top}}(V, X) \cap \operatorname{Int}(V/K).$$

The evaluation-topology neighborhood basis and openness of affinoid interior justify this choice. If a function in these conditions vanishes at x, it lies in $\mathfrak{p}$; its only possible condition is a positive upper bound, automatically satisfied on V_0. Delete these conditions when working in V_0. Every remaining function is nonzero at x.

Adjoin the condition $|h| > \delta$ and positive lower bounds smaller than the values at x for all remaining functions. Adding finite upper bounds larger than their values at x, if necessary, gives a list $g_1, \dots, g_N$ of elements of A, nonzero at x, and real intervals (l_j, u_j) with

$$0 < l_j < |g_j(x)| < u_j < \infty.$$

Their simultaneous strict locus G' contains x, lies in V_0, and satisfies $G' \subseteq G$. For each j choose

$$l_j < L_j < |g_j(x)| < U_j < u_j.$$

Set

$$W = \{y \in V : L_j \le |g_j(y)| \le U_j \text{ for every } j\}.$$

The actual rational-domain point and joint-presentation theorems make W an affinoid domain. It is an ordinary neighborhood of x in X, since its inequalities are strict at x and $x \in \mathrm{Int}_{\mathrm{top}}(V, X)$. Each $g_j|_W$ is a unit, with inverse supplied by its Laurent presentation. Moreover $W \subseteq G$.

Choose $0 \le \Phi_j \le 1$ smooth with compact support in $(-\log U_j, -\log L_j)$, equal to 1 near $-\log|g_j(x)|$, and put $\Phi = \prod_j \Phi_j$. These real profiles are those constructed in v037:forms:smoothcutoff. The compact set

$$C = t_g^{-1}(\operatorname{supp}\Phi) \subseteq W$$

contains the support of $b_W = t_g^*\Phi$. Every point of C satisfies all defining inequalities of W strictly. Thus $C \subseteq \mathrm{Int}_{\mathrm{top}}(W, X)$: use the strict locus in V and $W \subseteq \mathrm{Int}_{\mathrm{top}}(V, X)$. Also $C \subseteq \mathrm{Int}(V/K)$. The domain-interior theorem and composition give $C \subseteq \mathrm{Int}(W/K)$.

Finally glue b_W on $\mathrm{Int}_{\mathrm{top}}(W, X)$ to zero on $X \setminus C$. These are an ordinary open cover of X and the sections agree on the overlap. The ordinary sheaf theorem gives a global smooth moment function b. On $W \setminus C$ both its restriction and b_W are zero locally, so they agree on all of W. Compactness of C and Hausdorffness of X are essential for this zero-extension argument. □

Lemma NAG-002580 (Extension with a compact collar)**.** *Let $W \subseteq X$ be an affinoid domain in a good Hausdorff space, and let $\theta \in \mathcal{A}^{p,q}(W)$ have support in a compact set $C \subseteq \mathrm{Int}_{\mathrm{top}}(W, X)$. There is a unique extension $e_!\theta$ on X with support contained in C and restriction θ on W. It is zero outside W and satisfies*

$$d' e_!\theta = e_! d'\theta, \qquad d'' e_!\theta = e_! d''\theta, \qquad J e_!\theta = e_! J\theta.$$

All displayed supports lie in C. If X is pure of dimension d, $\mathcal{F}$ is coherent, and θ has bidegree (d, d), then

$$\int_{X,\mathcal{F}} e_!\theta = \int_{W,\mathcal{F}|_{W_G}} \theta.$$

Proof. Use the open cover $\mathrm{Int}_{\mathrm{top}}(W, X)$, $X \setminus C$, and glue θ to zero. On their overlap θ has zero ordinary germs. Every differential and J is local on the ordinary sheaf and preserves the zero section, by v037:forms:germsheaf;

hence the same gluing proves the three commutations. At a point of W outside this ordinary interior, the compact set C is absent from a neighborhood, so the resulting restriction still agrees with θ. Uniqueness follows from the same open cover. The integral equality is compact-neighborhood independence in `v037:forms:compactintegral`. No distributional boundary derivative is introduced: the section is already zero on a neighborhood of every newly crossed boundary point. □

Proposition NAG-002581 (Finite single-representative decomposition)**.** *Let X be good, Hausdorff and pure of analytic dimension $d \geq 1$, and let $\beta \in \mathcal{A}_c^{d-1,d}(X)$ have support $S \subseteq \mathrm{Int}(X/K)$. There exist finitely many affinoid domains $W_i \subseteq X$ and global functions $0 \leq b_i \leq 1$ such that:*

1. *the loci on which $b_i = 1$ cover an ordinary neighborhood of S;*
2. *on W_i, both β and b_i have one global unit-moment representative, and $\mathrm{supp}(b_i) \subseteq C_i$ for a compact $C_i \subseteq \mathrm{Int}_{\mathrm{top}}(W_i, X) \cap \mathrm{Int}(X/K)$;*
3. *for $W_I = \bigcap_{i \in I} W_i$, $I \neq \varnothing$, the section*

$$\theta_I = \left(\prod_{i \in I} b_i|_{W_I} \right) \beta|_{W_I}$$

has one global unit-moment representative, with compact support in both ordinary interior and absolute analytic interior:

$$\mathrm{supp}(\theta_I) \subseteq \mathrm{Int}_{\mathrm{top}}(W_I, X) \cap \mathrm{Int}(W_I/K).$$

4. *as ordinary sections on X,*

$$\beta = \sum_{\varnothing \neq I \subseteq \{1,\dots,m\}} (-1)^{|I|+1} e_! \theta_I. \tag{F7.10}$$

Empty domains and zero terms are omitted.

Proof. If $S = \varnothing$, use the empty sum. For $x \in S$, choose an ordinary affinoid neighborhood V_x on which $\beta = t_{f_x}^* \alpha_x$. It is pure of dimension d by `v037:integration:puritylocality`. The point is interior in V_x/K by `fnd:goodinteriorlocaltesting`, since it is interior in X/K and V_x is an ordinary neighborhood. The germ is nonzero, so Lemma NAG-002578 applies. Choose the bump of Lemma NAG-002579, with its ordinary support neighborhood

contained in $\mathrm{Int}(X/K)$. Compactness of S gives finitely many such bumps, with domains W_i, which equal one on neighborhoods covering S. Write

$$\beta|_{W_i} = t_{f_i}^*\alpha_i, \qquad b_i|_{W_i} = t_{g_i}^*\Phi_i.$$

Each W_I is an actual affinoid domain by `v037:integration:separatedintersections`, and every nonempty W_I is pure of dimension d. Choose any $i_0 \in I$. The joint tuple

$$F_I = (f_{i_0}, (g_i)_{i\in I})|_{W_I}$$

consists of units on W_I. A single ambient representative of θ_I is

$$\alpha_I = \left(\prod_{i\in I} \pi_{g_i}^*\Phi_i\right) \pi_{f_{i_0}}^*\alpha_{i_0}, \tag{F7.11}$$

defined near its actual compact image. No extension of an analytic unit from one domain to another has been made; all tuples are restricted to the intersection. The ordinary sheaf and unit-adjunction faithfulness ensure that this representative is the displayed section, independently of the choice of i_0.

Put $C_I = \bigcap_{i\in I} C_i$. It is compact and contains $\mathrm{supp}_{W_I}(\theta_I)$. Every point of C_I lies in all the ordinary interiors of the W_i, and hence in $\mathrm{Int}_{\mathrm{top}}(W_I, X)$. It is also interior in X/K. Applying `fnd:goodinteriorlocaltesting` to this ordinary affinoid neighborhood gives

$$C_I \subseteq \mathrm{Int}(W_I/K).$$

Consequently θ_I is zero on an ordinary neighborhood of $\partial_K W_I$. Indeed C_I is compact and closed and is disjoint from that boundary.

The function

$$P = 1 - \prod_{i=1}^{m}(1 - b_i)$$

equals one on an ordinary neighborhood of S. Thus $\beta = P\beta$ everywhere as an ordinary section: off S its germs are zero. Expand the finite product to obtain (F7.10). The global product $(\prod_{i\in I} b_i)\beta$ is $e_!\theta_I$, by Lemma NAG-002580. This proves all four assertions. □

The global derivative integral

The proof applies the actual finite decomposition (Proposition NAG-002581), compact-collar zero extension (Lemma NAG-002580), and the affinoid input (Theorem NAG-002495).

Proof of Theorem NAG-002577. Put $S = \operatorname{supp}(\beta)$ and apply Proposition NAG-002581. On each nonempty intersection W_I, the resulting $\theta_I = t_{F_I}^{*}\alpha_I$ has compact support inside both the ordinary interior in X and the absolute analytic interior of W_I. Locality keeps the support of $d'\theta_I$ in the same collar. All sums are finite. The commutation in Lemma NAG-002580 gives

$$d'\beta = \sum_{I\neq\varnothing}(-1)^{|I|+1}e_!(d'\theta_I).$$

Let $M_I = \Gamma(W_I, \mathcal{F}|_{(W_I)_G})$. The affinoid coherent-module equivalence `fnd:fullgkiehltheoremb` makes this a finite module with its actual restriction interpretation. Each W_I is a compact carrier for its extended derivative. The compact-carrier and single-chart comparisons in `v037:forms:compactintegral`, with these same restricted coefficients, give

$$\int_{X,\mathcal{F}} d'\beta = \sum_{I\neq\varnothing}(-1)^{|I|+1}\int_{W_I,\widetilde{M}_I} d'\theta_I = \sum_{I\neq\varnothing}(-1)^{|I|+1}\mathcal{I}_{M_I,F_I}(d'\alpha_I).$$

Every summand is zero by Theorem NAG-002495 (AFF). The compact support of θ_I in $\operatorname{Int}(W_I/K)$ gives an ordinary zero neighborhood of the *actual absolute analytic boundary* of W_I. Here W_I is pure of dimension d, F_I is the restricted unit tuple, and α_I is defined near its actual compact moment image. All generic module lengths are retained.

Put $P = 1 - \prod_i(1-b_i)$. If $b_I = \prod_{i\in I} b_i$, the scalar product rule gives

$$d'(b_I\beta) = d'b_I \wedge \beta + b_I\, d'\beta.$$

The scalar b_I has degree zero, so the sign is plus. Summing with $(-1)^{|I|+1}$ gives $d'P \wedge \beta + P\, d'\beta$. Near S, $P = 1$ and $d'P = 0$; off S, both β and $d'\beta$ are locally zero. This is exactly $d'\beta$, as used above. The same check applies to d''.

For the second assertion use the frozen convention `v037:integration:conventions`: all one-form generators anticommute, J exchanges the two copies and fixes functions, and $d'' = Jd'J$. The positive interleaved top generator

$$\omega_N = d'x_1 \wedge d''x_1 \wedge \cdots \wedge d'x_d \wedge d''x_d$$

satisfies $J\omega_N = (-1)^d\omega_N$. On each top cell J changes the coefficient in this same generator by $(-1)^d$ and leaves its weight and lattice measure fixed. Thus the finite-chart integral satisfies $\int J\zeta = (-1)^d\int\zeta$ for top forms ζ. The

section $J\gamma$ has bidegree $(d-1,d)$ and the same support as γ. The proved assertion yields

$$0=\int_{X,\mathcal{F}} d'(J\gamma)=\int_{X,\mathcal{F}} J(d''\gamma)=(-1)^d\int_{X,\mathcal{F}} d''\gamma.$$

This proves the d'' formula with the exact frozen sign. $\square$

Proper direct image on historical ordinary compact tests

Supplement to Chapter 8.

The direct image below uses the pullback of Supplement 8.T4.RA on the support families of Definition 8.15.9 and the ordinary tests of Definition 8.15.10.

Work in the historical refined G-tropical category of 8.T4.RA, with its ordinary smooth real forms and its locally convex final topology for compact supports and interior-covering affine chart families. Write $E_r^{p,q}(Z)$ for the vector space of ordinary smooth (p,q)-forms of compact support on Z, with its C^r test topology. The index $r \in \mathbb{N}_0 \cup \{\infty\}$ specifies the topology on smooth tests. On a fixed stage $(\mathcal{D}, K)$ it uses the subspace topology generated by $\rho_{f,W,m}$ for $f \in \mathcal{D}$, compact chart domains W and $m \le r$, all finite m when $r = \infty$. A current of bidimension (p,q) is an element of $D_{p,q}(Z) = (E_\infty^{p,q}(Z))'$, the continuous real dual. It has order at most $r < \infty$ if its functional is continuous for $E_r^{p,q}(Z)$.

Proposition (Proper direct image)**.** *Let $u : Y \to X$ be a morphism as in* 8.T4.RA*. Suppose $u^{-1}K$ is compact for every ordinary compact subset K of X. For $T \in D_{p,q}(Y)$ the formula*

$$\langle u_* T, \eta \rangle = \langle T, u^* \eta \rangle, \qquad \eta \in E_\infty^{p,q}(X),$$

defines a current of bidimension (p,q) on X. The map u_* is linear and continuous for pointwise convergence on smooth compact tests. It preserves each finite upper bound on order.

Proof. Use all ordinary compact sets as the support families in 8.T4.RA. They contain the empty set and are closed under finite unions and closed subsets. The inverse-support condition follows from the hypothesis on u. A section vanishing on an open has pullback zero on the inverse open, so $\operatorname{supp}(u^*\eta) \subset u^{-1} \operatorname{supp} \eta$. For an input stage $(\mathcal{D}, K)$, 8.T4.RA fixes the interior-covering pullback chart family $\mathcal{E}$ on Y and the compact carrier $u^{-1}K$. The estimate of 8.T4.RA bounds each output seminorm of order m by a constant times an input seminorm of the same order, with the chart and compact restriction fixed before η varies. This gives a continuous linear map into that output stage for every r.

If T is continuous for $E_r^{p,q}(Y)$, its restriction to this output stage is bounded by a constant times the maximum of finitely many defining seminorms.

Substituting the pullback estimates gives a continuous functional on $(\mathcal{D}, K)$ in the input C^r topology. The linear final-topology property gives continuity on $E_r^{p,q}(X)$. For $r = \infty$, the orders in the finite bound may depend on the stage. For finite r, every seminorm used still has order at most r. The formula has the same test bidegree on both spaces, hence preserves bidimension. For pointwise continuity, evaluation of u_*T at a fixed η is evaluation of T at the single fixed test $u^*\eta$. □

Transport of a closed carrier. If $S \subset Y$ is closed and T vanishes on all compact tests supported in $Y \setminus S$, then $u(S)$ is a closed carrier for u_*T in the same sense. Indeed, for $x \notin u(S)$, take a compact ordinary neighbourhood K of x, using local compactness in 8.T4.RA. The set $u(S \cap u^{-1}K)$ is compact and is closed in the Hausdorff space X. Its complement inside the interior of K is an open neighbourhood of x disjoint from $u(S)$. For a test supported in $X \setminus u(S)$ its pullback is compactly supported in $Y \setminus S$. Apply the defining vanishing of T. In a current convention in which ordinary localization identifies the support as a least closed carrier, taking $S = \operatorname{supp} T$ gives $\operatorname{supp}(u_*T) \subset u(\operatorname{supp} T)$.

Compatibility with the usual chart differentials. For the two exterior differentials d' and d'' on the ordinary chart coefficients, tangential restriction and affine pullback commute with the operators by the constant-coefficient chain rule on the two factors. Computing on each cell shows that this descends to intrinsic coefficients: if a tangential coefficient vanishes there so do its tangential derivatives. Applying a differential preserves the support carrier and the chart family. Each order-m seminorm after application is bounded by a constant times the order-$(m+1)$ seminorm before application, by the coordinate formula for exterior differentiation. This gives continuity on the smooth compact tests and defines the two transposed differentials on currents. The transpose uses the Reader sign $(-1)^{a+b+1}$ on a current of bidegree (a, b). In bidimension (p, q) the sign is $(-1)^{p+q+1}$, since a space of level l has $a + b = 2l - p - q$. For a test of degree $(p-1, q)$ the two pairings for $d'u_*T$ and $u_*d'T$ are therefore

$$(-1)^{p+q+1}\langle T, u^*(d'\eta)\rangle \quad \text{and} \quad (-1)^{p+q+1}\langle T, d'(u^*\eta)\rangle.$$

The chart chain rule makes them equal. With a test of degree $(p, q-1)$ the same argument applies to d''; a negative test degree denotes the zero space.

Degree-zero descent for a finite rational cover

Let A be a norm-admissible generalized affinoid algebra over a complete real-valued non-Archimedean field K, including the trivially valued case. Take a finite rational cover of $\mathcal{M}_K(A)$ with defining rows $(g_i, f_{ia}; \rho_{ia})$, where $(g_i, (f_{ia})_a) = A$ and every $\rho_{ia} > 0$. For each one- or two-index list J, use the actual quotient B_J obtained by imposing all rows in the list, with separate variable blocks and equations $g_i T_{ia} = f_{ia}$. Use matched coefficient and quotient norms for the proof, and transport boundedness to any prescribed equivalent admissible norms. For the free rank-one coefficient $M = A$, the sequence

$$0 \longrightarrow A \xrightarrow{u} C^0 = \prod_i B_i \xrightarrow{\delta} C^1 = \prod_{i<j} B_{ij}, \qquad \delta(z)_{ij} = z_j|_{ij} - z_i|_{ij},$$

is exact through C^0, and u has bounded inverse onto its closed image. Products carry the maximum norm. In particular u identifies the structure algebra with the bounded equalizer of the two restrictions on every actual pair intersection.

Terms and arrows. The weighted coefficient algebra and its actual closed relation ideals use the selected NAG-001554 coefficient clause with NAG-001552 and NAG-001560. The restrictions $B_i \to B_{ij}$ send the variables to the corresponding block. Quotient infima give contractions with the matched norms. The actual two-block joint is the bounded Banach pushout: compatible bounded maps from the two rows supply scaled bounds on powers of all their variable images. Substitution by NAG-001398, the equations and quotient infima give the unique bounded joint map. This also identifies the joint with the separated completed algebra tensor, if that convention is used, as in NAG-001578. On finite balanced sums the product of the two structural maps is bounded for the projective seminorm, and the variable substitutions give the inverse on the actual joint and on dense pure tensors. All these comparisons retain the two structural maps.

For rank one the module terms are just the same actual Banach algebras. Multiplication identifies $B_J \otimes_A A$ with B_J, with inverse $b \mapsto b \otimes 1$. Both maps are contractive for the matched projective and coefficient norms, by the finite tensor estimate and the pure tensor representatives, respectively. Since B_J is complete, the separated completion gives the same term and the

same restrictions. Equivalent norms give the bounded version of the same comparison.

One free scalar extension and simultaneous powered rows. Use the reviewed extra-radii clause of NAG-001557 with one closed presentation of A and all the radii in the finite cover. Over the resulting free field $L = K_r$, put $R = A_L$. It is strict if nonzero. There are $N \geq 1$ and $c_{ia} \in L^\times$ with $|c_{ia}| = \rho_{ia}^N$. The reviewed NAG-001580 algebra and existing-map clause identifies $(B_J)_L$ with the actual weighted quotient of the same lists over R. It carries the bounded restrictions and augmentation just defined to their coefficient extensions.

In the weighted quotient each g_i with $i \in J$ is a unit by the row's unit-ideal identity. In the upper unit-radius quotient P_J, use the simultaneous rows

$$g_i^N W_{ia} = c_{ia}^{-1} f_{ia}^N \qquad (i \in J).$$

Each powered tuple generates the unit ideal: in a sufficiently high power of the original unit-ideal identity every monomial contains an N-th power of some generator. Hence every g_i^N, and thus g_i, is a unit in P_J. Sending W_{ia} to T_{ia}^N/c_{ia} gives a contraction to the weighted joint. In the other direction put $b_{ia} = f_{ia}/g_i$ in P_J. For $m = Nq + j$ with $0 \leq j < N$,

$$\|b_{ia}^m\| \leq \rho_{ia}^m \max_{0 \leq j < N} \rho_{ia}^{-j} \|b_{ia}^j\|.$$

Indeed $b_{ia}^N = c_{ia} W_{ia}$. Bounded substitution descends through the actual relations and sends T_{ia} to b_{ia}. The composites are identities by the equations and density. These are the NAG-001507 maps on the actual single and joint rows. They commute with every block inclusion because they fix R and use the same formula for each shared variable. The zero quotients satisfy the same identities. Every powered row has the original inequalities over R by NAG-001444. The upper family therefore covers because each upper spectral point restricts to a point of A. If the original cover is empty, NAG-001452 and the isometric constant embedding force $A = 0$. We treat a zero base or coefficient quotient by its zero algebra.

The upper ordered equalizer, including nonzero intersections. For a nontrivially valued L, use the finite product refinement of NAG-001474 on the powered unit-radius rows. Write the powered row as (p_{i0}, p_{ia}), with

$p_{i0} = g_i^N$. Index the standard tuple by λ having at least one zero slot, with $F_\lambda = \prod_i p_{i,\lambda_i}$. At a point of R, choose a coarse member containing it, use the denominator in that slot, and choose a nonvanishing entry of each other unit-ideal tuple. This gives a nonvanishing F_λ. NAG-001452 gives the unit-ideal condition for the standard tuple, so its standard quotients S_λ cover by taking maxima.

Choose once a zero slot $k(\lambda)$ of each λ. At a point of S_λ, if a containing coarse row is $i \neq k$, replace slot i by zero and slot $k = k(\lambda)$ by any numerator index a. The defining maximal inequality gives

$$\left|\frac{p_{i0}}{p_{i,\lambda_i}}\right| \left|\frac{p_{ka}}{p_{k0}}\right| \leq 1.$$

The factors divided by are nonzero since F_λ is nonzero. The first factor is at least one since the point lies in row i. When $i = k$ the desired inequality already holds. Thus the point lies in the chosen row k. The corresponding bounded map $P_k \to S_\lambda$ follows on the actual strict S_λ by NAG-001452 for invertibility of the denominator, the selected NAG-001457(1)⇒(4) for scaled ratios of radius one, and the reviewed NAG-001443/001442 supplied-power substitution. For a zero target the map is the unique zero map.

All strict mixed and pair restrictions are the concatenations of their actual relation lists, or the successive quotients with the same norms and arrows by NAG-001434 and NAG-001437. In the unit-radius product version of NAG-001471 the additional pair-product variable maps to the product of the two separate variables. Each original denominator is a unit after imposing its own row, and the product denominator is a unit in the product version. The substitutions in both directions are contractive and preserve the original blocks and all equations. In particular two owner maps into a standard joint give a bounded map from the actual coarse joint to that standard joint. There is generally a nonzero joint when the owners differ. For the mixed term P_i, S_λ, keep both lists even when $i \neq k(\lambda)$. If the owner is i, its coarse row is redundant by the already supplied power bounds, with bounded inverse to adjoining it. The restricted standard family over P_i is the image of the same unit-ideal tuple (F_λ) in that actual algebra.

Here is the degree-zero part of the standard-family argument NAG-001473 used over R and over each nonzero P_i. For a unit tuple, apply selected NAG-001462 to the fixed signed list of pair ratios at radius one. Each leaf maps boundedly from a standard member with all its ratios of norm at most one by the directed-path calculation of NAG-001467. The leaf maps remain valid

under further quotients. A matching standard tuple thus gives a matching signed tuple, since on a signed pair both standard blocks can be adjoined and eliminated by bounded substitution. Glue by the signed ordered equalizer. To verify each standard entry, test the resulting section on the signed family over that very standard algebra. The signed augmentation there is injective by NAG-001462 applied afresh. This gives a bounded inverse, and injectivity follows by the signed tests.

For a general unit-ideal tuple F_λ, choose $\sum a_\lambda F_\lambda = 1$ and $0 < |\kappa|$ with $\theta = |\kappa| \max_\lambda \|a_\lambda\| < 1$. Take all signs on F_λ/κ. On a leaf write its relations as $F_p = \kappa X_p$ for positive indices and $F_n X_n = \kappa$ for negative ones. For a positive denominator F_p, in its joint with that leaf set $T_p = 1$. The relation ideal contains $1 - \kappa X_p \sum_\lambda a_\lambda T_\lambda$, a unit by the geometric series (NAG-000184) since the subtracted term has norm at most θ. An all-positive leaf is itself zero by the same argument with $1 - \kappa \sum a_\lambda X_\lambda$. For a negative denominator F_n, its inverse is X_n/κ, and each positive numerator gives $F_p/F_n = X_p X_n$ of norm at most one. Eliminating precisely these redundant variables gives the actual standard family of the remaining units. These norm-one substitutions persist on every further joint leaf with its other blocks retained. This replays the NAG-001468 small-scalar calculation.

A matching standard tuple glues on each leaf by the unit case just proved. On a joint of two leaves the two glued values restrict to the same standard entries. The standard family on that joint is again a unit family after the same eliminations from either one of its leaves. Its injective augmentation gives equality on the actual joint. Glue the leaf tuple by NAG-001462. Now apply its augmentation injection to the signs over each actual standard member to check the prescribed standard values. The inverse bound is finite: take the maximum of the finitely many leaf inverse bounds and multiply by the signed inverse bound on the base. This proof supplies the needed degree-zero equalizer and injection over each actual strict base used above, without applying coefficient change to an exact complex.

Given a matching coarse tuple, restrict its owner entries to the standard members. On a joint of two standard members the entries match by the map from the actual coarse pair, including when that pair is nonzero. Glue by the standard equalizer over R. On each P_i, compare its prescribed entry with the glued section on every mixed P_i, S_λ. Equality follows from the original coarse matching condition after mapping $P_{i,k(\lambda)}$ to that mixed joint. For repeated owners both restrictions come from the same entry. Injectivity of

the restricted standard augmentation over P_i then gives the prescribed coarse value. Global injectivity follows by testing over the standard members, and the inverse bound is the standard bound times the maximum owner-map bound. All bounds concern the fixed finite data.

If L is trivially valued, use a defining strict quotient norm. Unit-radius Tate coefficient rings then consist of polynomials, with norm one on nonzero classes. Write d_i for the powered denominators. The unit-ideal identities identify P_i and P_{ij} with $R[1/d_i]$ and $R[1/(d_i d_j)]$, respectively, with the ordinary restriction maps. At every maximal ideal the trivial residue seminorm is bounded for this defining norm. The cover implies that some d_i is nonzero there, so the d_i generate the unit ideal. To glue a matching tuple, write its entries a_i/d_i^m with a common exponent $m \geq 1$. Pair equality allows clearing all pair differences by a common power of $d_i d_j$. Increasing the exponent and the numerators accordingly yields entries b_i/d_i^n with $d_j^n b_i = d_i^n b_j$ in R. Choose $\sum e_i d_i^n = 1$. Then $\sum e_i b_i$ has all the prescribed localizations. Injectivity follows because an element vanishing in each localization is killed by fixed powers of all d_i, which still generate the unit ideal. The inverse is bounded for the discrete norms. Equivalent admissible norms preserve the finite inverse bound.

Kernel and norm-controlled descent. Use the coefficient description NAG-001549 with the fixed free tuple r. Finite products commute isometrically with the weighted Laurent c_0 coefficient spaces. The upper complex, before power conversion, has differential δ_L acting as δ on each Laurent coefficient, including the displayed sign. Indeed NAG-001580 identifies both actual maps into each actual pair algebra, and the power comparisons commute with these maps. For $E = \ker \delta$, give E its induced norm. It is closed because δ is bounded. In coefficient norms the equality

$$E \widehat{\otimes}_K L \;\simeq\; c_0(\mathbf{Z}^{|r|}, r; E) \;=\; \ker \delta_L$$

is isometric: a coefficient family has zero difference exactly when every coefficient belongs to E, and the weighted norm and finite-tail condition are inherited. Transport to the powered diagram by the bounded inverse comparison maps.

For $z \in E$, the constant coefficient family is an upper matching tuple. The upper equalizer yields a preimage $w \in A_L$ with $\|w\| \leq Q\|z\|$, where Q includes the finite norm comparison factors. Naturality of the contractive

linear zeroth coefficient gives $u(p_0 w) = z$ and $\|p_0 w\| \leq Q\|z\|$. Upper injectivity and isometric constant embedding give injectivity of u. Thus the image is the closed kernel E and the augmentation has the asserted inverse norm. The inverse is an algebra map because it inverts the algebra map $u : A \to E$.

Final-space and coefficient estimates

Example C.1.10 (Finality cannot be omitted)**.** Let $E = \mathbb{R}^{(\mathbb{N})}$ be the finitely supported sequences, but give it the ℓ^2 norm topology. Let E_N consist of sequences supported in $\{1, \dots, N\}$ and let $D_m(x) = x_m$. Every D_m is continuous; $D_m|_{E_N} = 0$ for $m > N$; and $D_m(x)$ is eventually zero for each x. Nevertheless $D_m \not\to 0$ in the strong dual of this normed space.

Proof. The unit vectors form a bounded set $B = \{e_m : m \geq 1\}$ and $\sup_{b \in B} |D_m(b)| = 1$ for every m. The norm topology is strictly coarser than the locally convex final topology of the inclusions E_N: the seminorm $x \mapsto \sum_{m \geq 1} m|x_m|$ is continuous on every E_N, hence final-continuous, but is unbounded on the norm-bounded set B. With the final topology, this B is not bounded. □

Example C.1.11 (No presentation-independent extension constant)**.** Even integral finite polyhedral complexes with weight one can require unbounded constants in estimates of an ambient quotient seminorm by finitely many intrinsic seminorms. For $k \geq 1$, put

$$v_k = (k, 1), \quad w_k = (k{+}1, 1), \qquad P_k = \{tv_k : |t| \leq (k{+}1)^{-1}\} \cup \{tw_k : |t| \leq (k{+}1)^{-1}\}.$$

Subdivide at the origin and use the primitive integral tangent vectors on the segments. In scalar degree, let a_k be the restriction of $x - ky$. Every intrinsic derivative seminorm of order at least one is at most one, but every ambient representative has coefficient C^1 seminorm at least k on any compact neighbourhood of the origin.

Proof. On the v_k-segment the restriction is zero, and on the w_k-segment it is t. The values are bounded by $(k+1)^{-1}$, first tangential derivatives have absolute value at most one, and all higher derivatives vanish. If F is any ambient representative, its gradient at zero satisfies

$$kF_x(0) + F_y(0) = 0, \qquad (k+1)F_x(0) + F_y(0) = 1.$$

Thus $F_x(0) = 1$ and $F_y(0) = -k$. Taking the quotient infimum does not remove this lower bound. The two vectors are primitive and their matrix determinant is -1; each line has two opposite rays, so unit weights balance at the central vertex. The outer endpoints are simply truncation boundaries. □

Closed-fibre lengths

Lemma C.1.12 (Closed-fibre length; F8ST-L)**.** *Let $(R,\mathfrak{m}) \to (S,\mathfrak{n})$ be a flat local map of Noetherian rings. Suppose $S/\mathfrak{m}S$ is Artinian. For every finite-length R-module M,*

$$\operatorname{length}_S(M \otimes_R S) = \operatorname{length}_R(M)\, \operatorname{length}_S(S/\mathfrak{m}S). \tag{C.1.9}$$

If the map is regular and the closed fibre is zero-dimensional, its closed fibre is a field and the last factor is one. In particular a regular local map between Artinian rings preserves these lengths.

Proof. Tensor a composition series of M with S. Flatness preserves its injections and quotients; every quotient is $S/\mathfrak{m}S$. Additivity of finite length gives (C.1.9). A zero-dimensional regular local ring has zero maximal ideal, hence is a field. Thus $\mathfrak{m}S = \mathfrak{n}$ in the regular case. A local map is faithfully flat when it is flat, so a nonzero composition factor is never lost. □

Lemma C.1.13 (Regular elements avoid minimal primes; F8ZP-N)**.** *Let A be a nonzero ring and suppose multiplication by $f \in A$ is injective. Then $f \notin \mathfrak{p}$ for every $\mathfrak{p} \in \operatorname{Min}(A)$.*

Proof. Localization preserves the injection. If $f \in \mathfrak{p}$, its image in the nonzero ring $A_{\mathfrak{p}}$ belongs to the unique prime of that ring and is therefore nilpotent, by the nilradical criterion. A nilpotent element cannot act injectively on a nonzero ring: iterating an injective multiplication would make the zero multiplication injective. This contradiction proves the assertion. No associated-prime or S_1 assertion is used. □

Proposition C.1.14 (Full lengths at a regular principal prime; F8CR-L)**.** *Let A be Noetherian, let $f \in A$ be a non-zero-divisor, and let $\mathfrak{p}$ be minimal over (f). Then $R = A_{\mathfrak{p}}$ has Krull dimension one, f is a regular nonunit in R, and R/fR is Artinian. For $\mathfrak{q}_i \in \operatorname{Min} A$ contained in $\mathfrak{p}$, put $m_i = \operatorname{length}_{A_{\mathfrak{q}_i}} A_{\mathfrak{q}_i}$. Then*

$$\operatorname{length}_{A_{\mathfrak{p}}}(A_{\mathfrak{p}}/fA_{\mathfrak{p}}) = \sum_{\mathfrak{q}_i \subset \mathfrak{p}} m_i \operatorname{length}_{(A/\mathfrak{q}_i)_{\mathfrak{p}/\mathfrak{q}_i}} \left((A/\mathfrak{q}_i)_{\mathfrak{p}/\mathfrak{q}_i}/f_i\right). \tag{C.1.10}$$

No S_1 hypothesis on A is made. The proof uses Stacks 00E0(7) with the zero ideal for the nilradical steps in the local rings and quotients, 00KV(1) for the height bound, and 02QG, second clause with $I = 0$, for the length formula.

Proof. A regular element avoids every minimal prime $\mathfrak{q}$: in the nonzero zero-dimensional local ring $A_{\mathfrak{q}}$, an element of its maximal ideal is nilpotent, whereas an injective multiplication map cannot be nilpotent. Localization preserves injectivity. By 00KV(1), $\operatorname{ht}\mathfrak{p} \leq 1$; height zero would make $\mathfrak{p}$ minimal in A, which was excluded. Thus $\dim R = 1$. Minimality over (f) says that the only prime of R containing f is its maximal ideal. Hence R/fR is zero-dimensional Noetherian local and Artinian. The element f is not a unit there and remains regular. In particular R has depth one and is Cohen–Macaulay, although the second clause of 02QG already uses exactly the hypotheses just checked.

The minimal primes of R are precisely $\mathfrak{q}_i R$ with $\mathfrak{q}_i \subset \mathfrak{p}$. Indeed, localization of a minimal prime contained in $\mathfrak{p}$ is minimal, and contraction identifies all such primes. Each has one-dimensional quotient in R: a zero-dimensional local quotient would force $\mathfrak{q}_i R$ to be the maximal ideal, contrary to $f \notin \mathfrak{q}_i R$. Also $R_{\mathfrak{q}_i R} = A_{\mathfrak{q}_i}$. Apply 02QG with this Noetherian local R, $x = f$, and $I = 0$. Its generic factors are exactly m_i. Its other factors are $\operatorname{length}_R R/(f, \mathfrak{q}_i R)$. Computing this length over the quotient local ring $R/\mathfrak{q}_i R$ changes no composition factors; both have residue field $\kappa(\mathfrak{p})$. This gives (C.1.10), with no extra residue-degree factor. This argument says nothing about embedded primes in other localizations of A. □

Let K be a complete non-Archimedean field with its specified absolute value. Trivial valuation, positive characteristic, and generalized affinoid radii are allowed. All rings are commutative with identity; all modules in the assertions are finite over the indicated Noetherian ring. "Regular function" means non-zero-divisor, not smooth function. A regular ring map is flat with geometrically regular algebraic fibres. We use ordinary local rings on good analytic spaces. A finite module M satisfies S_1 if

$$\operatorname{depth}_{R_{\mathfrak{p}}} M_{\mathfrak{p}} \geq \min\{1, \dim \operatorname{Supp}_{R_{\mathfrak{p}}} M_{\mathfrak{p}}\} \quad (\mathfrak{p} \in \operatorname{Supp} M).$$

This is a condition at all localizations, including the localizations of an ordinary analytic stalk.

Local algebra used in Serre comparison. Let $(R, \mathfrak{m})$ be a Noetherian local ring and M a nonzero finite module. If an element r kills a nonzero element of M, choose a nonzero element v in its kernel whose annihilator is maximal among those annihilators. This annihilator is prime. Indeed, if $abv = 0$ and $bv \neq 0$, then bv is in the same kernel, and its annihilator contains

both the annihilator of v and a. Maximality forces a into the annihilator of v. Thus the zero divisors on M are the union of its associated primes.

These primes are finite. Repeatedly choose an element with prime annihilator in the current nonzero quotient module, and add its cyclic submodule to a filtration. The process terminates by Noetherianity. An embedded copy of $R/\mathfrak{p}$ in a module either meets a given submodule nontrivially, in which case the intersection has a nonzero element with annihilator $\mathfrak{p}$, or maps injectively to the quotient. Applying this to the filtration shows that all associated primes occur among its cyclic factors.

If M has depth zero, every element of $\mathfrak{m}$ is a zero divisor on M. Discard contained primes from the finite union and write the remaining incomparable primes as $\mathfrak{p}_i$. If $\mathfrak{m}$ is contained in none of them, choose $a_i \in \mathfrak{m} \setminus \mathfrak{p}_i$ and $b_i \in (\bigcap_{j\neq i} \mathfrak{p}_j) \setminus \mathfrak{p}_i$. One can take b_i to be a product of one element from each $\mathfrak{p}_j \setminus \mathfrak{p}_i$, with the empty product one. Then $\sum_i a_i b_i$ is in $\mathfrak{m}$ and in none of the primes, a contradiction. Thus $\mathfrak{m}$ is associated and $R/\mathfrak{m}$ embeds in M.

A nonzero zero-dimensional Noetherian local ring has nilpotent maximal ideal. Its finitely many generators are nilpotent by the nilradical criterion, and their degree bound makes the ideal nilpotent. The ideal-power filtration has finite-dimensional residue-field factors, so the ring is Artinian. The last nonzero power (or the field itself) supplies a nonzero socle. A finite module supported only at the closed point has finite length by the same argument over the quotient by its annihilator. Indeed its support is the vanishing set of that annihilator, as is seen by clearing the local denominators on a finite set of generators.

Lemma C.1.15 (Serre comparison for finite modules; F8ST-S)**.** *Let $R \to S$ be a regular map of Noetherian rings and M a finite R-module. If M is S_1, then $M \otimes_R S$ is S_1. If the map is also faithfully flat, the converse holds. The converse in fact needs only faithful flatness, not regular fibres.*

Proof. For ascent, fix $\mathfrak{q} \in \operatorname{Supp}(M \otimes_R S)$, put $\mathfrak{p} = \mathfrak{q} \cap R$, and work with the flat local map $R_\mathfrak{p} \to S_\mathfrak{q}$. Write $M_0 = M_\mathfrak{p}$ and $N = M_0 \otimes S_\mathfrak{q}$. We need a non-zero-divisor on N in its maximal ideal only when $\dim \operatorname{Supp} N > 0$. If $\dim \operatorname{Supp} M_0 > 0$, the S_1 condition supplies such an element $a \in \mathfrak{p}R_\mathfrak{p}$ on M_0; flatness preserves its injectivity on N.

Otherwise M_0 is nonzero of finite length. Its composition series tensors to a filtration of N by copies of $F = S_\mathfrak{q}/\mathfrak{p}S_\mathfrak{q}$. Hence $\operatorname{Supp} N = \operatorname{Spec} F$. The ring F is regular local. If its dimension is positive, its maximal ideal contains a

nonzero element that is regular on F, because F is a domain (STACKS-00NP). Lift that element to $\mathfrak{q}S_{\mathfrak{q}}$. It is injective on each filtration quotient, and therefore on N. This proves ascent.

For descent, suppose M is not S_1. Choose a prime $\mathfrak{p}$ for which $M_{\mathfrak{p}}$ has positive support dimension and depth zero. There is an injection $\kappa(\mathfrak{p}) \hookrightarrow M_{\mathfrak{p}}$: equivalently, the maximal ideal is associated to this finite local module. In $(R \setminus \mathfrak{p})^{-1}S$, choose a prime minimal over the extension of $\mathfrak{p}$. Such a prime exists by faithful flatness; let $\mathfrak{q}$ be its preimage in S. Its contraction is $\mathfrak{p}$, and $F = S_{\mathfrak{q}}/\mathfrak{p}S_{\mathfrak{q}}$ is a nonzero Artinian local ring. Tensoring the injection gives $F \hookrightarrow N$. The socle of F is nonzero, so $\operatorname{depth} N = 0$.

Choose $\mathfrak{p}_0 \subsetneq \mathfrak{p}$ in $\operatorname{Supp} M$. Flat going down (STACKS-00HS) gives $\mathfrak{q}_0 \subsetneq \mathfrak{q}$ over $\mathfrak{p}_0$. The localized map is faithfully flat, so $(M \otimes_R S)_{\mathfrak{q}_0} \neq 0$. Consequently $\dim \operatorname{Supp} N > 0$, contradicting S_1 upstairs. □

Finite extensions of complete discretely valued fields

Let K be complete for a specified nontrivial discretely valued non-Archimedean absolute value. Put

$$R = K^\circ, \qquad k = R/\mathfrak{m}_R, \qquad \lambda_K = -\log|\pi| > 0$$

for a uniformizer π of R.

Lemma C.1.16 (The valuation-ring factors)**.** *Let L/K be a finite field extension of degree n, with the unique extension of the given absolute value, and put $R' = L^\circ$ and $k' = R'/\mathfrak{m}_{R'}$. Then R' is a complete DVR, finite free of rank n over R. If ϖ is its uniformizer,*

$$\pi = u\varpi^e, \quad u \in (R')^\times, \qquad f = [k' : k], \qquad n = ef, \qquad \lambda_L = -\log|\varpi| = \lambda_K/e.$$

No separability assumption is required.

Proof. The extending absolute value, completeness of L, and equivalence with a coordinate maximum norm follow from Lemma 1.12.1. Write the value groups additively inside $\mathbb{R}$. Elements of $L^\times$ whose values represent distinct cosets modulo $\lambda_K\mathbb{Z}$ are linearly independent over K: in a nontrivial linear relation the nonzero terms would have distinct values, so the smallest could not cancel. Hence the index of $\lambda_K\mathbb{Z}$ in the value group of L is finite, at most n. A subgroup of $\mathbb{R}$ containing this lattice with finite index e is $(\lambda_K/e)\mathbb{Z}$: multiplication by the order of the finite quotient first embeds it in a discrete

cyclic group. Choose ϖ with its least positive value. Every nonzero ideal of R' is generated by an element of least value, so R' is a DVR, and $\pi = u\varpi^e$.

Fix a K-basis of L. The coordinate norm bound puts the unit ball R' inside $\pi^{-N}R^n$ for some integer N. It is an R-submodule and is finite free: for a submodule of R^n, project to one coordinate, whose image is a principal ideal, lift a generator, and apply induction to the kernel in R^{n-1}. This also proves finite generation, without assuming it beforehand. Scaling the chosen basis by powers of π puts it inside R', so the rank is n. The ϖ-adic topology is the induced valuation topology; the closed unit ball is complete.

Consequently $\dim_k R'/\pi R' = n$. Its filtration by $\varpi^j R'/\varpi^e R'$ has e quotients isomorphic to k'. The residue extension is finite (it is a quotient of this finite k-space), and comparison of dimensions proves $n = ef$. The absolute-value formula follows from the displayed equation for π, since a unit of R' has absolute value one. □

Ordinary height-one rings and normalization coefficients

Lemma C.1.17 (Ordinary height-one model local rings)**.** *Let $\mathcal{T}$ be a Noetherian normal integral scheme and x a point of height one. The ordinary algebraic local ring $A = \mathcal{O}_{\mathcal{T},x}$ is a DVR. Its normalized order* $\mathrm{ord}_x : K(\mathcal{T})^\times \to \mathbf{Z}$ *satisfies*

$$\mathrm{length}_A(A/fA) = \mathrm{ord}_x(f) \qquad (0 \neq f \in A).$$

For a rational local equation f/g, its signed divisor coefficient is therefore $\mathrm{ord}_x(f/g) = \mathrm{ord}_x(f) - \mathrm{ord}_x(g)$.

Exact external input: Tag 00PD, Lemma 10.119.7, implication (5) ⇒ (1) and its normalized uniformizer expansion.

Proof. The ring A is local and Noetherian, and normality makes it a normal domain. Height one means $\dim A = 1$. These are exactly condition (5) of Tag 00PD, so condition (1) gives a DVR. For a generator t of its maximal ideal, every nonzero element is ut^n with u a unit. The successive quotients of the t-adic filtration of $A/(t^n)$ are copies of the residue field; hence their total length is n. Subtracting orders gives the assertion for a rational equation. □

For an integral model $\mathcal{T}$ and a codimension-one point v, write $A = \mathcal{O}_{\mathcal{T},v}$. A Cartier divisor with local rational equation $f = a/b \in \mathrm{Frac}(A)^\times$ has coherent cycle coefficient

$$\mathrm{ord}_A(f) = \mathrm{length}_A(A/aA) - \mathrm{length}_A(A/bA).$$

A unit contributes length zero. These lengths are finite, and the formula is independent of a/b: for nonzero a, b the exact sequence $0 \to A/aA \xrightarrow{b} A/abA \to A/bA \to 0$ gives additivity of lengths.

Lemma C.1.18 (Normalization preserves the coefficient with branch weights)**.** *Let A be a one-dimensional Noetherian local domain whose integral closure B in $F = \mathrm{Frac}(A)$ is finite over A. Let $\mathfrak{q}_1, \dots, \mathfrak{q}_r$ be the maximal ideals of B. Their contractions are the maximal ideal $\mathfrak{m}$ of A; each $B_{\mathfrak{q}_j}$ is a DVR. For every $f \in F^\times$,*

$$\mathrm{ord}_A(f) = \sum_{j=1}^{r} [\kappa(\mathfrak{q}_j) : \kappa(\mathfrak{m})] \, \mathrm{ord}_{B_{\mathfrak{q}_j}}(f). \tag{C.1.11}$$

In particular, for nonzero $t \in \mathfrak{m}$,

$$\operatorname{length}_A(A/tA) = \sum_j [\kappa(\mathfrak{q}_j) : \kappa(\mathfrak{m})] \operatorname{length}_{B_{\mathfrak{q}_j}}(B_{\mathfrak{q}_j}/t). \tag{C.1.12}$$

All residue degrees are full degrees; no separable-degree substitution or reduction of the quotient rings is permitted.

Proof input. Finite module length, the affine integral-closure construction, and the proposed Tag 00PD; no determinant or pending F9 claim.

Proof. The finite algebra $B/\mathfrak{m}B$ is Artinian. A prime of B over (0) is (0), since localization by $A \setminus \{0\}$ gives the field F. A prime over $\mathfrak{m}$ is maximal, because its quotient is a finite domain over $A/\mathfrak{m}$, hence a field. A maximal ideal cannot lie over (0): this would make B a field finite over A; a monic equation for $1/t$, with $0 \neq t \in \mathfrak{m}$, would then imply $1/t \in A$. Thus B is Noetherian and semilocal, and each of its maximal localizations is a normal local domain of dimension one. Tag 00PD gives the DVR assertion. The residue extensions are finite because B is finite over A.

The finite A-module $Q = B/A$ is torsion and has finite length. Indeed, clearing the denominators of finitely many generators kills Q by a nonzero element of A; in dimension one its support is contained in $\{\mathfrak{m}\}$. Multiplication by t is injective on both A and B. The kernel-cokernel sequence gives

$$0 \longrightarrow Q[t] \longrightarrow A/tA \longrightarrow B/tB \longrightarrow Q/tQ \longrightarrow 0.$$

On a finite-length module the kernel and cokernel of any endomorphism have the same length. Hence $\operatorname{length}_A(A/tA) = \operatorname{length}_A(B/tB)$. The finite-length B-module B/tB has a composition series with simple factors $\kappa(\mathfrak{q}_j)$, their numbers being the lengths after localization at $\mathfrak{q}_j$. The A-length of such a factor is its full dimension over $\kappa(\mathfrak{m})$. This proves (C.1.12). The same equality for a nonzero unit has both sides zero. Apply it to a and b and subtract to obtain (C.1.11). □

Finite restriction of scalars

This is the proof of Lemma 1.14.6.

Finite restriction of scalars (NAG-001485). For the finite valued extension L/K use a K-basis (ℓ_i). NAG-001450 gives bounded coordinate maps λ_i and the completeness of the finite extension. For every Banach K-space E, sending (e_i) to $\sum e_i \otimes \ell_i$ is bounded for the projective seminorm. On any finite tensor expression $1_E \otimes \lambda_i$ is bounded by $\|\lambda_i\|$; taking its projective infimum bounds the inverse. Consequently the ordinary tensor is already complete with the finite coordinate norm, up to equivalence. Applying the same estimates to each Tate coefficient identifies $L\langle T\rangle$ with $K\langle T\rangle \otimes_K L$ as an actual finite free algebra with equivalent norm. The selected finite strict algebra theorem NAG-001483 makes it a strict K-affinoid. A strict L-affinoid is an actual closed quotient of this algebra. Composing its quotient with a strict K-presentation yields a strict K-presentation with equivalent admissible norm, using successive quotient infima. Bounded L-maps are bounded K-maps with the same inequality. This assertion uses the finite extension with its given absolute value; there is no separability hypothesis.

Proposition C.1.19 (The source-factor inclusion for relative interior)**.** *Let $Z \xrightarrow{g} Y \xrightarrow{f} X$ be composable affinoid morphisms over a specified complete non-Archimedean field. Then*

$$\mathrm{Int}(Z/X) \subseteq \mathrm{Int}(Z/Y).$$

Proof. Write $X = \mathcal{M}(A)$, $Y = \mathcal{M}(B)$, and $Z = \mathcal{M}(C)$. For $z \in \mathrm{Int}(Z/X)$, choose an admissible presentation $q_A : A\{r^{-1}T\} \twoheadrightarrow C$ with $|q_A(T_i)(z)| < r_i$ for every i. Give C the equivalent quotient norm from q_A. Then $\|q_A(T_i)^n\| \leq r_i^n$. The bounded coefficient map $B \to C$ and these bounds give a bounded map $q_B : B\{r^{-1}T\} \to C$ by Proposition 1.9.3. The coefficientwise map $j : A\{r^{-1}T\} \to B\{r^{-1}T\}$ is bounded by the bound for $A \to B$. The identity $q_B j = q_A$ holds on polynomials and hence on the completions. In particular q_B is surjective.

Write $\|c\|_{q_B} = \inf_{q_B(v)=c} \|v\|$. Applying j to lifts through q_A and taking infima gives $\|c\|_{q_B} \leq \|j\|\|c\|$. Boundedness of q_B gives $\|c\| \leq \|q_B\|\|c\|_{q_B}$. Thus q_B is admissible. It has the same variable values and radii as q_A, so Definition 2.7.1 gives $z \in \mathrm{Int}(Z/Y)$. □

Strict zero-space purity

The strict ring in NAG-002944 is catenary

The native affinoid-ring step of NAG-001783 uses the ring clause of NAG-001760 for a generalized Tate algebra, followed by Stacks 00NQ, 00NM, and 0ECE. The application in NAG-002944 takes $R = (A/\mathfrak{p})_{\mathfrak{m}/\mathfrak{p}}$. If $A = T/I$ is strict, with $T = K\langle X_1, \dots, X_e\rangle$ and $\mathfrak{n}$ the inverse image of $\mathfrak{m}$, then R is a quotient of $T_{\mathfrak{n}}$. Thus only the regularity of this prescribed maximal Tate localization is needed. Here is an algebraic replacement of that input in the same strict scope.

For any specified maximal ideal $\mathfrak{n}$ of T, use NAG-001452 to take the bounded quotient $T \to E = T/\mathfrak{n}$. The complete specified extension E/K is finite, and the image a_i of X_i has $|a_i| \le 1$. Put $S = E\langle X_1, \dots, X_e\rangle$. By the coordinate norm equivalence of NAG-001450, a restricted coefficient family in E is exactly a tuple of separated restricted coefficient families in K, after choosing a finite K-basis. This gives the ordinary ring isomorphism $S = T \otimes_K E$ and finite freeness over T. Evaluation $S \to E$ at a restricts to the original quotient $T \to E$: the bounded maps agree on the dense polynomial subalgebra. The kernel in S is $\mathfrak{l} = (X_1 - a_1, \dots, X_e - a_e)$, as follows also from the translation and constant-term calculation below. Hence $\mathfrak{l} \cap T = \mathfrak{n}$.

The substitutions $X_i \mapsto X_i \pm a_i$ are mutually inverse by NAG-000232. In translated coordinates $U_i = X_i - a_i$, the kernel of total degree $< k$ truncation of S is the ordinary ideal $(U)^k$: assign each monomial of degree at least k to one chosen degree-k divisor, and divide the finitely many resulting groups by their divisors. Each shifted restricted series still converges. The truncated ring has nilpotent maximal ideal and residue field E, so localizing at this ideal does not change it. Thus the maximal ideal completion of $S_{\mathfrak{l}}$ is $E[[U_1, \dots, U_e]]$, using exactly the truncation argument of NAG-001717. The rings T and S are Noetherian by NAG-001403 at K and E, respectively. Stacks 032C makes the completion regular, and 07NY makes $S_{\mathfrak{l}}$ regular. Its maximal ideal modulo its square has dimension e by the same degree-< 2 truncation. In particular $\dim S_{\mathfrak{l}} = e$, by the definition of a regular local ring.

The map $T_{\mathfrak{n}} \to S_{\mathfrak{l}}$ is flat and local: S is free, localization of a flat module is flat, and the maximal ideal contracts to the specified $\mathfrak{n}$. Stacks 00OF gives regularity of $T_{\mathfrak{n}}$. Applying 00NQ and 00NM to this Noetherian regular local ring gives universal catenarity. The actual quotient $R = T_{\mathfrak{n}}/I_{\mathfrak{p}}T_{\mathfrak{n}}$, where $I_{\mathfrak{p}}$ is the inverse image of $\mathfrak{p}$ in T, is an algebra of finite type over it, so 0ECE

applies. This establishes the exact catenarity needed in the strict proof, for trivial and nontrivial valuations and without separability of E/K.

The prescribed maximal dimensions in the same proof

The preceding construction also supplies the strict integral application of NAG-002292 used twice in NAG-002944. Along $T \to S$, use flat going down (00HS) to lift a chain ending at $\mathfrak{n}$ to one ending at $\mathfrak{l}$. Conversely use integrality of the finite map (00GK) and incomparability (00GT) to contract every strict chain ending at $\mathfrak{l}$ to a strict chain. It follows that $\dim T_{\mathfrak{n}} = e$ for each specified maximal ideal $\mathfrak{n}$, and $\dim T = e$.

For a nonzero strict integral affinoid B and a specified maximal ideal $\mathfrak{m}_B$, take the actual finite injection $T \hookrightarrow B$ of NAG-001451. Write $\mathfrak{n}_B = \mathfrak{m}_B \cap T$. The image of T in $B/\mathfrak{m}_B$ is a finite-dimensional K-domain by NAG-001452. Multiplication by a nonzero element of this domain is injective and therefore surjective, so the image is a field and $\mathfrak{n}_B$ is maximal. The strict Tate domain T is normal by NAG-001454; the integral map is between domains. Stacks 00H8 now lifts chains starting from the specified prime $\mathfrak{m}_B$ downwards. Incomparability contracts strict chains. Thus $\dim B_{\mathfrak{m}_B} = \dim T_{\mathfrak{n}_B} = e$. The finite injective map has $\dim B = \dim T = e$ by 00GK and 00OK.

For NAG-002944 apply this calculation to the actual strict integral quotients $A/\mathfrak{p}$ and $A/\mathfrak{q}$, with maximal ideals $\mathfrak{m}/\mathfrak{p}$ and $\mathfrak{m}/\mathfrak{q}$. The strict quotient follows from NAG-001403: the inverse image ideal in the defining Tate algebra is closed, and the successive quotient norm is the same as the direct quotient norm. Choose $\mathfrak{m}$ by 00E0(2) on $A/\mathfrak{q}$. The existing chain calculation now uses the two prescribed dimensions and catenarity of R. The dimension of a strict affinoid is the Krull dimension of its algebra by Definition 2.8.1. Purity here means that every actual minimal-prime quotient has this dimension equal to the given n.

Proposition C.1.20 (Componentwise strict dimension; F8ZP-E)**.** *Let A be a nonzero strict K-affinoid algebra pure of dimension n. For primes $\mathfrak{p} \in \operatorname{Min}(A)$ and $\mathfrak{q} \supseteq \mathfrak{p}$,*

$$\operatorname{ht}_{A/\mathfrak{p}}(\mathfrak{q}/\mathfrak{p}) + \dim(A/\mathfrak{q}) = n. \tag{C.1.13}$$

In particular, for each $\mathfrak{q} \in \operatorname{Spec}(A)$ the ordinary algebraic localization $A_{\mathfrak{q}}$ is equidimensional, of dimension $n - \dim(A/\mathfrak{q})$. This assertion concerns $A_{\mathfrak{q}}$, not an identification with an ordinary analytic stalk.

Proof. Choose a maximal ideal $\mathfrak{m} \supseteq \mathfrak{q}$. Both $A/\mathfrak{p}$ and $A/\mathfrak{q}$ are strict integral affinoids. Apply the prescribed maximal-dimension calculation to these two rings separately. With $d = \dim(A/\mathfrak{q})$ this gives

$$\dim(A/\mathfrak{p})_{\mathfrak{m}/\mathfrak{p}} = n, \qquad \dim(A/\mathfrak{q})_{\mathfrak{m}/\mathfrak{q}} = d.$$

The first equality uses the dimension of the particular component $A/\mathfrak{p}$, not merely $\dim A_{\mathfrak{m}} = n$. The integral local ring $R = (A/\mathfrak{p})_{\mathfrak{m}/\mathfrak{p}}$ is catenary by the strict quotient calculation. Write $\mathfrak{r} = (\mathfrak{q}/\mathfrak{p})R$ and let $\mathfrak{n}$ be its maximal ideal. A saturated chain from 0 to $\mathfrak{r}$, followed by one from $\mathfrak{r}$ to $\mathfrak{n}$, is saturated from 0 to $\mathfrak{n}$. Finite dimension permits such chains. Catenarity makes their lengths respectively h, d, and n, where h is the height of $\mathfrak{r}$. Thus $h + d = n$.

Localization at $\mathfrak{m}$ does not remove any prime contained in $\mathfrak{q}$, so $h = \mathrm{ht}_{A/\mathfrak{p}}(\mathfrak{q}/\mathfrak{p})$. This proves (C.1.13). The minimal primes of $A_{\mathfrak{q}}$ are exactly $\mathfrak{p}A_{\mathfrak{q}}$ for $\mathfrak{p} \in \mathrm{Min}(A)$ contained in $\mathfrak{q}$: use prime correspondence for localization and choose a minimal prime below a contracted prime. Each corresponding component localization has dimension $h = n - d$, independently of $\mathfrak{p}$. Their prime-chain spectra cover the spectrum of $A_{\mathfrak{q}}$, proving the last assertion. Equidimensionality has therefore been derived at the precise algebraic localizations used, rather than assumed for analytic stalks. □

Proposition C.1.21 (Strict principal zero purity; F8ZP-P)**.** *Let A be a nonzero strict K-affinoid algebra pure of dimension $n \geq 1$. Suppose f avoids every minimal prime of A. Then A/fA is zero or every one of its minimal-prime quotients has Krull dimension $n-1$. For every prime $\mathfrak{q}$ minimal over fA and every $\mathfrak{p} \in \mathrm{Min}(A)$ contained in $\mathfrak{q}$,*

$$\mathrm{ht}_{A/\mathfrak{p}}(\mathfrak{q}/\mathfrak{p}) = 1.$$

If instead $n = 0$, such an f is a unit. These conclusions apply in particular when f is a non-zero-divisor.

Proof. If f is a unit, the quotient is zero. Otherwise choose $\mathfrak{q} \in \mathrm{Min}_A(fA)$ and a minimal prime $\mathfrak{p} \subseteq \mathfrak{q}$. The image of f in the Noetherian domain $A/\mathfrak{p}$ is nonzero. The prime $\mathfrak{q}/\mathfrak{p}$ is minimal over this element: a smaller prime containing it would lift to a prime strictly below $\mathfrak{q}$ containing f. Tag 00KV applies and bounds its height by one. It is not the zero prime, because it contains that nonzero element. Its height is therefore exactly one. Equation (C.1.13) gives $\dim(A/\mathfrak{q}) = n - 1$ for every such $\mathfrak{q}$. These are exactly the minimal-prime quotients of A/fA.

When $n = 0$, the same reasoning would give height one in a zero-dimensional component, an impossibility. Thus no prime can contain f, and f is a unit. Lemma C.1.13 proves the final clause. Components on which f is a unit simply contribute no zero component; no assumption that f is a nonunit on every component was made. Nilpotents and embedded primes have not been removed. □

Finite polyhedral ends

Write $N = \mathbb{Z}^r$, $E = N_{\mathbb{R}} \times \mathbb{R}$, with coordinates (y, t), projection $\pi : E \to N_{\mathbb{R}}$, and ambient lattice $N \oplus \mathbb{Z}$. A polyhedron below is closed and given by finitely many affine linear inequalities, with rational directions and arbitrary real constants. For its tangent space L_σ, its lattice is the saturated lattice $N_\sigma = L_\sigma \cap (N \oplus \mathbb{Z})$.

Definition C.1.22 (Finite graph datum)**.** Fix $n \geq 1$, a compact set $B \subset N_{\mathbb{R}}$, and $a \in \mathbb{R}$. A finite graph datum is a finite polyhedral complex in $B \times [a, \infty)$, with an n-chain

$$C = \sum_{\dim \sigma = n} m_\sigma [\sigma], \qquad m_\sigma \in \mathbb{Z}.$$

Zero-weight cells may be discarded. The analytic application uses nonnegative integral weights. All cycle statements in this patch are restricted to this integer-weight scope. For a top coefficient expression γ, write its tangential restriction in lattice coordinates as $\gamma|_\sigma = c_\sigma \omega_{N_\sigma}$, and set

$$\|\gamma\|_{C,1} = \sum_\sigma |m_\sigma| \int_\sigma |c_\sigma| \, d\mu_\sigma, \qquad I_C(\gamma) = \sum_\sigma m_\sigma \int_\sigma c_\sigma \, d\mu_\sigma$$

only when the indicated scalar cell integrals have first been defined and the first sum is finite. On a bounded polytope we use the grid integral constructed for continuous coefficients in the proof of NAG-002389. On an unbounded cell we use that construction for continuous coefficients with compact tangential support, cutting outside that support; an identically zero coefficient has integral zero. All expressions integrated below meet these conditions. In particular, finiteness of a formal domination bound is not a definition of an integral for arbitrary measurable coefficients. This absolute cell norm is attached to this presentation. It is not a newly constructed analytic Radon measure.

Lemma C.1.23 (Eventual cylinders; F8LA-P1)**.** *There is $H > a$ such that all bounded cells lie below H, and every unbounded cell has the form*

$$\sigma \cap \{t > H\} = Q_\sigma \times (H, \infty),$$

where $Q_\sigma \subset B$ is a compact polytope. For an unbounded n-cell, $\dim Q_\sigma = n - 1$, and

$$N_\sigma = N_{Q_\sigma} \oplus \mathbb{Z}e_t. \tag{2.1}$$

In fact $\pi|_{L_\sigma}$ has rank $n - 1$ on the whole unbounded cell, not just on its tail.

Proof. Represent a nonempty unbounded cell by inequalities

$$\ell_j(y) + b_j t \le c_j.$$

Include equalities as pairs of inequalities. Since y is bounded and $t \ge a$, unboundedness gives a sequence with $t \to +\infty$. Each inequality then implies $b_j \le 0$. Let Q be the set defined by the inequalities with $b_j = 0$. For any $y \in Q$, all remaining inequalities can be satisfied by taking t sufficiently large. Thus $Q = \pi(\sigma)$, so Q is a closed polyhedron contained in B, hence compact. The inequalities with $b_j < 0$ have the form $t \ge L_j(y)$. Their finitely many affine lower bounds have a common finite upper bound on Q. Above that bound the cell is precisely the displayed cylinder.

Its tangent space is $L_Q \oplus \mathbb{R}e_t$. Intersecting this direct sum with $N \oplus \mathbb{Z}$ gives (2.1). This also proves the dimension and rank assertions. Choose a common H above these finitely many bounds and above the maxima of t on every bounded cell. □

Theorem C.1.24 (Uniform top-degree excision; F8LA-P2R)**.** *Let C be a finite graph datum, and let α be a smooth (n, n)-superform on a neighbourhood of B. There is a constant $A_C < \infty$, depending only on the fixed weighted cells and coordinate lattices, such that for every continuous function $v : \mathbb{R} \to \mathbb{R}$,*

$$\|v(t)\pi^*\alpha\|_{C,1} \le A_C \sup_{a \le s \le H} |v(s)| \max_{I,J} \sup_{y \in B} |\alpha_{I,J}(y)|. \tag{2.3}$$

The coefficient bound is taken to be zero when the coefficient index set is empty (in particular when $n > r$), or when B is empty. The integral is the continuous-coefficient cell integral just specified, and the displayed supremum is finite by continuity. On an unbounded cell the horizontal top pullback is

identically zero, so its product with the finite-valued v is identically zero. In particular

$$\|t\pi^*\alpha\|_{C,1} < \infty. \tag{2.4}$$

If $v_R : \mathbb{R} \to \mathbb{R}$ is continuous and $v_R(t) = v(t)$ for $t \leq R$, then for every $R \geq H$,

$$I_C(v_R(t)\pi^*\alpha) = I_C(v(t)\pi^*\alpha). \tag{2.5}$$

The same H works for every α in this fixed presentation. No balancing assumption is needed.

Proof. On an unbounded n-cell the projection has rank $n-1$, by lemma C.1.23. Both exterior factors of a pulled-back (n,n) form therefore restrict to zero. All remaining n-cells are bounded and lie in $B \times [a, H]$.

Choose an integral tangent basis on each bounded cell. Write the restriction of $\pi^*\alpha$ in the positive lattice generator. Its coefficient is a finite sum of terms $\alpha_{I,J}(\pi(y,t))\Delta_{\sigma,I}\Delta_{\sigma,J}$, up to the fixed exterior signs, where the Δ's are minors of the matrix of π in that tangent basis. Put

$$A_C = \sum_{\sigma \text{ bounded}, \dim\sigma = n} |m_\sigma| \operatorname{vol}_{N_\sigma}(\sigma) \sum_{I,J} |\Delta_{\sigma,I}\Delta_{\sigma,J}|. \tag{2.6}$$

This is finite. On each bounded cell the product coefficient and its absolute value are continuous on a neighbourhood of the cell. Thus their grid integrals exist by NAG-002389 before the estimate is used. The pointwise determinant bound, positivity of grid sums, and finite addition give (2.3). The unbounded cells have zero coefficient throughout. For (2.4), use $\sup_{[a,H]} |t| < \infty$. The integrands in (2.5) agree on every bounded contributing cell and are both zero on every unbounded cell. □

Further proofs for Gauss fields and Banach spaces

Proof of 3.24.4.

NAG-001598. Coordinate changes in a free Gauss field. Let K be complete, let $r = (r_i)$ be free over K, and let $S_i \in K_r$ have $|S_i| = r_i$. Then $T_i \mapsto S_i$ induces an isometric automorphism of K_r. In particular the complete subfield generated by the S_i over K is K_r.

The weighted-null Laurent expansion has a unique dominant monomial. By freeness the dominant monomial of S_i is $\alpha_i T_i$ with $\alpha_i \in K$ and $|\alpha_i| = 1$. Composing with a coordinate scaling, assume $\alpha_i = 1$. Choose $q < 1$ with $|S_i - T_i| \le q r_i$ for all i. Such a bound follows from weighted nullity and finiteness of the tuple. The inverse difference has $|S_i^{-1} - T_i^{-1}| \le q/r_i$. A telescoping product for each signed monomial ν therefore gives $|S^\nu - T^\nu| \le q r^\nu$. For any Laurent polynomial f this gives $|f(S) - f(T)| \le q|f(T)|$. Consequently substitution is isometric and extends to a K-algebra endomorphism U of K_r. The operator $I - U$ has norm at most q, so for each a the convergent sum $\sum_{j\ge 0}(I-U)^j a$ maps to a. This gives surjectivity. Laurent polynomials in the new coordinates are dense.

Proof of 3.24.7.

NAG-001601. A discrete field with its coefficient field. Let E be complete with nontrivial cyclic value group, and let $K \subset E$ be trivially valued with reduction $K \simeq \widetilde{E}$. For a uniformizer τ, set $r = |\tau| < 1$. Then $T \mapsto \tau$ defines an isometric isomorphism $K_r = K((T)) \simeq E$. Indeed, the terms of each nonzero Laurent polynomial in τ have distinct norms, so substitution extends isometrically. Weighted nullity at negative exponents is exactly the requirement of finitely many negative terms. For $a_0 \in E^\circ$ choose $c_j \in K$ recursively with the residue of a_j, and set $a_{j+1} = (a_j - c_j)/\tau$. Cyclicity ensures $|a_{j+1}| \le 1$. The remainder after N steps has norm at most r^N. Multiplying any element of E by a power of τ brings it into E°, which gives surjectivity.

Proof of 3.21.2.

Coordinates on a Banach space of countable type (NAG-001658). Enumerate a dense linear spanning set. Fix $0 < c < 1$ and choose $0 < c_j < 1$ with product $> c$. At each new vector v_j outside the previous finite span

W, let $\delta = \operatorname{dist}(v_j, W) > 0$. This span is closed by finite-dimensional norm equivalence. Choose $w_j \in W$ with $\|v_j - w_j\| < \delta/c_j$ and set $e_j = v_j - w_j$. If $\|w\| > |a|\|e_j\|$, then $\|w + ae_j\| = \|w\|$. Otherwise for $a \neq 0$ it is at least $|a|\delta$, hence at least $c_j \max(\|w\|, |a|\|e_j\|)$; the zero case is immediate. Inductively the finite sums have lower bound c times their weighted maximum and upper bound equal to that maximum. The sum map on the complete weighted-null families therefore has closed image containing the dense spanning set. It is an isomorphism, and the bounds give uniqueness and bounded coordinate maps. The zero space has the empty family.

Three norm sanity checks

Proof of 3.21.3.

NAG-001659. Geometric reducedness of the strict Gauss completion. Let $R = K\langle T_1, \dots, T_n\rangle$ be the unit-polyradius Tate algebra over the complete field K. Set $F = \operatorname{Frac} R$ with its Gauss absolute value and $H = \widehat{F}$. For every field extension E/F, $H \otimes_F E$ is reduced.

In characteristic zero, each element of the tensor comes from a finitely generated subfield E_0/F of E, and this smaller tensor maps injectively to the full tensor. For a transcendence basis t of E_0/F, $H \otimes_F F(t)$ embeds into $H(t)$ by polynomial localization. Tensoring this injection over $F(t)$ with E_0 preserves injectivity. The resulting ambient algebra $H(t) \otimes_{F(t)} E_0$ is reduced. In fact adjoin finitely many algebraic generators of $E_0/F(t)$ in succession. At each step the monic minimal polynomial is relatively prime to its derivative over the preceding field, so this relation persists after mapping that field to each current field factor. Quotienting by this polynomial gives a finite product of fields at the next step.

In characteristic $p > 0$ endow each p-root field with the absolute value $|u| = |u^p|^{1/p}$. Taking pth powers shows that $K^{1/p}$ and $H^{1/p}$ are complete and identifies $R^{1/p} = K^{1/p}\langle S_1, \dots, S_n\rangle$ with $S_i^p = T_i$. For an F-independent family $u_1, \dots, u_m \in F^{1/p}$, first multiply all its members by a common nonzero element of R so they lie in $R^{1/p}$. If $u_i^p = a_i/b_i$, $\prod_i b_i$ suffices. The K-algebra generated by all coefficients of the resulting series is a field, since $a^p \in K$ and $a^{-1} = a^{p-1}/a^p$ for its nonzero elements. Its closure K' in $K^{1/p}$ is a field by continuity of inversion. Monomials in the countably many coefficients have dense K-span in K'.

Use NAG-001658 to take bounded K-linear coordinate maps $\lambda_j : K' \to K$ separating its points. For $0 \le \mu_i < p$ the maps

$$L_{j,\mu}\left(\sum_{\nu} a_\nu S^\nu\right) = \sum_{\eta \in \mathbf{N}^n} \lambda_j(a_{\mu+p\eta}) T^\eta$$

are bounded with norm at most $\|\lambda_j\|$. They are R-linear, first for polynomial multipliers and then by density and continuity. They separate all series. The columns $(L_{j,\mu}(u_i))_{j,\mu}$ are independent over F: clear denominators in a putative column relation and apply separation and R-linearity. Some m rows give an invertible $m \times m$ matrix over F, since the rows span the full dual of F^m. Its inverse and the bounds on the rows give $C > 0$ with

$$\max_i |b_i| \le C \left|\sum_i b_i u_i\right| \qquad (b_i \in F).$$

For coefficients in R use the bounds directly and for fractions clear a common denominator and divide the inequality by its Gauss absolute value. Passing to limits in $H^{1/p}$ gives the same inequality for $b_i \in H$. Thus $H \otimes_F F^{1/p} \to H^{1/p}$ is injective.

If $a_i \in H$ are F-linearly independent then the a_i^p are also independent. In fact an F-linear relation on the pth powers yields, on taking the pth root, a relation on the a_i with coefficients in $F^{1/p}$. The proved injection followed by linear independence in the scalar-extended vector space kills all coefficients. For any E/F, express a nonzero tensor as $\sum_i a_i \otimes e_i$, with the a_i independent over F and some $e_i \neq 0$. Its pth power is nonzero by independence of the a_i^p. Iterating excludes all nilpotents.

Proof of 2.37.1.

Matching kernels before any sheaf theorem (NAG-001826). For a bounded map $d : E \to F$ of Banach K-spaces, $N = \ker d$ is closed and carries its induced norm. With any one free tuple, NAG-001549 represents extension as weighted Laurent coefficients, and the extended map acts coefficientwise. A weighted-null family is in its kernel exactly when each coefficient is in N, with the same norm on that family. Over a finite product the maximum and the coefficient supremum commute, and the finite union of the exceptions to a fixed tail bound is finite. These identifications are isometric and natural. Module actions agree on finite Laurent sums and then by continuity, using the coefficient algebra and constant maps of NAG-001559. This statement places no closed-image condition on d.

Points, finite residue extensions, and exact spectral comparisons

Finite self-tensor over a complete field

For the application in Lemma 1.14.8 with base a complete field, use the following proof of the comparison in Proposition 1.14.5 with $A = K$ and $C = B$. The norm comparisons are Proposition 1.14.4 and Proposition 1.18.7.

The actual finite strict tensor (NAG-001484). Let $A \to B$ and $A \to C$ be bounded maps of strict affinoids, with B finite over A. By the selected finite-algebra norm comparison NAG-001483, the given norm on B is equivalent to its canonical finite-A-module norm. Apply accepted NAG-001565 to that module and the actual bounded map to C. The ordinary tensor $B \otimes_A C$, finite over C, is already complete with its canonical norm and identifies with the separated completion with bounded inverse. Its ordinary multiplication is the projective multiplication by the estimate on finite tensor expressions. The resulting finite algebra is strict by NAG-001483. The two structural maps are bounded for the projective seminorm and thus for its equivalent norm on the finite tensor. This is the printed finite-base-change scope using the accepted generalized tensor comparison.

The tame discrete ramified coefficient tensor

Let K be a complete nontrivially real-valued field, with additive value group $\Gamma = v(K^\times)$, valuation ring O, maximal ideal $\mathfrak{m}$, and residue field k. Fix $e \geq 2$, invertible in O, and a primitive e-th root $\zeta \in O$ whose reduction also has order e. Let $L = K(s)$, with its extended valuation, satisfy

$$s^e = c \in K^\times, \qquad \gamma = v(s) > 0, \qquad i\gamma \notin \Gamma \quad (1 \leq i < e). \tag{K}$$

Thus the e value cosets are distinct. In particular the degree is exactly e, and $G = \langle\sigma\rangle$, $\sigma(s) = \zeta s$, is the cyclic Galois group. Put $O' = L^\circ$, its *actual* valuation ring. No equality $O' = O[s]$, and no module finiteness of O'/O, is assumed.

For $0 \leq i < e$, define the fractional O-module

$$I_i = \{a \in K : v(a) + i\gamma \geq 0\}, \qquad v(0) = +\infty. \tag{1}$$

Here $I_0 = O$; an I_i need not be finitely generated. The distinct value cosets give the orthogonal expansion

$$v\left(\sum_{i=0}^{e-1} a_i s^i\right) = \min_{a_i \neq 0}\big(v(a_i) + i\gamma\big), \qquad O' = \bigoplus_{i=0}^{e-1} I_i s^i. \tag{2}$$

Indeed nonzero summands have distinct valuations, so none can cancel a summand of least valuation. The same argument proves linear independence of $1, s, \ldots, s^{e-1}$, hence the degree assertion above. Completeness follows coefficientwise from (2). Only the $i = 0$ summand can have value zero, so O' has residue field k, and G acts trivially on that field. The value index and degree are both e; this is the totally ramified, defectless tame class considered here.

For this section let R be a complete discrete valuation ring with uniformizer π, residue field k, and valuation $v(\pi) = 1$. Assume e and ζ as above, and take

$$R' = R[s], \qquad s^e = \pi, \qquad R' = \bigoplus_{i=0}^{e-1} R s^i, \tag{5}$$

where R' is the valuation ring of $K(s)$. These are discrete hypotheses; (5) is not used for general O'.

Lemma C.1.25 (The ramified coefficient map is not a torsor map)**.** *In (5), consider the natural map*

$$\theta : R' \otimes_R R' \longrightarrow \prod_{j=0}^{e-1} R', \qquad a \otimes b \longmapsto (a\sigma^j(b))_j. \tag{6}$$

It is injective. In Fourier coordinates its image is $\bigoplus_{i=0}^{e-1} s^i R'$*, so*

$$\operatorname{coker}(\theta) \simeq \bigoplus_{i=1}^{e-1} R'/(s^i), \qquad \operatorname{length}_{R'} \operatorname{coker}(\theta) = e(e-1)/2. \tag{7}$$

In particular (6) is not an isomorphism.

Proof. Using $u = 1 \otimes s$, the source is $R'[u]/(u^e - s^e)$, free over R' on $1, u, \ldots, u^{e-1}$. The column for u^i in (6) is $s^i(\zeta^{ji})_{j=0}^{e-1}$. The Fourier matrix (ζ^{ji}) is invertible over R', with inverse given by $e^{-1}(\zeta^{-ij})$. Thus (6) is equivalent to the diagonal map with entries $1, s, \ldots, s^{e-1}$. These are nonzero in the DVR R', proving all assertions. □

Algebraic unit groups

Let K be an algebraically closed field and A a nonzero finitely generated integral K-algebra. Put $U = \operatorname{Spec} A$, $F = \operatorname{Frac} A$, and $M_A = A^\times/K^\times$. A lattice is a finite-rank free abelian group. A subgroup is saturated when its quotient is torsion-free.

Lemma C.1.26 (Subgroups of an integer lattice)**.** *Every subgroup of* $\mathbb{Z}^s$ *is free of rank at most* s *and is finitely generated.*

Proof. Induct on s. The image of a subgroup H under the last coordinate is either zero or $d\mathbb{Z}$ for some $d > 0$. In the first case apply the induction hypothesis in $\mathbb{Z}^{s-1}$. In the second, choose $h \in H$ with last coordinate d. Subtracting integer multiples of h gives $H = (H \cap \mathbb{Z}^{s-1}) \oplus \mathbb{Z}h$. The induction proves both assertions, including $s = 0$. □

The algebraic closedness assumption also gives a direct torsion check: if $u^n = c \in K^\times$, then $T^n - c$ splits over K, and in the domain A one linear factor vanishes, so $u \in K^\times$.

Proposition C.1.27 (Two different saturation questions)**.** *For chosen units $u_1, \dots, u_r \in A^\times$, the relation kernel*

$$R_u = \{a \in \mathbb{Z}^r : \textstyle\prod_i u_i^{a_i} \in K^\times\}$$

is saturated in $\mathbb{Z}^r$. Thus $\mathbb{Z}^r/R_u$ is the actual subgroup $H_u \subset M_A$ generated by these units. The inclusion $H_u \subset M_A$ need not be saturated, even when A is normal and the chosen units and their inverses generate A.

Proof. The relation kernel is the kernel of $\mathbb{Z}^r \to M_A$. Its quotient embeds in the torsion-free group M_A, proving saturation of the kernel. For the last assertion take, over an algebraically closed field of characteristic different from 2,

$$A = K[t, t^{-1}, (t-1)^{-1}], \qquad u_1 = t^2, \quad u_2 = t - 1.$$

Factorization of polynomials over K gives $A^\times = K^\times t^{\mathbb{Z}}(t-1)^{\mathbb{Z}}$: a unit cannot have a zero or pole at any other finite point, and conversely these monomials are units. The ring is normal, as a fraction integral over this localization cannot have a pole at a non-inverted linear factor: a monic equation would have a unique term of lowest order there. In the basis $[t], [t-1]$ of M_A, the two chosen units generate $2\mathbb{Z} \oplus \mathbb{Z}$, of index 2. Their relation kernel is zero. Nevertheless they generate the algebra with their inverses, since

$$t = u_2 + 1, \qquad t^{-1} = (u_2 + 1)u_1^{-1}.$$

The corresponding closed embedding in $\mathbb{G}_m^2$ has equation $u_1 = (u_2+1)^2$. This proves the asserted distinction. □

Units on the unit-radius Laurent affinoid

In this section only, assume that K is complete, algebraically closed and nontrivially valued with its fixed real-valued non-Archimedean absolute value. Put

$$\mathcal{B} = K\langle T, T^{-1}\rangle = \left\{ \sum_{k\in\mathbb{Z}} a_k T^k : |a_k| \longrightarrow 0 \ (|k| \longrightarrow \infty) \right\}, \qquad \|f\| = \max_k |a_k|.$$

The coefficient space is complete and convolution is submultiplicative; finite Laurent polynomials are dense. The actual Banach presentation $K\langle X, Y\rangle/(XY - 1) \simeq \mathcal{B}$ with this norm is the $d = 1$, $r = 1$, $E = K$ case of frozen `NAG-001553`. Its spectrum is the Laurent affinoid $|T| = 1$ in

$\mathbb{G}_m^{\mathrm{an}}$: a bounded multiplicative seminorm has $|T|, |T^{-1}| \le 1$, and conversely evaluation with $|T| = 1$ extends continuously from Laurent polynomials. The Laurent presentation used here is the one-variable, unit-radius instance of Theorem 1.17.2. The bound at a point uses Lemma 1.6.1.

Proposition C.1.28 (The full analytic unit group is not a finite lattice)**.** *The group $\mathcal{B}^\times/K^\times$ is not finitely generated. In fact, for any prime ℓ with $|\ell| = 1$, it contains a subgroup isomorphic to $\mathbb{Z}[1/\ell]$, represented by units whose absolute value is identically 1 on $\mathcal{M}(\mathcal{B})$.*

Proof. Choose $c \in K$ with $0 < r = |c| < 1$. Such a prime ℓ exists by taking one different from the residue characteristic when that characteristic is positive. For $m \ge 0$ set $n = \ell^m$. On the closed ball $\|v\| \le r$ consider

$$\Phi_n(v) = n^{-1}\left(cT - \sum_{j=2}^{n} \binom{n}{j} v^j\right).$$

The sum is empty when $n = 1$. Since $|n| = 1$ and integer coefficients have norm at most 1, this map preserves the ball. Moreover

$$\|\Phi_n(v) - \Phi_n(w)\| \le r\|v - w\|,$$

using $v^j - w^j = (v - w)\sum_{a=0}^{j-1} v^{j-1-a}w^a$. Iteration from zero is Cauchy, because the successive differences are bounded by a geometric sequence with ratio $r < 1$; completeness gives a unique fixed point v_m in the ball. Set $u_m = 1 + v_m$. The fixed-point equation says

$$u_m^{\ell^m} = 1 + cT. \tag{8}$$

The geometric series in $-v_m$ proves that u_m is a unit. Also u_{m+1}^{ℓ} lies within distance r of 1 and satisfies the same equation as u_m, so uniqueness yields $u_{m+1}^{\ell} = u_m$.

Consequently $a/\ell^m \mapsto [u_m^a]$ defines a homomorphism $\mathbb{Z}[1/\ell] \to \mathcal{B}^\times/K^\times$. If its value is zero for $a \neq 0$, raising to the ℓ^mth power would make $(1 + cT)^a$ constant. This is impossible: for positive a its top coefficient c^a is nonzero, and negative a reduces to the positive case by inversion. Uniqueness of Laurent coefficients justifies this test inside $\mathcal{B}$. Thus the homomorphism is injective.

Every subgroup of a finitely generated abelian group is finitely generated: lift it to a subgroup of a finite-rank free group and apply Lemma C.1.26.

But a finite collection of elements of $\mathbb{Z}[1/\ell]$ has bounded denominator and cannot generate this group. This proves non-finite-generation. Finally frozen `NAG-000655` gives $|v_m(x)| \le \|v_m\| < 1$ at every analytic point x, so $|u_m(x)| = 1$. All represented tropical logarithms therefore vanish. □

Minimal primes of a product

For a Noetherian ring A, write $\mathrm{Min}_A(a)$ for the primes of A minimal over (a), and set $\mathrm{Min}_A(a) = \varnothing$ when a is a unit. A finite collection of primes is an antichain if no two distinct members are comparable by inclusion.

Lemma C.1.29 (Minimal primes of a product; F8CA-M)**.** *For any $a, b \in A$, $\mathrm{Min}_A(ab)$ is exactly the set of inclusion-minimal members of $\mathrm{Min}_A(a) \cup \mathrm{Min}_A(b)$. Consequently*

$$\mathrm{Min}_A(ab) = \mathrm{Min}_A(a) \cup \mathrm{Min}_A(b) \tag{C.1.14}$$

holds if and only if that union is an antichain. This assertion is in the one actual common ring A; it is not an identification of unrelated chart components.

Proof. A prime containing ab contains a or b, and therefore contains a prime minimal over one of those two ideals. If it is itself minimal over (ab), it must equal that smaller prime, which is then an inclusion-minimal member of the union. Conversely, let p be an inclusion-minimal member of the union and suppose $q \subset p$ contains ab. Choose inside q a prime r minimal over a factor contained in q. Then $r \subset q \subset p$ and r belongs to the union, so its minimality gives $r = p$, hence $q = p$. Thus p is minimal over (ab). This proves both the description and the equivalence. Units cause no exception. □

Minimal-prime choices in the two factor quotients. For a factor c in the specified prime Q, put $B = A/(c)$. The prime-filtration assertion of Lemma 5.19.1 applies to the finite B-module B, since B is Noetherian. If its nonzero filtration factors are $B/\mathfrak{p}_i$, the product of the $\mathfrak{p}_i$ annihilates B: successively multiplying by each factor prime takes a filtration step into the preceding one. It follows that every prime of B contains a factor prime. Choose an inclusion-minimal factor prime contained in $Q/(c)$. Any smaller prime would itself contain a smaller factor prime. The inverse image is therefore minimal over (c) and lies in Q. This gives both minimal-prime choices in the proof.

Product boundary sign

The following display records the sign convention for the boundary terms used in the polyhedral calculation.

$$\int_A u\, d'd''\eta_1 - \int_A d'd''u \wedge \eta_1 = \int_{\partial A} u\, d''\eta_1 - \int_{\partial A} d''u \wedge \eta_1. \tag{C.1.15}$$

Proposition C.1.30 (Product boundary sign; F8RC-S)**.** *For a calibrated integral $(n-1)$-chain P, with the standard product lattice, the facet convention in* (C.1.15) *gives*

$$\int_{\partial(P\times[\sigma,\tau])} d''x \wedge \chi(x)\alpha = -\int_P \alpha, \tag{C.1.16}$$

provided $\chi = 1$ near σ, $\chi = 0$ near τ, and α is pulled back from the horizontal factor. This is a polyhedral identity and does not supply R-GREEN.

Proof. Subdivide into products of $(n-1)$-cells with the interval. On the upper face the coefficient is zero. On a lateral face the horizontal primed degree is $n-1$ but its horizontal tangent space has dimension at most $n-2$, so the restriction is zero. On the lower face the outward primitive interval normal is $-\partial_x$. With the same superform boundary convention as (C.1.15), contraction leaves $-\alpha$ with its original horizontal calibration. Equivalently, on one product cell the one-variable boundary contribution is $(\chi(\tau)-\chi(\sigma))\int_C \alpha = -\int_C \alpha$. For an explicit sign check, put $d = n-1$ and $s_d = (-1)^{d(d-1)/2}$. If $\alpha = s_d A\, d'y_1 \wedge \cdots \wedge d'y_d \wedge d''y_1 \wedge \cdots \wedge d''y_d$, then the vertical term of $d'(d''x \wedge \chi\alpha)$ is $\chi'(x)d'x \wedge d''x \wedge \alpha$. Its coefficient in the positive product generator is $\chi'(x)A$, since $s_{d+1} = (-1)^d s_d$. One-dimensional integration gives the displayed endpoint difference. Weights and shared facets add linearly. This checks both the outward normal and the cutoff sign; no limiting operation is involved. □

Proposition C.1.31 (Two precise failures of weaker analytic premises)**.** *The following elementary examples are topology and convergence obstructions, not asserted native analytic spaces.*

First, let $C = \{0\} \cup \{1/k : k \geq 1\}$ *and let* E_N *be the functions on* C *constant on* $\{0\} \cup \{1/k : k > N\}$*. Put* $E = \bigcup_N E_N$ *with its final locally convex topology from the finite-dimensional supremum-norm spaces* E_N*. Then*

$$F(f) = \sum_{k \geq 1} (f(1/k) - f(0))$$

is well-defined and has order-zero bound $|F(f)| \leq 2N\|f\|_C$ *on* E_N*, but it has no finite signed Radon representation on* C*. Indeed there are* $f_N \in E_N$ *with* $0 \leq f_N \leq 1$ *and* $F(f_N) = N$*.*

Second, on $[0, 1]$ *the signed measures* $\sigma_m = m(\delta_{1/m^2} - \delta_0)$ *satisfy*

$$|\sigma_m(h)| \leq \|h'\|_\infty / m \quad (h \in C^1([0, 1])), \qquad |\sigma_m|([0, 1]) = 2m,$$

while $\sigma_m(\sqrt{x}) = 1$*. Thus convergence to zero against all smooth tests does not imply convergence against a fixed continuous multiplier without a suitable variation bound.*

Proof. Every $f \in E_N$ makes only its first N summands nonzero, proving the first bound and continuity by finality. Let f_N be one on the first N nonzero points and zero on the remaining points and on zero. This is a continuous member of E_N and gives $F(f_N) = N$. A finite signed representing measure ν would instead give $|F(f_N)| \leq |\nu|(C)$ for every N, a contradiction. The space E is uniformly dense in $C(C)$, by uniform continuity at zero, so lack of smooth-density analogues is not the issue.

For the second assertion, the fundamental theorem gives $|h(1/m^2) - h(0)| \leq \|h'\|_\infty / m^2$. The two atoms are distinct with opposite masses of size m, so their total variation is $2m$. Finally $m\sqrt{1/m^2} = 1$. All claimed inequalities and failures follow directly. □

Lemma C.1.32 (A finite vertical module with zero closed fibre vanishes)**.** *Let R be a valuation ring of a nontrivially real-valued field F, with maximal ideal $\mathfrak{n}$. Let S be any R-algebra, and let C be a finitely generated S-module. If*

$$C \otimes_R F = 0, \qquad C = \mathfrak{n}C, \tag{1}$$

then $C = 0$. Neither S nor R is required to be Noetherian.

Proof. Choose finitely many S-module generators $c_1, \dots, c_q$. The generic vanishing means that each c_j is annihilated by some nonzero $a_j \in R$. The product $a = \prod_j a_j \neq 0$ therefore annihilates all of C. If there are no generators, or a is a unit, the assertion follows.

For each j, write c_j as a finite sum

$$c_j = \sum_{\ell} \beta_{j\ell} d_{j\ell}, \qquad \beta_{j\ell} \in \mathfrak{n}, \quad d_{j\ell} \in C.$$

If every coefficient in these finitely many expressions is zero, then $C = 0$. Otherwise choose a nonzero coefficient λ having least valuation among this *finite* list. Every $\beta_{j\ell}/\lambda$ belongs to R, so $c_j \in \lambda C$ for all j. Since these elements generate over S, this proves $C = \lambda C$, with $v(\lambda) > 0$.

Rank one now supplies an integer $N \geq 1$ with $Nv(\lambda) \geq v(a)$. Thus $\lambda^N/a \in R$. Iteration gives

$$C = \lambda^N C = (\lambda^N/a)\, aC = 0.$$

Only a finite list of coefficients was minimized. No least positive element of $v(F^\times)$, and no generator of $\mathfrak{n}$, was used. □

Lemma C.1.33 (Finite type makes the additive descent defect finite)**.** *Let A' be a commutative algebra, let a finite group G of order e act on A', and let $R' \subset A'$ be a subring. Put $B = (A')^G$ and let $S = R'[B] \subset A'$ be the subalgebra generated by R' and B. If $A' = R'[z_1, \dots, z_r]$, then A' is a finite S-module, generated by the e^r monomials*

$$z_1^{j_1} \cdots z_r^{j_r}, \qquad 0 \leq j_\nu < e. \tag{2}$$

Consequently the additive quotient A'/S is a finite S-module. No Noetherian hypothesis and no assumption that G fixes R' pointwise are required.

Proof. For each z_ν, the orbit polynomial

$$\prod_{g\in G}(T-g(z_\nu))$$

is monic of degree e, vanishes at z_ν, and has all coefficients in B: every group element permutes its factors. Since $B\subset S$, powers of z_ν of exponent at least e reduce to lower powers with coefficients in S. The equality $A'=S[z_1,\dots,z_r]$ follows from the definition of S. Repeated reduction in each variable proves (2). The subring S is an S-submodule of A', so its additive quotient is a finitely generated S-module as well. □

Lemma C.1.34 (Uniform norm preservation)**.** *Let B be a unital non-Archimedean Banach K-algebra with submultiplicative norm, and let $R\subset B$ be a norm-dense K-subalgebra. Given $f_1,\dots,f_m\in B^\times$, there are $g_i\in R$ such that*

$$\|g_i-f_i\|<\varepsilon,\qquad 0<\varepsilon<\min_i\|f_i^{-1}\|^{-1}.$$

For every $z\in\mathcal{M}(B)$, $|g_i(z)|=|f_i(z)|$. Each g_i is also a unit of B.

Proof. Choose one positive ε satisfying the displayed finite list of inequalities and then approximate each f_i by density. By contractivity of bounded multiplicative seminorms (NAG-001496),

$$|f_i(z)|\geq\|f_i^{-1}\|^{-1}>\varepsilon>|g_i(z)-f_i(z)|.$$

The ultrametric inequality gives equality of the first two absolute values. The element $u_i=f_i^{-1}(g_i-f_i)$ has norm less than one. The convergent series $\sum_{j\geq0}(-u_i)^j$ is the inverse of $1+u_i$, proving invertibility of g_i. For an empty tuple there is nothing to approximate. □

A smooth superform on a polyhedral subset means an ambient smooth form modulo restriction to the tangent space of every cell at every point of that cell. Both alternating factors are restricted.

Lemma C.1.35 (Detection through an affine image)**.** *Let Q be a finite union of compact convex polytopes in a real affine space, let π be an affine map, and put $P=\pi(Q)$. If α is a smooth ambient superform near P, then*

$$\pi^*\alpha|_Q=0\quad\Longleftrightarrow\quad\alpha|_P=0.$$

Moreover, if $P=\bigcup_{i=1}^r P_i$ is a finite union of compact polyhedral subsets and $\alpha|_{P_i}=0$ for every i, then $\alpha|_P=0$.

Proof. Take a finite common polyhedral subdivision of the images of the polytopes of Q, then triangulate it compatibly on its faces. Each resulting simplex τ is contained in the image of one convex polytope $\sigma \subset Q$. Choose a lift in σ of each vertex of τ. Affine interpolation in barycentric coordinates gives a section $j_\tau : \tau \to \sigma$ of π. Convexity ensures that its image stays in σ. Pullback along j_τ proves $\alpha|_\tau = 0$ if $\pi^*\alpha|_Q = 0$. This detects both alternating factors and applies also to zero-dimensional simplices. Vanishing on the full-dimensional pieces of any original cell extends to its boundary by continuity, giving all-face vanishing on P. For the converse, subdivide each source polytope by the inverse images of target cells; affine pullback carries its tangent vectors into the target tangent vectors.

For the last assertion, a finite common subdivision makes every P_i a subcomplex of P. Every cell of the resulting union lies in some P_i, so the same restriction and continuity argument applies. The common subdivision is obtained from the finitely many face hyperplanes. A compatible triangulation can be obtained by induction on faces, joining an interior point of each remaining polytope to the already triangulated boundary. No integral splitting or saturation is used. □

Let A be a nonzero Noetherian ring. Set

$$S = A \setminus \bigcup_{\mathfrak{p} \in \operatorname{Min}(A)} \mathfrak{p}, \qquad T(A) = \ker\left(A \longrightarrow \prod_{\mathfrak{p} \in \operatorname{Min}(A)} A_{\mathfrak{p}} \right), \qquad A^{\mathrm{u}} = A/T(A). \tag{1.1}$$

We call $T(A)$ the embedded torsion ideal. No reduction of the generic Artinian local rings is performed.

Lemma C.1.36 (Algebraic quotient and regular elements; F8U-A)**.** *The ideal $T(A)$ is finite and nilpotent, and $T(A)_{\mathfrak{p}} = 0$ at every minimal prime. The ring A^{u} has the same minimal primes and generic local rings as A, and has no embedded associated primes; hence it satisfies S_1. If f is a non-zero-divisor in A, it is a non-zero-divisor in both $T(A)$ and A^{u}, and*

$$0 \longrightarrow T(A)/fT(A) \longrightarrow A/fA \longrightarrow A^{\mathrm{u}}/fA^{\mathrm{u}} \longrightarrow 0 \tag{1.2}$$

is exact.

Proof. All ideals are finite. If $a \in T(A)$, then for each minimal $\mathfrak{p}$ some element outside $\mathfrak{p}$ kills a. Finite prime avoidance applied to $\operatorname{Ann}(a)$ produces

$s \in S$ with $sa = 0$. Conversely such an s is a unit in every $A_{\mathfrak{p}}$, so $sa = 0$ implies $a \in T(A)$. Thus $T(A)$ is exactly the S-torsion, and A^{u} embeds in $S^{-1}A$. Each $a \in T(A)$ belongs to every minimal prime of A; hence $T(A)$ lies in the nilradical and is nilpotent. Localizing (1.1) at a minimal prime gives $T(A)_{\mathfrak{p}} = 0$, including for a finite generating set, so the generic local rings are unchanged.

Every $s \in S$ acts injectively on A^{u}. An associated prime $\mathfrak{q}$ of A^{u} is therefore disjoint from S. Finite prime avoidance implies $\mathfrak{q} \subseteq \mathfrak{p}$ for some minimal prime $\mathfrak{p}$, so $\mathfrak{q} = \mathfrak{p}$. This proves absence of embedded primes. The equivalence with S_1 is the Noetherian algebra criterion Stacks 031Q; no analytic claim is hidden in this step.

A regular f avoids every minimal prime, so $f \in S$ and its action on A^{u} is injective. It acts injectively on $T(A) \subseteq A$ as well. Moreover $fa \in T(A)$ implies $a \in T(A)$. Thus $T(A) \cap fA = fT(A)$, which proves (1.2). $\square$

Affine coefficient comparison in NAG-002060. Take the finite separable extension in the original statement, with its actual monic lift $L = K(\alpha)$ from NAG-002050. Use the original coefficient maximum calculation in lines 45–51. It makes L° finite free over O with basis $1, \alpha, \dots, \alpha^{d-1}$ and gives $L^{\circ\circ} = K^{\circ\circ} L^\circ$.

For an actual flat finitely presented affine chart with completed algebra A_0, the formal clause of NAG-002037 and the finite free coefficient basis identify its coefficient extension after completion with $B_0 = A_0 \otimes_O L^\circ$. The maps are those given on the affine coefficients. The finite basis makes tensor extension commute with each quotient modulo π^n, with the completion, and with the completed principal restrictions. Also

$$B_0[1/\pi] = A \otimes_K L, \qquad A = A_0[1/\pi].$$

Apply NAG-001918 on the actual admissible affine charts to obtain the strict generic norms. In NAG-001702 take the finite algebra to be L over K, and the bounded target to be A. NAG-001483 gives the strict affinoid structure on the finite K-algebra L. Its actual absolute value is the canonical coefficient maximum norm, by the calculation above. Over A the finite free maximum norm on $A \otimes_K L$ has closed unit ball $\bigoplus_i A_0 \alpha^i = B_0$. The defining strict norm of $B_0[1/\pi]$ has the same closed unit ball by NAG-001918. For any nonzero element, scale by an integer power of π to put its norm in $(|\pi|, 1]$ for either norm. Applying the common unit-ball inclusion in both directions compares those norms with bound $|\pi|^{-1}$. Thus the natural algebra identification is bounded for the defining norms and gives

$$B_0[1/\pi] \simeq A \widehat{\otimes}_K L.$$

On the target it is an isomorphism of affinoid algebras, with bounded inverse. It commutes with every displayed principal restriction because the maps agree on the affine coefficients and on α. This supplies the operation at lines 64–67 of NAG-002060 that uses the finite-coordinate part of NAG-002023. It also gives the displayed special-fibre tensor formula by the equality of the open unit ideals. The clause concerns supplied affine models and their actual restrictions. The global generic glue and the separate reducedness assertion retain their original premises.

Lemma C.1.37 (Schematic closure of the generic graph)**.** *Let K be complete and nontrivially real-valued, put $O = K^\circ$, and fix $0 \neq \pi \in K^{\circ\circ}$. Let C/K be a smooth projective geometrically connected curve. Let $\mathcal{X}_1, \mathcal{X}_2$ be projective flat finitely presented O-models of C. The schematic closure $\mathcal{G}$ of the generic diagonal in $\mathcal{X}_1 \times_O \mathcal{X}_2$ is integral, projective, flat and finitely presented over O. Its two projections*

$$p_i : \mathcal{G} \longrightarrow \mathcal{X}_i$$

are proper and induce the identity on C. If $\mathcal{X}_i$ is integral, p_i is birational and surjective.

Proof. On an affine open $\operatorname{Spec} B$ of the product, let $I \subset B[1/\pi]$ be the ideal of the generic diagonal. Its closure has ring

$$B/(I \cap B).$$

These ideals commute with localization and hence define a closed subscheme of the product. A nonempty such affine closure has coordinate ring contained in the coordinate ring of a nonempty open of the integral curve C. It is therefore a domain and has no O-torsion. The generic diagonal is dense, so these affines give an integral scheme. Torsion-freeness over a valuation ring gives flatness by [StacksAlg, Tag 0539]. Each affine ring is of finite type over O, as a quotient of the coordinate ring of the product. It is consequently finitely presented by [StacksAlg, Tag 053E(1)]. The closure is projective as a closed subscheme of the projective product; in particular it is quasi-compact and separated. The local finite presentation just proved is therefore a finite presentation.

The projections are proper, being restrictions of the proper product projections to a closed subscheme. On the generic fibre they are the given identities. If a target is integral, their closed images contain its dense generic fibre, proving surjectivity and birationality. □

Lemma C.1.38 (The full finite flat cycle)**.** *Let $q : Y \to Z$ be finite locally free of constant rank n, with Z integral and Noetherian. Every irreducible component of Y dominates Z. For its generic points η_j, write*

$$m_j = \operatorname{length}_{\mathcal{O}_{Y,\eta_j}} \mathcal{O}_{Y,\eta_j}.$$

Then, with full field degrees,

$$\sum_j m_j[\kappa(\eta_j) : K(Z)] = n, \qquad q_*[Y] = n[Z]. \tag{C.1.17}$$

Here $[Y] = \sum_j m_j[\overline{\{\eta_j\}}]$ is the full fundamental cycle.

Proof. On an affine open put $Z = \operatorname{Spec} B$ and $Y = \operatorname{Spec} C$. The finite locally free B-module C is torsion free. If a nonzero $b \in B$ belonged to a minimal prime $\mathfrak{q}$ of C, its image in the zero-dimensional Noetherian local ring $C_{\mathfrak{q}}$ would be nilpotent; this ring is Artinian (Tag 00KH). Clearing a denominator gives $sb^r = 0$ for some $s \notin \mathfrak{q}$, contradicting torsion freeness. Thus every minimal prime lies over (0). Conversely a prime of C over (0) is minimal: after localization it is a prime in the finite-dimensional $K(Z)$-algebra $C \otimes_B K(Z)$, whose primes are all maximal. Its local factors are precisely $C_{\mathfrak{q}}$.

This finite-dimensional algebra has dimension n and is the product of these Artinian local factors (Tag 00JB). A composition series of one factor has m_j quotients equal to $\kappa(\eta_j)$. Taking dimensions proves the sum in (C.1.17). The definition of proper cycle pushforward, Tag 02R4, proves the second identity. In particular, inseparable degrees and generic nilpotent lengths are separate factors and both are retained. □

Finite tropical graphs and Gauss fibres

A finite logarithmic graph

Fix a complete field K with its original real-valued non-Archimedean absolute value, possibly trivial. Fix $k \geq 1$, $d \geq 0$, and $n = k + d$. Choose real numbers

$$A_i > 0, \quad B_i > 0 \quad (1 \leq i \leq k), \qquad q_\nu^- < q_\nu^+ \quad (1 \leq \nu \leq d), \qquad Q = \prod_{\nu=1}^{d} [q_\nu^-, q_\nu^+].$$

An empty product Q is a point. Put

$$V_0 = \left\{ \begin{array}{ll} |T_i| \leq e^{A_i}, & |T_i - 1| \geq e^{-B_i} \quad (1 \leq i \leq k), \\ e^{-q_\nu^+} \leq |Z_\nu| \leq e^{-q_\nu^-} & (1 \leq \nu \leq d). \end{array} \right\}. \tag{1.1}$$

This is the actual generalized affinoid rational domain in the corresponding closed polydisc. In particular $T_i - 1$ and Z_ν are analytic units on V_0.

Let $M \in M_{r,n}(\mathbb{Z})$ have column rank n. Choose $m_i \in \mathbb{Z}_{>0}$, $b = (b_1, \ldots, b_d) \in \mathbb{Z}^d$, and $a, c_1, \ldots, c_r \in K^\times$. Define

$$f_0 = a \prod_{i=1}^{k} T_i^{m_i} \prod_{\nu=1}^{d} Z_\nu^{b_\nu}, \tag{1.2}$$

$$g_{0,\ell} = c_\ell \prod_{i=1}^{k} (T_i - 1)^{M_{\ell i}} \prod_{\nu=1}^{d} Z_\nu^{M_{\ell,k+\nu}} \qquad (1 \leq \ell \leq r). \tag{1.3}$$

Thus f_0 is analytic, with zeros allowed, and the $g_{0,\ell}$ are units. Put

$$\lambda = -\log|a|, \quad \kappa_\ell = -\log|c_\ell|, \quad y_i = -\log|T_i - 1|, \quad x_\nu = -\log|Z_\nu|, \quad s_i = -\log|T_i|.$$

The coordinates s_i are used only where all $T_i \neq 0$. Write $v = (y_1, \ldots, y_k, x_1, \ldots, x_d)$.

For each i, let $\Gamma_i \subset \mathbb{R}^2_{y_i,s_i}$ consist of the following three edges, including their endpoints:

$$D_i = \{(u,u) : -A_i \leq u \leq 0\}, \quad H_i = \{(u,0) : 0 \leq u \leq B_i\}, \quad E_i = \{(0,u) : u \geq 0\}. \tag{1.4}$$

Let

$$P = \Gamma_1 \times \cdots \times \Gamma_k \times Q \subset \mathbb{R}^{n+k}_{v,s}, \qquad \mathcal{P} = \sum_{\dim \sigma = n} [\sigma], \tag{1.5}$$

using its product complex, with weight one on every n-cell. Every cell has its saturated tangent lattice in $\mathbb{Z}^{n+k}$. Define the integral affine map

$$F(v,s) = \left(\kappa + Mv,\ \lambda + \sum_i m_i s_i + b\cdot x\right) =: (Y,t). \tag{1.6}$$

Translations here come from the specified constants in $K^\times$; the absolute value is unchanged.

For a real cutoff S, use the restrictions

$$V_{0,S} = \{z \in V_0 : |f_0(z)| \geq e^{-S}\}, \qquad P_S = P \cap \left\{\lambda + \sum_i m_i s_i + b\cdot x \leq S\right\}. \tag{1.7}$$

Write $C_0 = F_*\mathcal{P}$, counting full-rank cells with their lattice index and discarding lower-rank images.

For an integral linear map $L : N_\sigma \to \mathbb{Z}^{r+1}$ of rank n, the pushforward index used throughout is

$$\delta(L) = [\, L(N_{\sigma,\mathbb{R}}) \cap \mathbb{Z}^{r+1} : L(N_\sigma)\,]. \tag{2.1}$$

Lemma C.1.39 (Actual source image; F8GP-2)**.** *On $V_0 \setminus \{f_0 = 0\}$, the moment tuple*

$$h = (T_1 - 1, \dots, T_k - 1, Z_1, \dots, Z_d, T_1, \dots, T_k)$$

has image exactly P. Its restriction to $V_{0,S}$ has image exactly P_S. These are statements about all analytic points over the original field.

Proof. For one variable, the strong triangle inequality applied to $T = (T-1)+1$ gives three possibilities. If $|T| > 1$, then $|T-1| = |T|$. If $|T| < 1$, then $|T-1| = 1$. If $|T| = 1$, then $|T-1| \leq 1$. Since $T \neq 0$ and $T-1$ is a unit, these are precisely the three edges in (1.4), with the stated outer bounds.

Conversely, every point of an edge is attained by a Gauss seminorm: on D_i or E_i, use the variable T_i with radius e^{-s_i}; on H_i, use $T_i - 1$ with radius e^{-y_i}. At the common vertex, the radius-one Gauss seminorm in T_i has both $|T_i| = |T_i - 1| = 1$. Together with radii e^{-x_ν} for the Z_ν, the multivariable Gauss seminorm is multiplicative over K. Its values satisfy all inequalities

of (1.1), so the actual rational domain property gives a point of V_0. All T_i have positive value, as required. This proves both inclusions for P. Finally $-\log|f_0| = \lambda + \sum_i m_i s_i + b \cdot x$ on every analytic point. Imposing its upper bound S proves the second equality. □

Lemma C.1.40 (Purity and regularity; F8GP-3)**.** *The space V_0 is nonempty and pure of dimension n. The function f_0 is a non-zero-divisor in its affinoid algebra. Every nonempty $V_{0,S}$ is pure of dimension n.*

Proof. A closed generalized n-polydisc is integral because its Gauss norm is multiplicative and has zero kernel. Its Gauss point has valued-field dimension n by `fnd:gaussvaluedfielddimension`. At every point, polynomials are dense in the evaluated Tate algebra; approximation of a nonzero denominator also approximates its inverse. The completed residue field is consequently the completion of a field generated by at most n coordinate elements over K. The upper bound follows from `fnd:valuedfieldabhyankar`, including passage to completion. The maximum theorem `fnd:affinoidabhyankarmaximum` therefore gives analytic dimension n. It has one minimal component.

The inequalities in (1.1) define a nonempty rational domain in a closed polydisc: a Gauss point from lemma C.1.39, or the point $T_i = 0$ with a torus Gauss point, witnesses nonemptiness. Domain purity gives pure dimension n. Multiplication by each T_i is injective in the ambient Tate algebra, as seen by shifting its coefficient indices. Its rational-domain algebra is flat over that algebra. Consequently multiplication by every T_i, and by their positive powers and product, remains injective. The factors a and Z^b are units on V_0, proving regularity of f_0.

The domain $|f_0| \geq e^{-S}$ is an actual generalized Laurent domain in V_0. Domain purity gives the last assertion. There is also a direct compact bound useful below: from P_S,

$$-A_i \leq s_i \leq U_i(S) := \frac{S - \lambda - \min_Q b \cdot x + \sum_{j \neq i} m_j A_j}{m_i}. \tag{3.1}$$

Thus every nonempty truncation lies in a closed n-polyannulus, allowing exact-radius intervals when an endpoint coincides. □

Lemma C.1.41 (A proper finite polyhedral pushforward; F8GP-5)**.** *The map $F : P \to \mathbb{R}^{r+1}$ is proper. The chain $C_0 = F_*\mathcal{P}$ has a finite polyhedral presentation, and for every real S,*

$$F_*\big(\mathcal{P}|_{\{t\circ F\le S\}}\big) = C_0|_{\{t\le S\}}. \tag{3.3}$$

Proof. The v-coordinates range over one fixed compact box. On the inverse image of a compact target set, its t-coordinate has an upper bound S. Equation (3.1) bounds each s_i above, while $s_i \ge -A_i$. Thus the inverse image is a closed subset of a bounded box, hence compact. Positivity of every m_i is used in these separate upper bounds.

There are only 3^k product n-cells before subdivision. The image of each is a polyhedron: eliminate the finitely many linear inequalities, or use the injective affine map on its span when the rank is n. The finitely many image faces admit a common finite polyhedral refinement. On a full-rank cell, F is an affine isomorphism onto its image, with the fixed finite index (2.1). Sum these indices over all cells above each image cell. Rank-deficient cells contribute zero. This constructs a finite nonnegative integral chain.

On a full-rank cell, intersecting its image with $t \le S$ is exactly the image of its intersection with $t \circ F \le S$. The tangent lattice and index are unchanged on surviving n-dimensional pieces. If the whole cell is at $t = S$, both operations retain the whole cell. Rank-deficient pieces remain rank-deficient after cutting. These facts prove (3.3) coefficient by coefficient, after finite refinement. □

For a full-dimensional product cell σ of P, let $J(\sigma)$ be the set of indices for which its factor is E_i. If $J = \varnothing$, use v as its lattice coordinates and write

$$\ell_\sigma = (\epsilon_1 m_1, \dots, \epsilon_k m_k, b_1, \dots, b_d), \qquad \epsilon_i = \begin{cases} 1, & \text{the factor is } D_i, \\ 0, & \text{the factor is } H_i. \end{cases}$$

The matrix of F on its tangent lattice is

$$L_\sigma = \begin{pmatrix} M \\ \ell_\sigma \end{pmatrix}. \tag{4.1}$$

Proposition C.1.42 (The three cell cases; F8GP-6)**.** *The coefficients before common refinement are as follows.*

(i) If $J = \varnothing$, the image is bounded, has dimension n, and has coefficient $\delta(L_\sigma)$.

(ii) If $J = \{j\}$, let $M_{\widehat{j}}$ be M with its j-th column removed and put

$$\delta_j = [\,\mathrm{span}_{\mathbb{R}}(M_{\widehat{j}}) \cap \mathbb{Z}^r : M_{\widehat{j}}\mathbb{Z}^{n-1}\,].$$

The image has dimension n, is unbounded, and has coefficient $m_j\delta_j$. For $n = 1$, the empty-lattice index is one.

(iii) If $|J| \geq 2$, the image has rank $n - |J| + 1 < n$; it contributes zero to C_0.

Coincident image pieces are counted by summing their coefficients. Moreover, one may take

$$H = \lambda + \max_{x \in Q} b \cdot x + 1 \tag{4.2}$$

as a common strict upper bound for all bounded image cells and a cylindrical-tail threshold for the unbounded image cells.

Proof. When $J = \varnothing$, M is injective over $\mathbb{R}$, so (4.1) has rank n, and the definition of pushforward gives its index. All coordinates of the source cell are bounded.

For $J = \{j\}$, the base coordinate y_j is zero and the source variable s_j is free in $[0, \infty)$. The target tangent space is

$$\mathrm{span}_{\mathbb{R}}(M_{\widehat{j}}) \oplus \mathbb{R}e_t,$$

with saturated lattice $(\mathrm{span}_{\mathbb{R}}(M_{\widehat{j}}) \cap \mathbb{Z}^r) \oplus \mathbb{Z}e_t$. Projection of the image lattice to the first factor has image $M_{\widehat{j}}\mathbb{Z}^{n-1}$, of index δ_j. Its intersection with the vertical lattice is exactly $m_j\mathbb{Z}e_t$: independence of the remaining columns of M forces all their coefficients to vanish in a vertical combination. Counting cosets first in the base and then vertically gives index $m_j\delta_j$.

For general J, the base has $n - |J|$ independent directions. All $|J|$ vertical source directions map into the same line, and at least one maps nontrivially since all $m_i > 0$. The rank is therefore $n - |J| + 1$.

On every bounded cell, $s_i \le 0$, so $t \le \lambda + \max_Q b\cdot x$. On a cell with unique vertical branch j, its image lies above the lower graph

$$t = \lambda + \sum_{i\neq j} \epsilon_i m_i y_i + b\cdot x,$$

where $y_i \le 0$ whenever $\epsilon_i = 1$. This lower graph is everywhere at most $\lambda + \max_Q b\cdot x$. Above (4.2), any t is obtained by choosing $s_j \ge 0$. The image is thus a vertical cylinder there. Common refinements may be taken after cutting at this same height, without introducing a new larger threshold. □

Whole Gauss fibres on finite charts

Let K be complete for its specified real-valued non-Archimedean absolute value, possibly trivial. All affinoid algebras and domains are actual generalized affinoid objects with their given Banach structures. A finite map is required to have the canonical finite-module topology. Fibre algebras retain their nilpotents. Purity refers to analytic dimension.

For a full-dimensional closed rectangular box $P \subset \mathbb{R}^d$, write $\mathbb{T}_P = \mathcal{M}(R_P)$ for its polyannulus, with coordinates $T_1, \dots, T_d$ and $t_T = -\log|T| \in P$. For $s \in P$, let η_s be its Gauss point, R_s the algebra of the entire exact-radius polytorus $\mathbb{T}_s = t_T^{-1}(s)$, and $H_s = \mathcal{H}(\eta_s)$. The Laurent presentations, density, and kernel-zero Gauss norms are those of 5.35.4. Radii need not belong to $|K^\times|$.

Lemma C.1.43 (Whole fibres outside finitely many walls)**.** *Let $s_0 \in \mathrm{int}(P)$ and let O be an ordinary open neighbourhood of η_{s_0} in $\mathbb{T}_P$. There are an open Euclidean neighbourhood $B_0 \subset \mathrm{int}(P)$ of s_0 and a finite union H of proper affine hyperplanes, with integral normals, such that*

$$\mathbb{T}_s \subset O \qquad (s \in B_0 \setminus H).$$

This includes every analytic point of each exact-radius polytorus.

Proof. The evaluation topology gives finitely many strict upper and lower bounds on $|g_j|$, $g_j \in R_P$, whose common locus contains η_{s_0} and lies in O. Discard identically zero functions, which impose no effective condition. Every remaining $r_j = |g_j(\eta_{s_0})|$ is positive by the kernel-zero Gauss norm. An absent lower or upper bound is interpreted as zero or infinity; thus r_j lies in an open interval I_j.

Choose finite Laurent polynomials $p_j = \sum_m c_{jm} T^m$ whose uniform errors on $\mathbb{T}_P$ are less than $\epsilon_j < r_j$, using Banach-norm density. Combine equal exponents and remove zero coefficients. Then $|p_j(\eta_{s_0})| = r_j$. The finite maximum

$$G_j(s) = \max_m |c_{jm}| e^{-\langle m, s \rangle}$$

is continuous. Shrink B_0 until $G_j(s) \in I_j$ and $G_j(s) > \epsilon_j$ for every j. Let H contain the equality hyperplane for every pair of distinct exponent terms in every p_j. These are finitely many proper hyperplanes with integral normals; a monomial contributes none.

For $s \notin H$ there is a unique largest term in each p_j at every point $y \in \mathbb{T}_s$. The strong triangle inequality gives $|p_j(y)| = G_j(s)$. The approximation error is smaller, so $|g_j(y)| = G_j(s) \in I_j$. Every point satisfies all the selected bounds and belongs to O. □

Definition C.1.44 (Finite Gauss chart with monomial moments)**.** Fix $d \geq 1$, $s_0 \in \operatorname{int}(P)$, and a norm-admissible finite morphism

$$p : Y = \mathcal{M}(B) \longrightarrow \mathbb{T}_P$$

with Y nonempty and pure of analytic dimension d. Assume that the entire fibre over the *analytic* Gauss point is $p^{-1}(\eta_{s_0}) = \{x\}$ as a set. Its finite algebra may have nontrivial length and residue-field degree. This does not assert that the tropical fibre $p^{-1}(\mathbb{T}_{s_0})$ is a singleton.

Let $A \in M_{n \times d}(\mathbb{Z})$ have rank d, with rows a_i, and let $c_i \in K^\times$. The moment tuple is

$$f_i = c_i p^* T^{a_i}, \qquad t_f = b + A\, t_T \circ p, \qquad b_i = -\log |c_i|.$$

Put $w_0 = b + A s_0$, $N = A\mathbb{R}^d \cap \mathbb{Z}^n$, and $j_A = [N : A\mathbb{Z}^d]$. Let M be a finite B-module, restricted to affinoid subdomains by the actual domain tensor.

Set $F = \operatorname{Frac}(R_P)$ and $D_M = \dim_F(M \otimes_{R_P} F)$, a finite integer. An admissible generic projection for these monomial moments is an integral $Q : \mathbb{Z}^n \to \mathbb{Z}^d$ injective on N; put $e_Q = [\mathbb{Z}^d : Q(N)]$. At $v = b + As$, let $R_{Q,v}$ be the exact-radius target algebra for the actual units $f^{q_1}, \dots, f^{q_d}$, and let $H_{Q,v}$ be its Gauss field.

Write $D_s = B \widehat{\otimes}_{R_P} R_s$, the algebra of the entire exact-radius inverse image by 2.33.19. For the original logarithmic normalization write $v = b + As$ and choose the normalizers only after the complete isometric extension in the statement.

Corollary C.1.45 (Lengths, field degrees, and normalization)**.** *Put* $E_s = B \otimes_{R_P} H_s$ *and* $M_s = M \otimes_{R_P} H_s$*. For every* $s \in P$*,*

$$D_M = \sum_{\mathfrak{q} \in \operatorname{Min} B} \operatorname{length}_{B_{\mathfrak{q}}}(M_{\mathfrak{q}})[\operatorname{Frac}(B/\mathfrak{q}) : F], \tag{C.1.18}$$

$$= \sum_{\mathfrak{m} \in \operatorname{Max} E_s} \operatorname{length}_{(E_s)_{\mathfrak{m}}}((M_s)_{\mathfrak{m}})[\kappa(\mathfrak{m}) : H_s]. \tag{C.1.19}$$

At $s = s_0$ *the second sum has one term, with residue field* $\mathcal{H}(x)$*. All degrees are full degrees, including inseparable degrees. The structure module retains nilpotent length.*

After any complete isometric extension realizing the needed radii, the normalized Gauss dimensions and lattice divisors give the same coefficient on the full base-changed fibre. All its factors must be retained; a selected lift of x *is not that full fibre.*

Proof. Every minimal prime of B contracts to zero in R_P, by 5.35.4. Apply the generic-length calculation 5.40.1 to $B \to D_s$ with its finite R_s-map. For a minimal prime $\mathfrak{q}$, its reduced generic factor over F is $\operatorname{Frac}(B/\mathfrak{q})$; extending to H_s preserves vector-space dimension. This proves (C.1.18). The finite-dimensional algebra E_s is Artinian. Every simple quotient in a composition series over a local factor is its residue field. Adding dimensions gives (C.1.19). By 2.33.11, the singleton analytic fibre means that E_{s_0} has one local factor; its residue field is the finite complete extension $\mathcal{H}(x)$ of H_{s_0}.

The actual finite tensor identities of 5.36.2 apply to finite modules as well: a vector-space basis remains a basis after extension of the Gauss field. For normalizers $|a_i| = e^{-v_i}$ of f_i, use $\prod_i a_i^{q_{ji}}$ for f^{q_j}. Changing these normalizers is an isometric target coordinate change. The model formula 5.36.3 retains the generic lengths and full field degrees. Only finite fibre normalization is asserted here, not scalar-extension compatibility of a global integral. □

Puncture products

The ground field K is complete for its specified real-valued non-Archimedean absolute value, which may be trivial. Every finite analytic map below is required to carry the canonical finite-module norm, up to uniform equivalence. All fibres are actual analytic fibres over K, with their full algebras and nilpotents. No scalar extension is used in the construction.

Definition C.1.46 (Puncture-product data and positive projections)**.** Choose integers $p \geq 1$, $k \geq 0$, and $m_\ell \geq 1$; put $d = p + k$ and $n = \sum_\ell m_\ell + k$. For $1 \leq \ell \leq p$, choose $c_{\ell j} \in K^\circ$ such that

$$|c_{\ell j} - c_{\ell h}| = 1 \qquad (j \neq h).$$

Thus the punctures in each block have distinct residues. Set

$$Z = \prod_{\ell=1}^{p} \big(\mathbb{A}^1_K \setminus \{c_{\ell 1}, \dots, c_{\ell m_\ell}\}\big) \times (\mathbb{G}_{m,K})^k.$$

Write t_ℓ, z_b for its coordinates, and use the actual unit tuple

$$g = ((t_\ell - c_{\ell j})_{\ell,j}, (z_b)_b).$$

Let $\eta \in Z^{\mathrm{an}}$ be the unit Gauss point in the variables $t_1, \dots, t_p, z_1, \dots, z_k$; then $t_g(\eta) = 0$. For $\varepsilon > 0$ put

$$Y_\varepsilon = \{y \in Z^{\mathrm{an}} : |\log |g_\nu(y)|| \leq \varepsilon \text{ for every } \nu\}.$$

For an array $a = (a_{\ell j})$ of positive integers, define

$$A_\ell = \sum_j a_{\ell j}, \qquad P_{\ell,a}(T) = \prod_j (T - c_{\ell j})^{a_{\ell j}}, \qquad D_a = \prod_{\ell=1}^{p} A_\ell.$$

The projection $Q_a : \mathbb{Z}^n \to \mathbb{Z}^d$ sends the ℓ-th block to $\sum_j a_{\ell j} v_{\ell j}$ and is the identity on the final k coordinates. Its actual analytic map is

$$q_a = (P_{1,a}(t_1), \dots, P_{p,a}(t_p), z_1, \dots, z_k) : Z^{\mathrm{an}} \longrightarrow (\mathbb{G}_m^d)^{\mathrm{an}}.$$

For a full-dimensional closed rectangular box P with $0 \in \mathrm{int}(P)$, $\mathbb{T}_P$ denotes the complete closed polyannulus $t^{-1}(P)$, and $R_P = \mathcal{O}(\mathbb{T}_P)$.

Lemma C.1.47 (Explicit base collars and their whole Gauss fibre)**.** *The domain Y_ε is a nonempty generalized affinoid, pure of dimension d, and $\eta \in \mathrm{Int}(Y_\varepsilon/K)$. For every positive array a, q_a is finite, with*

$$q_a^{-1}(\mathbb{T}_P) = \mathcal{M}\big(R_P[T_1, \dots, T_p]/(P_{\ell,a}(T_\ell) - S_\ell)_{\ell=1}^{p}\big), \tag{1}$$

where S_ℓ are the first p target coordinates. The displayed algebra is free of rank D_a over R_P and has its canonical finite-module norm.

Put $b_\ell = \min_j a_{\ell j}$. *If* P *satisfies*

$$|u_\ell| < b_\ell \varepsilon \ (1 \le \ell \le p), \qquad |u_{p+b}| < \varepsilon \ (1 \le b \le k) \quad \textit{for every } u \in P, \tag{2}$$

then the entire *inverse image in (1) lies in the ordinary interior of* Y_ε *in* Z^{an}. *Consequently it is exactly the saturated collar* $(Q_a t_g|_{Y_\varepsilon})^{-1}(P)$.

If η_a *is the target unit Gauss point, then*

$$q_a^{-1}(\eta_a) = \{\eta\}. \tag{3}$$

For its actual Artinian fibre algebra E_a,

$$\dim_{\mathcal{H}(\eta_a)} E_a = D_a = \sum_{\mathfrak{m} \in \operatorname{Max} E_a} \operatorname{length}((E_a)_{\mathfrak{m}})[\kappa(\mathfrak{m}) : \mathcal{H}(\eta_a)]. \tag{4}$$

Equation (3) concerns points; (4) retains all length and field-degree data and does not replace E_a *by its reduction.*

Proof. Set $R = e^\varepsilon > 1$. A presentation of Y_ε uses $t_\ell, z_b, z_b^{-1}, (t_\ell - c_{\ell j})^{-1}$, all with radius R, and their polynomial inverse relations. Indeed $|t_\ell| \le R$ and $|c_{\ell j}| \le 1 < R$ give every upper bound $|t_\ell - c_{\ell j}| \le R$; conversely one such upper bound gives $|t_\ell| \le R$. The inverse coordinates give the lower bounds. This is an actual generalized affinoid presentation. All its coordinates have value $1 < R$ at η, so the presentation witnesses absolute interiority there. It is an affinoid domain of the closed polyannulus in $(t_\ell - c_{\ell 1}, z_b)$, cut out by the additional puncture bounds. That polyannulus is integral and pure of dimension d by 5.35.4; domain purity 5.35.3 proves the assertion for Y_ε.

The algebraic coordinate ring of Z is

$$K[S_1^{\pm 1}, \dots, S_p^{\pm 1}, Z_1^{\pm 1}, \dots, Z_k^{\pm 1}][T_1, \dots, T_p]/(P_{\ell,a}(T_\ell) - S_\ell)_\ell.$$

To check the inverse coordinates in this identity, use

$$(T_\ell - c_{\ell j})^{-1} = S_\ell^{-1}(T_\ell - c_{\ell j})^{a_{\ell j}-1} \prod_{h \ne j} (T_\ell - c_{\ell h})^{a_{\ell h}}.$$

Successive division by the separate monic polynomials gives the free basis $\prod_\ell T_\ell^{i_\ell}$, $0 \le i_\ell < A_\ell$. The frozen analytification theorem 2.33.26 identifies the *whole* inverse image of any target affinoid with its ordinary tensor algebra and canonical finite-module norm. It gives (1).

Here is the estimate which supplies saturation. At any analytic point, fix a block ℓ. If $|t_\ell| > 1$, all its puncture distances are equal to $|t_\ell|$. If $|t_\ell| \le 1$,

all those distances are at most 1, and at most one is less than 1, because the difference of two punctures has norm 1. Thus its weight vector belongs to

$$F_\ell = \bigcup_{j=1}^{m_\ell} \mathbb{R}_{\geq 0} e_{\ell j} \ \cup \ \mathbb{R}_{\geq 0}(-e_{\ell 1} - \cdots - e_{\ell m_\ell}). \tag{5}$$

On the positive ray j, $u_\ell = a_{\ell j} v_{\ell j}$; on the last ray, $u_\ell = -A_\ell s$ with all $v_{\ell j} = -s$. In either case

$$|v_{\ell j}| \leq |u_\ell| / b_\ell. \tag{6}$$

The final k weights are unchanged. Bounds (2) therefore put every inverse-image point in the strict moment inequalities. This proves the collar assertion without selecting any branch.

We prove (3) over the original field. The unit Gauss point maps to η_a: after reduction, the separate nonconstant monic polynomials $\overline{P}_{\ell,a}(\overline{t}_\ell)$, together with the $\overline{z}_b$, are algebraically independent over $\widetilde{K}$. For example, their distinct leading multidegrees prove the injectivity of polynomial substitution. Scaling a largest coefficient of any Laurent polynomial then proves the unit Gauss norm identity.

Conversely let y map to η_a. Equation (6), with $u = 0$, gives $|t_\ell - c_{\ell j}| = |z_b| = 1$ at y, hence $|t_\ell| \leq 1$. In the residue field of $\mathcal{H}(y)$, the elements $\overline{P}_{\ell,a}(\overline{t}_\ell), \overline{z}_b$ are algebraically independent: any relation would contradict the target Gauss seminorm after lifting its finitely many coefficients. Each $\overline{t}_\ell$ is integral over the field generated by these elements. Consequently the field generated by $\overline{t}_1, \ldots, \overline{t}_p, \overline{z}_1, \ldots, \overline{z}_k$ has transcendence degree d. These d elements are therefore algebraically independent. For any nonzero polynomial in t, z, divide by a largest coefficient. Its reduction is nonzero at y, so its value is the maximum coefficient norm. The same holds at η. Inverting the puncture coordinates and the z_b proves equality on the entire algebraic coordinate ring, hence equality of the analytic points $y = \eta$. No separability or defectlessness assertion enters this argument.

Finally the finite tensor comparison 1.18.7 identifies E_a with the ordinary base change of the free module in (1). Its dimension is D_a. An Artinian composition series gives the second equality in (4), with full residue-field degrees. □

Finite local lengths and a nodal example

Example C.1.48 (A regular parameter without S_1; F8SC-X)**.** For any field K, set

$$R = \big(K[u,v,\epsilon]/(\epsilon^2, u\epsilon)\big)_{(u,v,\epsilon)}. \tag{4.1}$$

The element v is a non-zero-divisor in the maximal ideal, but R does not satisfy S_1. Its unique minimal component has dimension two. For the unlocalized algebra $A = K[u,v,\epsilon]/(\epsilon^2, u\epsilon)$, the morphism $\operatorname{Spec} A \to \mathbf{A}^1_K$ with parameter v has pure one-dimensional fibres; R is its local ring at the origin.

Proof. Before localization the algebra is the direct sum $K[u,v] \oplus \epsilon K[v]$ as a $K[u,v]$-module. Multiplication by v is injective on both summands and remains so after localization. The unique minimal prime is (ϵ). The prime $\mathfrak{q} = (u,\epsilon)$ is embedded, with $\operatorname{Ann}(\epsilon) = \mathfrak{q}$. In $R_{\mathfrak{q}}$, the element ϵ is nonzero, $\dim R_{\mathfrak{q}} = 1$, and every member of the maximal ideal annihilates ϵ. Its depth is zero, contradicting S_1. Every fibre of $\operatorname{Spec} A \to \mathbf{A}^1_K$ has underlying ring $L[u]$ after reduction, where L is the residue field of the parameter; hence it is pure of dimension one. The same local calculation is available in the convergent analytic germ at the origin over a complete nontrivially valued K, replacing the polynomial summands by convergent power-series germs. □

Proposition C.1.49 (Finite-presentation accounting; F8ST-F)**.** *For a norm-admissible finite map $p : \mathcal{M}(C) \to \mathcal{M}(A)$, $R = \mathcal{O}_{\mathcal{M}(A),x}$, and a finite C-module M, there are canonical identifications*

$$C \otimes_A R = \prod_{y \in p^{-1}(x)} \mathcal{O}_{\mathcal{M}(C),y}, \qquad M \otimes_A R = \bigoplus_{y \in p^{-1}(x)} \widetilde{M}_y.$$

If the module on the right has finite R-length, then

$$\operatorname{length}_R(M \otimes_A R) = \sum_{y \in p^{-1}(x)} [\kappa(y) : \kappa(x)] \operatorname{length}_{\mathcal{O}_{\mathcal{M}(C),y}} \widetilde{M}_y. \tag{C.1.20}$$

For a finite algebra E over a field H, correspondingly,

$$\dim_H E = \sum_{\mathfrak{q} \in \operatorname{Spec} E} [\kappa(\mathfrak{q}) : H] \operatorname{length}_{E_{\mathfrak{q}}} E_{\mathfrak{q}}. \tag{C.1.21}$$

These formulas do not assert that a finite map preserves each local length.

Proof. The ring product is `NAG-001735`. Tensor a finite presentation of M with that product to obtain the module formula; a finite direct product is

a direct sum as modules. Each local factor is finite over R. A composition factor at y is $\kappa(y)$, which has R-length $[\kappa(y) : \kappa(x)]$. Additivity proves (C.1.20); the same argument over H proves (C.1.21). Finite tensor comparison `NAG-001565` identifies the ordinary and completed finite-module tensors with their canonical norms. It does not by itself assert flatness or a reduced closed fibre. □

Here K is algebraically closed, and $M_A = A^\times/K^\times$ for the indicated K-algebra A. For its localization use the same quotient by $K^\times$.

Example C.1.50 (Nonsaturation on an irreducible very affine nodal curve)**.** Assume $\operatorname{char} K \neq 2$. There is an integral, reduced, connected very affine curve $U = \operatorname{Spec} A$ and a nonempty principal open U_h such that $M_A \to M_{A_h}$ has a quotient containing an element of exact order 2. Explicitly, take

$$A = K[x^{\pm 1}, z^{\pm 1}]/\big((z-1)^2 - x(x-1)^2\big), \qquad h = x - 1. \tag{6}$$

Proof. Inside $K(t)$ put $x = t^2$ and $z = 1 + t(t^2 - 1)$. Before inverting z, division by the monic relation in $y = z - 1$ writes every element uniquely as $a(x) + b(x)y$ with $a, b \in K[x, x^{-1}]$. Its image is $a(t^2) + t(t^2-1)b(t^2)$, whose even and odd powers of t cannot cancel. This proves injectivity, and localization by the nonzero element z preserves it. Hence (6) is an integral domain. Every nonzero prime contains a nonzero Laurent polynomial in x: choose a nonzero element of the prime, take its algebraic equation over $K(x)$ with nonzero constant term, and clear denominators. In the quotient, algebraic closedness then forces x to be a scalar; the defining equation forces z to be a scalar as well. Thus every nonzero prime is maximal. The nonzero prime $(x-1, z-1)$ exists, so the dimension is exactly one.

Its fraction field is $K(t)$ because $t = (z-1)/(x-1)$ there. Its normalization is

$$B = K[t, t^{-1}, (1 + t^3 - t)^{-1}] = A[t].$$

Indeed $t^2 = x$, so t is integral over A, and $t^{-1} = t/x$ shows the displayed ring equals $A[t]$, hence is finite over A. Factorization in $K[t]$ shows that this localization is integrally closed, by the pole argument used in Proposition C.1.27. It follows that it is the normalization in the common fraction field.

The two evaluations at $t = 1$ and $t = -1$ are defined on B and agree on A: both give $x = z = 1$. They differ on t, since the characteristic is not 2. Thus $t \notin A$. After inverting h the formula $t = (z-1)/(x-1)$ gives $A_h = B_h$. In

particular $t \in A_h^\times$, while its class modulo constants does not come from $A^\times$: an equality $t = cu$ would put t in A. But $t^2 = x \in A^\times$. Its image in $A_h^\times/A^\times$ therefore has exact order 2.

The presentation gives a closed embedding of U in $\mathbb{G}_m^2$, and A_h is generated by the units x, z, h and their inverses, so U_h is also very affine. Both rings are integral and $h \neq 0$, giving irreducibility, reducedness and connectedness. At $x = z = 1$, with local coordinates $X = x - 1$ and $Y = z - 1$, the equation is $Y^2 - X^2 - X^3$; its two distinct tangent lines are $Y = \pm X$. Thus this is an ordinary node. □

Very affine charts and the smooth test kernel

Throughout the new arguments, K is complete, algebraically closed and nontrivially valued, with its specified real-valued absolute value. Put $v = -\log|\cdot|$, $\Gamma = v(K^\times)$, $O = K^\circ$, $\mathfrak{m} = K^{\circ\circ}$ and $k = O/\mathfrak{m}$. Let X be an irreducible, reduced, separated scheme of finite type over K, and let $W \subset X^{\mathrm{an}}$ be ordinary open. The dimension may be zero. An analytic moment tuple is a finite tuple of units in $\mathcal{O}(W)$. A very affine chart starts with an actual closed embedding of a Zariski open $U \subset X$ into a split torus. An intrinsic chart, when used, is exactly the one in GK [GK17, 4.1–4.4]: it uses $\mathcal{O}(U)^\times/K^\times$ and its original universal pullback kernel.

Proposition C.1.51 (Simultaneous algebraic replacement)**.** *Let $x \in W$ and let $f_1, \dots, f_m \in \mathcal{O}(W)^\times$. There exist a compact affinoid domain $C \subset W$, an ordinary open neighborhood V of x in C, a very affine Zariski open $U \subset X$ with $C \subset U^{\mathrm{an}}$, and $g_i \in \mathcal{O}(U)^\times$ such that*

$$|f_i(z)| = |g_i(z)| \quad (z \in C,\ 1 \le i \le m).$$

Moreover, V is the inverse image of an open real set under an explicit algebraic closed embedding of U into a torus. All analytic coordinates and all finite germ relations specified in advance may use this same C.

Proof. Choose an affine Zariski neighborhood of the scheme point underlying x and shrink W within its analytification. Write it as $\operatorname{Spec} A$. By the evaluation topology in `NAG-001707`, an ordinary neighborhood of x inside W is specified by finitely many strict bounds on $|a|$, $a \in A$. We replace them by bounds on functions nonzero at x.

If $|a(x)| > 0$, choose a smaller positive lower and upper bound around this value. If $a(x) = 0$, the only relevant constraint is an upper bound $|a| < b$. Choose $c \in K^\times$ with $|c| < b$ and numbers $0 < s < |c| < r < b$. Then

$$s < |a - c| < r \quad \Longrightarrow \quad |a| < b,$$

and the new inequalities hold at x. Also choose algebra generators for A, translating any generator vanishing at x by a nonzero scalar. Translated generators still generate A.

Combining these finite lists gives $y_1, \dots, y_N \in A$ which generate A and satisfy $|y_j(x)| > 0$. We can choose

$$0 < s_j < |y_j(x)| < r_j, \qquad C = \{z \in (\operatorname{Spec} A)^{\mathrm{an}} : s_j \le |y_j(z)| \le r_j \ \forall j\} \subset W.$$

Choose all bounds strictly inside the earlier bounds. Since K is algebraically closed and nontrivially valued, $|K^\times|$ is dense in $\mathbb{R}_{>0}$: the rational powers of any element of absolute value different from one already have this property. Hence the s_j, r_j may belong to $|K^\times|$.

If $A = K[T_1, \dots, T_N]/I$, with $T_j \mapsto y_j$, the domain has the actual affinoid presentation

$$B = K\{r^{-1}T, sS\}/(I(T), T_jS_j - 1)_j. \tag{C.1.22}$$

Here the bound on S_j is s_j^{-1}. The affine analytification and rational-domain results `NAG-001707`, `NAG-001576` and `NAG-001577` identify its spectrum with C. Actual ideals are closed by `NAG-001562`; compactness is `NAG-001496`. Set

$$V = \{z : s_j < |y_j(z)| < r_j \ \forall j\}.$$

This is ordinary open, contains x and lies in C. The displayed strict inequalities on both sets of generators also put V in the analytic interior of this presentation of C over K.

The image of $A[(y_1 \cdots y_N)^{-1}]$ is dense in B: truncate a lift in the weighted Tate algebra in (C.1.22); the resulting polynomial in T, S is such a Laurent polynomial. This uses the actual quotient norm and does not require a Runge theorem. By `NAG-001610`, restriction of the analytic units and their inverses gives units of B. Apply Lemma C.1.34, writing each approximant as

$$g_i = p_i/(y_1 \cdots y_N)^{a_i}, \qquad p_i \in A.$$

The equality of absolute values holds on all of C, so every p_i is nonzero at every point of C. Define

$$U = \operatorname{Spec} A[(y_1 \cdots y_N p_1 \cdots p_m)^{-1}].$$

By NAG-001708, its analytification contains C. Its coordinate algebra is generated by the units y_j, p_i and their inverses, so these coordinates give an explicit closed embedding $\psi : U \hookrightarrow \mathbb{G}_m^{N+m}$. The open set V is exactly $\psi_{\mathrm{trop}}^{-1}(\Omega)$, where Ω imposes the strict bounds on the first N coordinates. Its remaining coordinates are unrestricted.

For a finite list of germ relations, first intersect their ordinary witness neighborhoods with W and include all analytic units occurring in them in one tuple. The preceding construction then applies once. This proves the last assertion without a compatibility choice between separate approximations. □

An ambient superform is tangentially zero when its restriction to the tangent space of every cell and face vanishes at every point of that cell or face.

Lemma C.1.52 (The universal GK kernel restricted to smooth forms)**.** *Fix an original GK tropical chart (V, φ_U), with tropical image P in a real open set $\widetilde{\Omega}$. Assume the canonical cycles of this chart and each compatible test chart have their actual tropical supports, finite pure polyhedral structures and strictly positive top-dimensional weights. Let $\mathcal{N}$ be GK's kernel from Definition 4.4, testing every compatible algebraic morphism and chart. For an ambient smooth (p, q)-form α,*

$$\alpha \in \mathcal{N} \quad \Longleftrightarrow \quad \alpha \text{ is tangentially zero on every face of } P.$$

This equality is independent of the numerical values of the positive weights.

Proof. For the reverse implication, take any compatible algebraic morphism and chart. Its integral affine map F carries its actual tropical image into P. Subdivide so that each source cell maps into a target cell. The differential of F maps the source tangent into the target tangent; hence $F^*\alpha$ is tangentially zero. Its product with the integration current of the source tropical cycle is zero, which is exactly the smooth instance of restriction in GK [GK17, 3.4 and 4.4]. This proves membership in every test kernel, including rank-dropping maps and maps whose source dimension differs from that of U.

Conversely, the identity morphism is one of the tests. It says $\alpha \wedge \delta_P = 0$. If a tangential coefficient of α were nonzero in the relative interior of a maximal cell, choose a small ball meeting no other maximal cell and a complementary constant superform which isolates that coefficient. Multiplication by a nonnegative smooth bump supported in the ball gives a nonzero pairing, because

the coefficient has fixed sign on a smaller ball and the weight is positive. Thus all coefficients vanish in every maximal relative interior. Continuity and purity give vanishing on every face. If p or q exceeds the cell dimension, the tangential restriction is already zero by exterior degree. The zero-dimensional case is the same assertion for functions on a finite set. □

Tame coefficient descent and split nodes

Kummer coefficients and effective descent

Let K be a complete nontrivially real-valued field, with additive value group $\Gamma = v(K^\times)$, valuation ring O, maximal ideal $\mathfrak{m}$, and residue field k. Fix $e \geq 2$, invertible in O, and a primitive e-th root $\zeta \in O$ whose reduction also has order e. Let $L = K(s)$, with its extended valuation, satisfy

$$s^e = c \in K^\times, \qquad \gamma = v(s) > 0, \qquad i\gamma \notin \Gamma \quad (1 \leq i < e). \tag{K}$$

Thus the e value cosets are distinct. In particular the degree is exactly e, and $G = \langle\sigma\rangle$, $\sigma(s) = \zeta s$, is the cyclic Galois group. Put $O' = L^\circ$, its *actual* valuation ring. No equality $O' = O[s]$, and no module finiteness of O'/O, is assumed.

For $0 \leq i < e$, define the fractional O-module

$$I_i = \{a \in K : v(a) + i\gamma \geq 0\}, \qquad v(0) = +\infty. \tag{1}$$

Here $I_0 = O$; an I_i need not be finitely generated. The distinct value cosets give the orthogonal expansion

$$v\left(\sum_{i=0}^{e-1} a_i s^i\right) = \min_{a_i \neq 0}\big(v(a_i) + i\gamma\big), \qquad O' = \bigoplus_{i=0}^{e-1} I_i s^i. \tag{2}$$

Indeed nonzero summands have distinct valuations, so none can cancel a summand of least valuation. The same argument proves linear independence of $1, s, \ldots, s^{e-1}$, hence the degree assertion above. Completeness follows coefficientwise from (2). Only the $i = 0$ summand can have value zero, so O' has residue field k, and G acts trivially on that field. The value index and degree are both e; this is the totally ramified, defectless tame class considered here.

An affine semilinear G-algebra means an O'-algebra B' with an O-algebra action of G inducing this action on O'. An *effective descent* means an O-algebra D and a G-equivariant isomorphism $O' \otimes_O D \simeq B'$, where G acts only on the first factor on the left.

Theorem C.1.53 (Character modules give an exact integral test)**.** *Assume (K), and let B' be flat over O'. Set*

$$B = (B')^G, \qquad M_i = \{b \in B' : \sigma(b) = \zeta^i b\}, \qquad \Lambda_i = s^{-i} M_i \subset B_K, \quad B_K = K \otimes_O B. \tag{3}$$

The displayed inclusion is well-defined. In the expression $I_i B \subset B_K$, products mean finite sums *of ab with $a \in I_i$ and $b \in B$. Then multiplication*

$$\mu : O' \otimes_O B \longrightarrow B' \tag{4}$$

is injective, and the following conditions are equivalent:

1. *the given semilinear algebra B' has effective descent;*
2. *μ is an isomorphism;*
3. *$\Lambda_i = I_i B$ for every $0 \le i < e$.*

If B' is generated as an O'-algebra by $z_1, \dots, z_r$, condition 3 can equivalently be checked by the finitely many membership conditions

$$s^{-i} P_i(z_j) \in I_i B \qquad (0 \le i < e,\ 1 \le j \le r), \tag{4a}$$

where P_i is the Fourier projector defined in the proof. When these conditions hold, B is the uniquely identified invariant descent. It is flat over O. If B' is finitely presented over O', then B is finitely presented over O; if its structural morphism is a nodal curve, so is that of B. Effective descent necessarily makes the action on $B'/\mathfrak{m}'B'$ the identity.

Proof. The Fourier operators

$$P_i = \frac{1}{e} \sum_{j=0}^{e-1} \zeta^{-ij} \sigma^j$$

are O-linear orthogonal idempotents summing to the identity. The usual finite geometric sums prove $B' = \bigoplus_i M_i$ and $M_0 = B$. Flatness of B' over the domain O' makes B', and hence B, torsion free over O. Thus B is O-flat by Stacks Tag 0539.

Localizing O' at $O \setminus \{0\}$ gives L: multiply any element of L by a sufficiently high power of a fixed positive element of O. Invariants commute with this localization. Explicitly, if $b/d \in B'_L$, with $b \in B'$ and $d \in O \setminus \{0\}$, is invariant, then $(\sigma(b) - b)/d = 0$, so torsion-freeness gives $\sigma(b) = b$. Consequently $(B'_L)^G = B_K$. For $m \in M_i$, $s^{-i} m$ is invariant in B'_L, proving (3).

Tensor (2) with B. Flatness of B makes $I_i \otimes_O B \longrightarrow K \otimes_O B = B_K$ injective, with image exactly I_iB. Under this identification, (4) on the i-th summand is multiplication by s^i, with image $s^iI_iB \subset M_i$. This is injective since B' embeds in B'_L. Images of different summands are independent by the Fourier decomposition. This proves injectivity of μ and the equivalence of conditions 2 and 3. Each test (4a) says that $P_i(z_j)$ belongs to the image of μ. If all the tests hold, their sums put every z_j in that image. The image is an O'-subalgebra, so then equals B'. Necessity is immediate.

Condition 2 is an effective descent, so implies condition 1. Conversely, for any effective presentation $O' \otimes_O D \simeq B'$, the Fourier projectors on the left act on O' alone. Their weight-zero summand is $I_0 \otimes_O D = D$. Thus the isomorphism identifies D with B, and its multiplication map is (4). This proves condition 2, including the asserted uniqueness.

The valuation-ring extension $O \to O'$ is faithfully flat: it is torsion free and hence flat by Stacks Tag 0539, and $\mathfrak{m}O' \subset \mathfrak{m}'$ makes this local flat extension faithful. Its affine spectrum map is quasi-compact, so it is an fpqc cover. Once (4) is an isomorphism, finite presentation descends by Stacks Tag 02L0, and the nodal relative dimension-one property descends by Stacks Tag 0C5E. Finally the special fibre of an effective presentation is $k \otimes_O D$; the action on $k = O'/\mathfrak{m}'$ is the identity. Thus its entire special-fibre algebra has trivial action. □

Discrete specialization

For this section let R be a complete discrete valuation ring with uniformizer π, residue field k, and valuation $v(\pi) = 1$. Assume e and ζ as above, and take

$$R' = R[s], \qquad s^e = \pi, \qquad R' = \bigoplus_{i=0}^{e-1} Rs^i, \tag{5}$$

where R' is the valuation ring of $K(s)$. These are discrete hypotheses; (5) is not used for general O'. In (1) each I_i is now R.

Corollary C.1.54 (The affine special-fibre criterion over a DVR)**.** *For a flat R'-algebra B' with the specified semilinear cyclic action, effective descent over R holds if and only if G acts identically on B'/sB'. Under these equivalent conditions, finite presentation and nodality descend as in Theorem C.1.53. No smoothness, branch-splitting, or diagonalization of B' is required for this criterion.*

Proof. Necessity was proved in the theorem. Suppose the special-fibre action is the identity, and retain the Fourier eigenspaces M_i. For $1 \le i < e$ and $a \in M_i$, $(\zeta^i - 1)a \in sB'$. The coefficient $\zeta^i - 1$ is a unit, since its reduction is nonzero. Hence $a = sb$ for a unique $b \in B'$. Applying σ and cancelling the nonzerodivisor s gives $\sigma(b) = \zeta^{i-1}b$. Induction, with the indices $i, i-1, \dots, 1$, gives $M_i = s^i M_0$. The opposite containment is immediate. Thus $\Lambda_i = B = I_i B$, and the theorem applies. □

Split diagonal nodes

Proposition C.1.55 (Branch characters and the quotient of a node)**.** *In (5) let*

$$B' = R'[x,y]/(xy - s^n), \qquad n \ge 1, \qquad \sigma(x) = \zeta^a x, \quad \sigma(y) = \zeta^b y, \tag{8}$$

where $0 \le a, b < e$ and $a + b \equiv n \pmod e$. Let $B = (B')^G$. The images in $\operatorname{Spec}(B/\pi B)$ of the components $y = 0$ and $x = 0$ have generic multiplicities, respectively,

$$\frac{e}{\gcd(e,a)}, \qquad \frac{e}{\gcd(e,b)}. \tag{9}$$

Moreover the following conditions are equivalent:

1. *the given chart (8) effectively descends over R;*
2. *$a = b = 0$;*
3. *$\operatorname{Spec} B \to \operatorname{Spec} R$ is a semistable affine nodal chart.*

When these conditions hold, $e \mid n$ and

$$B = R[x,y]/(xy - \pi^{\,n/e}). \tag{10}$$

All these statements allow arbitrary k subject to the root-of-unity and tameness hypotheses. They concern the given split diagonal chart, without an assertion that every nonsplit node has such coordinates over its original residue field.

Proof. The ring B' is free over R' on $1, x^i, y^j$ for $i, j \ge 1$. Reduction of mixed monomials using $xy = s^n$ gives spanning; their distinct Laurent monomials in $L[x, x^{-1}]$ give independence. For an integer q, let $[q]_e$ denote its representative in $\{0, \dots, e-1\}$. The invariant ring is free over R on

$$1, \quad s^{[-ai]_e} x^i \ (i \ge 1), \quad s^{[-bj]_e} y^j \ (j \ge 1). \tag{11}$$

This follows by expanding each coefficient in the basis (5) and imposing the character equation. The elements in (11) with $1 \le i, j \le e$ generate the algebra, since multiplying by the invariant x^e or y^e handles the remaining exponents. Thus B is flat and of finite type, hence finitely presented, over the Noetherian ring R.

Set $d = \gcd(e, a)$, $h = e/d$. If $h > 1$, choose an integer v with $(a/d)v \equiv 1 \pmod{h}$; if $h = 1$, take $v = 0$. On the invariant open where x^e is invertible, put

$$z = s^d x^{-v}, \qquad w = x^h.$$

Both are invariant and w is a unit. We claim

$$B[1/x^e] \simeq R[z, w, w^{-1}]/(z^h w^v - \pi). \tag{12}$$

Indeed $B'[1/x^e] = R'[x, x^{-1}]$, and invariants commute with localization at the invariant nonzerodivisor x^e. An invariant monomial $s^r x^q$, $0 \le r < e$, satisfies $r + aq \equiv 0 \pmod{e}$. Thus $r = dj$ with $0 \le j < h$ and $q = -vj + h\ell$ for an integer ℓ. It is $z^j w^\ell$, which proves surjectivity in (12). The monic relation in z gives a spanning set $z^j w^\ell$, $0 \le j < h$. Its images have distinct pairs of s-exponent modulo e and x-exponent, so are R-linearly independent. This proves (12).

Reducing (12) modulo π gives $k[z, w, w^{-1}]/(z^h)$. At its sole generic point the local ring has length h, proving the first multiplicity in (9). Interchanging x, a with y, b proves the other. These are the generic points of the two component images: x^e, respectively y^e, is nonzero there and vanishes on the other component. The two images are therefore distinct. The finite invariant map introduces no ambiguity here: B' is finite over B, since s, x, y are integral and generate it as a B-algebra.

On $B'/sB' = k[x, y]/(xy)$, the action is the identity exactly when $a = b = 0$. The preceding corollary proves the equivalence of conditions 1 and 2. If either weight is nonzero, its multiplicity in (9) exceeds one, so $B/\pi B$ is not reduced on the corresponding open and condition 3 fails. If both weights vanish, the congruence in (8) gives $e \mid n$; (11) directly gives (10), which is flat with reduced nodal geometric special fibre and smooth generic fibre. □

Corollary C.1.56 (Invariant branches and integral length do not suffice)**.** *Take $e = 2, n = 2, a = b = 1$, with residue characteristic different from two. Then (8) fixes both branches setwise and every point of its geometric skeleton. Its length measured by $v(\pi) = 1$ is $1 \in v(K^\times)$, but its given semilinear chart has no effective descent. The quotient has multiplicity two along each component image.*

Proof. The congruence $a + b \equiv n \pmod 2$ holds. Multiplication of coordinates by -1 preserves every annular radius, and fixes the two branch labels. The interval in the x-valuation is $[0, v(s^2)] = [0, 1]$. But both weights are nonzero, so the proposition applies. More precisely, the invariant generic coordinate is $T = x/s$; its endpoint values are $-1/2, 1/2$, outside $v(K^\times) = \mathbb{Z}$. Thus an integral total length does not make the individual vertices integral over the original field. □

The ramified coefficient map is computed in Lemma C.1.25.

Three applications of analytic dimension drop

Purity and minimal primes

For a Noetherian ring A, write $\operatorname{Min}_A(a)$ for the primes of A minimal over (a), and set $\operatorname{Min}_A(a) = \varnothing$ when a is a unit. A finite collection of primes is an antichain if no two distinct members are comparable by inclusion.

Lemma C.1.57 (Analytic purity supplies incomparability; F8CA-P)**.** *Let A be a generalized affinoid over a complete non-Archimedean field with its specified absolute value, and let $a, b \in A$. Suppose the nonempty actual zero spaces $\mathcal{M}(A/(a))$ and $\mathcal{M}(A/(b))$ are both pure of one common analytic dimension d. Empty zero spaces are allowed. Then their minimal-prime union is an antichain, (C.1.14) holds, and the product zero space is empty or pure of dimension d.*

Proof. Every prime in the union defines an integral affinoid component of analytic dimension d. If distinct members $q \subsetneq p$ were comparable, the nonzero ideal p/q in the integral pure d-dimensional algebra A/q would, by frozen NAG-002374, give

$$\dim \mathcal{M}(A/p) \leq d - 1$$

(or an empty quotient when $d = 0$). This contradicts its dimension d. Apply Lemma C.1.29. The listed primes are exactly the irreducible components of the product zero space, so all its components have dimension d. This argument uses analytic dimension, not an unproved equality with the Krull dimension of a generalized affinoid ring. □

Dimension of the ordinary local ring

Fix a complete non-Archimedean field K with its specified absolute value. Arbitrary positive real radii, trivial valuation, and positive characteristic are allowed. Dimensions of analytic spaces are analytic dimensions. Ordinary analytic local rings are denoted by $\mathcal{O}_{X,x}$. Put

$$d_K(x) = \operatorname{trdeg}_{\widetilde{K}} \widetilde{\mathcal{H}(x)} + \dim_{\mathbb{Q}}\big((|\mathcal{H}(x)^\times|/|K^\times|) \otimes_{\mathbb{Z}} \mathbb{Q}\big).$$

Lemma C.1.58 (Ordinary local dimension bound; F8RC-D)**.** *Let X be good, Hausdorff, and pure of analytic dimension n. If $d_K(x) \geq n-1$, then* $\dim \mathcal{O}_{X,x} \leq 1$.

Proof. The ordinary local ring $R = \mathcal{O}_{X,x}$ is Noetherian. If its dimension were at least two, choose primes $P_0 \subsetneq P_1 \subsetneq \mathfrak{m}_R$, and choose $a \in P_1 \setminus P_0$ and $b \in \mathfrak{m}_R \setminus P_1$. Represent both germs on one ordinary affinoid neighbourhood $U = \mathcal{M}(C)$ of x, using NAG-001698. Contract the three primes to $q_0 \subsetneq q_1 \subsetneq q_2$ of C; strictness is witnessed by a, b, and $q_2 = \ker(C \to \mathcal{H}(x))$. Choose a minimal prime $p \subset q_0$. The affinoid C/p is integral and pure of dimension n, by purity of U. Twice applying the dimension-drop theorem NAG-002374, first to $C/p \to C/q_1$ and then to the integral algebra $C/q_1 \to C/q_2$, gives $\dim_K \mathcal{M}(C/q_2) \leq n-2$. The intermediate integral affinoid is pure of its own analytic dimension, so the second application has its stated hypothesis. The point x has the same completed residue field on this quotient. Its Abhyankar dimension is therefore at most $n-2$, a contradiction. This also covers $n = 1$, where a second nonempty strict dimension drop is impossible. □

The prime choice uses Stacks Tag 00E0(4) in C, with the zero ideal and the specified prime $\mathfrak{q}_0$.

The discarded Cartier contribution

Let A be a nonzero Noetherian ring. Set

$$S = A \setminus \bigcup_{\mathfrak{p} \in \operatorname{Min}(A)} \mathfrak{p}, \qquad T(A) = \ker\left(A \longrightarrow \prod_{\mathfrak{p} \in \operatorname{Min}(A)} A_{\mathfrak{p}} \right), \qquad A^{\mathrm{u}} = A/T(A). \tag{1.1}$$

We call $T(A)$ the embedded torsion ideal. No reduction of the generic Artinian local rings is performed.

Now let A be generalized K-affinoid and $V = \mathcal{M}(A)$ pure of analytic dimension $n \geq 1$. All dimensions in the following lemma are *analytic* dimensions. We do not identify $\dim_{\mathrm{Krull}} A$ with n for arbitrary generalized radii.

The exact sequence (1.2) is in Lemma C.1.36.

Lemma C.1.59 (The discarded Cartier contribution; F8U-D)**.** *The coherent module $T = T(A)$ has analytic support of dimension at most $n-1$. If $f \in A$ is regular, then*

$$\dim_K \operatorname{Supp}(T/fT) \le n-2, \tag{2.1}$$

where the right side means empty support when $n = 1$. Consequently

$$[A/fA]_{n-1} = [A^{\mathrm{u}}/fA^{\mathrm{u}}]_{n-1} \tag{2.2}$$

as integer cycles, with generic local lengths, on the common reduced zero support.

Proof. Since T is finite and $T_{\mathfrak{p}} = 0$ at all minimal primes, $\operatorname{Ann}(T)$ is contained in none of them. The frozen exceptional-image theorem NAG-002374, applied to this ideal, gives $\dim_K \mathcal{M}(A/\operatorname{Ann}(T)) \le n-1$.

Let $\mathfrak{q}$ be a minimal prime of $\operatorname{Supp}(T)$. The nonzero module $T_{\mathfrak{q}}$ has finite length. If $f \in \mathfrak{q}$, some power of f annihilates this module, contradicting injectivity of f on $T_{\mathfrak{q}}$. Hence $f \notin \mathfrak{q}$. Each reduced irreducible support component $Z_{\mathfrak{q}} = \mathcal{M}(A/\mathfrak{q})$ is pure of its analytic dimension $d_{\mathfrak{q}} \le n-1$. Apply NAG-002374 on this component to the nonzero image of f. Its zero set has dimension at most $d_{\mathfrak{q}} - 1 \le n-2$, and is empty if $d_{\mathfrak{q}} = 0$. The finite union of these sets contains $\operatorname{Supp}(T/fT)$, proving (2.1).

At every generic point of an $(n-1)$-dimensional zero component, the first term in (1.2) localizes to zero. The other two localized quotients are therefore isomorphic, not just equal after reduction. Their Artinian lengths agree. This proves (2.2). □

For the finite-length step, apply Stacks Tag 00E0(7) with the zero ideal in $A_{\mathfrak{q}}/\operatorname{Ann}(T_{\mathfrak{q}})$. Its sole prime is the maximal ideal. Finite generation makes this nil ideal nilpotent, so its powers give a finite filtration of $T_{\mathfrak{q}}$ with finite-dimensional residue-field quotients.

Ordinary compact partitions

Theorem C.1.60 (Finite smooth partitions near a compact set)**.** *Let X be good and Hausdorff, let $S \subseteq X$ be compact, and let $O_1, \dots, O_m$ be ordinary open sets covering S. There are compactly supported sections $\chi_i \in \mathcal{A}_X^{0,0}(X)$ such that*

$$0 \le \chi_i \le 1, \qquad \operatorname{supp}(\chi_i) \subseteq O_i,$$
$$\sum_i \chi_i = 1 \quad \text{on an ordinary neighbourhood of } S.$$

Proof. The case $S = \varnothing$ uses zero functions. Otherwise, apply Lemma 5.53.1 at each point of S, with one O_i containing it. Compactness gives finitely many resulting functions b_j whose loci where they equal one cover S by ordinary neighbourhoods. Group them by the chosen index and put

$$b_i' = \sum_{j \text{ assigned to } i} b_j, \qquad s = \sum_i b_i'.$$

Thus $s \ge 1$ on S and each b_i' has compact support contained in O_i. Choose a smooth real function η with $0 \le \eta \le 1$, equal to zero for $t \le 1/4$ and to one for $t \ge 1/2$, by the profile construction in that lemma. The function

$$h(t) = \begin{cases} \eta(t)/t, & t > 0, \\ 0, & t \le 0 \end{cases}$$

is smooth, since it is identically zero for $t \le 1/4$. Set $\chi_i = h(s) b_i'$. Smooth composition and the sheaf algebra of Theorem 5.52.3 make these global smooth moment sections. Since $0 \le b_i' \le s$, they take values in $[0, 1]$, and their supports are contained in those of b_i'. Their sum is $\eta(s)$, which equals one on the open neighbourhood $\{s > 1/2\}$ of S. This proves the partition assertion. □

Finite Gauss overlaps and algebraic Cartier coefficients

Whole fibres in smaller ordinary neighbourhoods

Use the polyannulus notation of Lemma C.1.43 and the finite Gauss charts of Definition C.1.44.

Proposition C.1.61 (A cofinal pointed overlap retains whole fibres)**.** *In Definition C.1.44, for every ordinary neighbourhood U of x in Y there are B_U and H_U as in Lemma C.1.43 such that*

$$p^{-1}(\mathbb{T}_s) \subset U \qquad (s \in B_U \setminus H_U).$$

This also holds for an ordinary affinoid neighbourhood inside U, and for a common smaller ordinary affinoid neighbourhood inside any pair of such neighbourhoods.

Proof. First replace U by an ordinary open neighbourhood of x contained in it. The compact set $C = Y \setminus U$ has compact image in the Hausdorff space $\mathbb{T}_P$. This image misses η_{s_0}, because its entire analytic fibre is $\{x\}$. Thus $O = \mathbb{T}_P \setminus p(C)$ is an ordinary open neighbourhood of η_{s_0} with $p^{-1}(O) \subset U$. Lemma C.1.43 gives the assertion.

The ordinary affinoid-neighbourhood basis used in 5.52.3 supplies an affinoid neighbourhood in U, or in the ordinary intersection of two given neighbourhoods. Apply the same argument there. Compactness was used on the whole source; no chosen sheet replaces $p^{-1}(O)$. □

Additivity over one Noetherian ring

For a Noetherian ring A, write $\mathrm{Min}_A(a)$ for the primes of A minimal over (a), and set $\mathrm{Min}_A(a) = \varnothing$ when a is a unit. A finite collection of primes is an antichain if no two distinct members are comparable by inclusion.

Theorem C.1.62 (Algebraic Cartier additivity under an antichain)**.** *Let A be Noetherian and let a, b be non-zero-divisors. Assume $\mathrm{Min}_A(a) \cup \mathrm{Min}_A(b)$ is an antichain. Define the effective cycle of a regular equation by its actual components and the ambient lengths*

$$\mathrm{div}(a) = \sum_{p \in \mathrm{Min}_A(a)} \mathrm{length}_{A_p}(A_p/aA_p)[\mathrm{Spec}(A/p)].$$

Then $\operatorname{div}(ab) = \operatorname{div}(a) + \operatorname{div}(b)$.

Proof. Lemma C.1.29 identifies all components on both sides, including the converse inclusion missing from the original proof. At a prime p in this union, each of $A_p/(a)$ and $A_p/(b)$ is either zero (when the factor is a unit in A_p) or Artinian (when p is minimal over that factor). It is minimal over every factor it contains: otherwise a smaller minimal prime of that factor would contradict the antichain condition. The regularity of b makes the sequence

$$0 \longrightarrow A/(a) \xrightarrow{b} A/(ab) \longrightarrow A/(b) \longrightarrow 0$$

exact. Localize at p and add finite lengths. This gives the coefficient equality on the now identical component sets. □

For a factor $e = a$ or b contained in p, apply Stacks Tag 00E0(4) in A to $(e) \subseteq p$. The antichain forces the resulting minimal prime to equal p. In the nonzero quotient $A_p/(e)$, apply Stacks Tag 00E0(7) to the zero ideal. The maximal ideal is the unique prime, so each of its finitely many generators is nilpotent. A power of the maximal ideal vanishes and the filtration by its powers has finite-dimensional residue-field quotients.

Operations on native ordinary currents

Native conventions. Let K be complete for its specified real-valued non-Archimedean absolute value, and let X be good and Hausdorff. The valuation may be trivial. Use the ordinary smooth moment sheaf $\mathcal{A}_X^{p,q}$ of ordinary smooth germ sheaf and its compactly supported test space

$$\mathcal{E}^{p,q}(U) = \mathcal{A}_{X,c}^{p,q}(U), \qquad \tau = \tau_{\mathrm{cut}} = \tau_{\mathrm{ord}}$$

on every ordinary open $U \subset X$, with the equality and fixed-stage descriptions of ordinary test topology. A cutoff stage is

$$Q_i\eta = \mathrm{ext}_0(\chi t_f^*\eta), \quad i = (V, f, \Omega, \chi), \quad t_f = -\log|f|,$$

where V is affinoid, f is a tuple of analytic units, Ω contains the actual compact image $t_f(V)$, and χ has compact support inside $\mathrm{Int}(V, X)$. Ambient seminorms are

$$p_{L,m}(\eta) = \max_{I,J,\,|a|\le m} \sup_L |\partial^a \eta_{I,J}|, \qquad L \Subset \Omega.$$

Ordinary stages $R_s : H_s \to \mathcal{E}^{p,q}$ use a fixed finite compatible chart family and a fixed compact support. All one-form generators anticommute, and d', d'' differentiate coefficients and wedge on the left. The positive top generator is $\bigwedge_{j=1}^n (d'x_j \wedge d''x_j)$.

Write $\mathcal{D}_{r,s}(U) = \mathcal{E}^{r,s}(U)'$ for the continuous real dual, called currents of bidimension (r, s). Negative test degrees and their current spaces are zero. If a pure analytic dimension n is specified, this is bidegree $(n - r, n - s)$. We use the transposition signs

$$(d'T)(\alpha) = (-1)^{r+s+1} T(d'\alpha), \qquad (d''T)(\alpha) = (-1)^{r+s+1} T(d''\alpha). \quad \text{(C.1.23)}$$

A current is closed when both transposed differentials vanish. Its support is the complement of the largest ordinary open set on which its restriction is zero. We do not identify closedness of the native integration current with a coefficientwise identity.

Theorem C.1.63 (Continuous test operations and gluing of currents)**.** *On every ordinary open $U \subset X$, the maps d', d'' and multiplication $\eta \mapsto \beta \wedge \eta$ by a fixed ordinary smooth form β are continuous on the native compact-support test spaces in their indicated degrees. Extension by zero from an ordinary open subset is continuous.*

The spaces $\mathcal{D}_{r,s}$ form sheaves of real vector spaces. Formula (C.1.23) defines currents and gives

$$(d')^2 = (d'')^2 = 0, \qquad d'd'' + d''d' = 0, \qquad (d'd''T)(\alpha) = T(d'd''\alpha).$$

For smooth h, $(hT)(\alpha) = T(h\alpha)$ defines a current. For a smooth form β of bidegree (a, a), set

$$(\beta \wedge T)(\alpha) = T(\beta \wedge \alpha).$$

These operations commute with ordinary restriction. Differentiation does not enlarge support; multiplication has support contained in $\operatorname{supp} T \cap \operatorname{supp} \beta$ (with $\beta = h$ for scalar multiplication). The statement concerns fixed smooth multipliers; it asserts no product of arbitrary currents or joint continuity on varying coefficient stages.

Proof. The algebraic operations and support locality exist by ordinary smooth germ sheaf. On an ordinary stage H_s, differentiation of each ambient representative maps continuously to the corresponding ordinary stage in the new degree: compatibility and vanishing off the fixed support are preserved. Coefficient order m is bounded by order $m+1$. The final topology of ordinary test topology therefore makes both differentials continuous.

For multiplication, fix a cutoff stage i and put $C = \operatorname{supp} \chi$. Cover C by finitely many affinoid neighborhoods W_j inside $\operatorname{Int}(V, X)$ on which the fixed forms χ and β have ordinary smooth representatives in fixed tuples g_j. This uses the neighborhood and restriction construction in ordinary smooth germ sheaf. Adjoin $f|_{W_j}$ to g_j. On the joint ambient open, the output is represented by

$$L_j\eta = c_j\, \pi_g^* \beta_j \wedge \pi_f^* \eta,$$

where c_j represents χ. For every compact L and integer m,

$$p_{L,m}(L_j\eta) \le C_{j,L,m}\, p_{\pi_f(L),m}(\eta).$$

The constant involves only the fixed coefficient functions and their derivatives. The representatives agree on ordinary overlaps and vanish off C. Thus they

belong to one fixed ordinary stage in the output degree, and depend continuously on η. The final-topology criterion proves continuity. All refinements and constants were chosen before the variable η.

For an open inclusion $j : W \hookrightarrow U$, a compactly supported cutoff on W extends smoothly by zero to U: its support is closed in the Hausdorff space and is contained in W. The extended cutoff gives exactly the same generating stage on U. This proves continuity of $j_!$ and defines restriction of a current by $T|_W(\eta) = T(j_!\eta)$.

To glue compatible currents T_j on an open cover, choose for each compact test support a finite subcover and a finite smooth partition χ_j equal to one in sum near that support, as supplied by compact partition. Define

$$T(\alpha) = \sum_j T_j(\chi_j \alpha).$$

Independence follows by multiplying two such partitions: each double term is supported compactly in an overlap, where the two currents agree. This also proves linearity, restriction and uniqueness. For continuity on one cutoff stage, its support is fixed, so choose the finite subcover and partition once. Each map $\eta \mapsto \chi_j Q_i \eta$, viewed as a test on the corresponding open set, has the fixed joint-chart factorization just proved. Each summand is continuous, so the glued current is continuous. No locally finite partition on all of X is required.

The transposed maps are continuous linear functionals because the test maps are continuous. If $r + s = N$, successive transpositions give the sign $(-1)^{N+1}(-1)^N = -1$. The test identity $d''d' = -d'd''$ therefore gives $(d'd''T)(\alpha) = T(d'd''\alpha)$; the other differential identities follow in the same way. The multiplication formulas are transposes of continuous fixed test multipliers. Locality gives restriction compatibility and the support assertions. □

Theorem C.1.64 (Closed-current harmonic annihilation)**.** *Let $r, s \geq 1$, let $T \in \mathcal{D}_{r,s}(U)$ be closed, and let $h \in \mathcal{A}^{0,0}(U)$. Then*

$$d'd''(hT) = (d'd''h) \wedge T \quad \text{in } \mathcal{D}_{r-1,s-1}(U). \tag{C.1.24}$$

In particular $d'd''(hT) = 0$ for every smooth harmonic function

$$h \in \mathcal{H}(U) := \ker(d'd'' : \mathcal{A}^{0,0}(U) \to \mathcal{A}^{1,1}(U)).$$

If g is an analytic unit, then $\log|g| \in \mathcal{H}(U)$ and hence $d'd''(\log|g|\,T) = 0$. This applies to an intermediate closed current without any Bedford–Taylor assumption or comparison of current sheaves.

Proof. All terms are currents by Theorem C.1.63. For $\alpha \in \mathcal{E}^{r-1,s-1}(U)$, closedness and the ordinary graded Leibniz rules imply

$$\begin{aligned} T(d''h \wedge d'\alpha) &= T(d'd''h \wedge \alpha), && \text{from } T(d'(d''h \wedge \alpha)) = 0,\\ T(d'h \wedge d''\alpha) &= -T(d'd''h \wedge \alpha), && \text{from } T(d''(d'h \wedge \alpha)) = 0. \end{aligned}$$

Every test here has compact support contained in $\operatorname{supp}\alpha$. Also

$$d'd''(h\alpha) = d'd''h \wedge \alpha - d''h \wedge d'\alpha + d'h \wedge d''\alpha + hd'd''\alpha.$$

Applying T gives zero on the left, and the two preceding identities yield $T(hd'd''\alpha) = T(d'd''h \wedge \alpha)$. By the positive double-transpose sign in Theorem C.1.63, this is precisely (C.1.24). This proof uses closedness of T and algebra on tests, not integration by parts on X.

For an analytic unit g, take the ordinary moment coordinate $t_g = -\log|g|$ on sufficiently small affinoid neighborhoods. The function $\log|g|$ has ambient representative $-x$, whose second derivatives vanish. The frozen differential sheaf ordinary smooth germ sheaf gives $d'd''\log|g| = 0$ on U. The first assertion now supplies the distributional conclusion for closed T. □

An admissible multiplication interface. Fix r, s and $p \le \min(r, s)$. Let $\mathcal{P}$ be a sheaf of real vector spaces of continuous functions containing $\mathcal{A}^{0,0}$. For $0 \le j \le p$, supply sheaves $\mathcal{C}_j$ of real vector spaces consisting of closed native currents of bidimension $(r-j, s-j)$. For $j < p$, suppose there are bilinear maps, commuting with ordinary restrictions,

$$M_j : \mathcal{P} \times \mathcal{C}_j \longrightarrow \mathcal{D}_{r-j,s-j}, \qquad R_j(u, S) = d'd''M_j(u, S),$$

with the following exact requirements: $M_j(h, S) = hS$ for every ordinary smooth h, and $R_j(u, S) \in \mathcal{C}_{j+1}$. Thus M_j supplies an actual continuous native functional on all tests, not only a candidate pairing or values on radial tests. Its existence and representative independence are hypotheses of this interface. Closedness of R_j as a raw current follows automatically from Theorem C.1.63; membership in any more restrictive admissible class remains a separate hypothesis.

Theorem C.1.65 (Frame descent and the ordinary smooth class)**.** *Under the multiplication interface, the ordered recursion*

$$S_0 = T \in \mathcal{C}_0, \qquad S_{j+1} = R_j(u_{j+1}, S_j)$$

is multilinear and depends on each u_i only modulo $\mathcal{H}$. If local potentials of metrized analytic line bundles lie in $\mathcal{P}$, these ordered currents glue independently of all local frames. They are symmetric in the metrized factors provided, in addition, the successive commutator identities

$$R_{j+1}(u, R_j(v, S)) = R_{j+1}(v, R_j(u, S)) \tag{C.1.25}$$

hold for every indicated $S \in \mathcal{C}_j$ and $j + 1 < p$.

There is an unconditional realization of this interface for $\mathcal{P} = \mathcal{A}^{0,0}$ and $\mathcal{C}_j$ equal to all closed currents of the stated bidimension: take $M_j(u, S) = uS$. For a supplied closed T, it gives a symmetric, multilinear, frame-independent product for ordinary smooth metric potentials on every native test, locally equal to

$$(d'd''u_p) \wedge \cdots \wedge (d'd''u_1) \wedge T. \tag{C.1.26}$$

It respects ordinary restriction. For positive integers e_i, replacing a power-metric potential u_i by its positive real root potential u_i/e_i scales the result by $\prod_i e_i^{-1}$. No closedness of a native integration current is assumed unless that particular current is supplied as the closed input T.

Proof. Theorem C.1.64 gives

$$R_j(u + h, S) - R_j(u, S) = d'd''M_j(h, S) = d'd''(hS) = 0 \qquad (h \in \mathcal{H}).$$

Induction proves independence modulo $\mathcal{H}$ in every slot, including those preceding further multiplications. Bilinearity gives multilinearity. Local frames $e_a = g_{ab}e_b$ have potentials

$$u_a = -\log \|e_a\| = u_b - \log |g_{ab}|.$$

Their differences are in $\mathcal{H}$ by Theorem C.1.64. Restriction compatibility therefore identifies the ordered currents on all overlaps; Theorem C.1.63 glues them. Adjacent transpositions using (C.1.25) prove symmetry when that extra condition holds.

In the ordinary smooth class, Theorem C.1.63 constructs uS, and $d'd''(uS)$ is closed because $(d')^2 = (d'')^2 = 0$ and the differentials anticommute. Theorem C.1.64 identifies it with $(d'd''u) \wedge S$. Iteration gives (C.1.26). The

even-degree forms $d'd''u$ commute in the frozen exterior algebra; their fixed test actions are associative, proving (C.1.25). The resulting product is a current by the same fixed-multiplier continuity. Restriction is built into the construction. Finally the power metric has potential e_i times its root potential. Multilinearity yields the stated factor, with no extraction of roots in K and no change of its absolute value. □

Fixed-stage certificates for scalar pairings

Native tests, support, and signs. Fix a complete field K with its specified real-valued non-Archimedean absolute value, possibly trivial. Spaces are good and Hausdorff. Purity means analytic pure dimension; generalized-affinoid radii, quotient norms, and finite-module norms retain their frozen conventions. Use the ordinary smooth moment sheaf of ordinary smooth germ sheaf and

$$\mathcal{E}^{p,q}(W) = \mathcal{A}_c^{p,q}(W), \qquad \tau = \tau_{\mathrm{cut}} = \tau_{\mathrm{ord}}$$

from ordinary test topology. A generating cutoff stage is

$$Q_i\eta = \mathrm{ext}_0(\chi t_f^*\eta), \qquad i = (V, f, \Omega, \chi), \qquad t_f = -\log|f|,$$

where V is affinoid, the tuple f consists of analytic units, $\Omega \supset t_f(V)$ is open in $\mathbb{R}^N$, and $C_i = \operatorname{supp}\chi$ is compact inside the ordinary interior of V in W. The coefficient seminorms are

$$p_{L,m}(\eta) = \max_{I,J,\,|a|\le m} \sup_L |\partial^a \eta_{I,J}|, \qquad L \Subset \Omega.$$

The ordinary stages use a fixed finite compatible chart family and a fixed compact support. Scalar continuity is equivalent to continuity after every Q_i, or every ordinary stage. No estimate uniform over changing stages is implied.

Write $\mathcal{D}_{r,s}(W) = \mathcal{E}^{r,s}(W)'$ for the continuous real dual, of bidimension (r,s). On a pure n-space its bidegree is $(n-r, n-s)$. All one-form generators anticommute; the positive top generator is $\bigwedge_{k=1}^{d}(d'x_k \wedge d''x_k)$. Put

$$(d'T)(\alpha) = (-1)^{r+s+1}T(d'\alpha), \qquad (d''T)(\alpha) = (-1)^{r+s+1}T(d''\alpha). \quad \text{(C.1.27)}$$

Negative test degrees are zero. Successive transpositions and $d''d' = -d'd''$ give $(d'd''T)(\alpha) = T(d'd''\alpha)$. Ordinary differential maps are continuous: on a fixed ordinary stage they differentiate the same ambient coefficients, keep the same support and overlap relations, and increase the required coefficient order by one. This argument uses ordinary smooth germ sheaf and ordinary test topology, not the pending Chern-interface packet. Compactly supported ordinary forms on an open subspace extend smoothly by zero; the sheaf property and their closed compact support give this extension, with commuting differentials. On cutoff stages it is the same stage in the ambient space, so it is continuous.

Restricted class for the next step. Fix a pure-dimensional starting structure current or a supplied cycle, of bidimension (r,r). Let $\mathcal{P}$ be a specified sheaf of real vector spaces of continuous functions generated by the actual continuous model potentials to be used and by ordinary smooth scalars. For $0 \le j \le p \le r$, supply sheaves $\mathcal{C}_j$ of real vector spaces of closed currents of bidimension $(r-j, r-j)$ containing the required reachable currents. The word "reachable" restricts the multiplier problem to this supplied class; it is not an assertion that arbitrary continuous functions multiply arbitrary currents. Write $M_j(u,S)$ for a proposed multiplier of $S \in \mathcal{C}_j$ by $u \in \mathcal{P}$, and $R_j(u,S) = d'd''M_j(u,S)$. Closedness of the raw differentiated current and membership in a class on which the next multiplication is defined are different statements.

Proposition C.1.66 (Scalar-test certificates for multiplication, symmetry, and a limit)**.** *Suppose real scalar pairings $B_j(u,S;\alpha)$ are supplied, trilinear in u, S, and compact tests $\alpha \in \mathcal{E}^{r-j,r-j}$, and compatible with ordinary restriction. Require smooth normalization*

$$B_j(h,S;\alpha) = S(h\alpha) \qquad (h \in \mathcal{A}^{0,0}). \tag{C.1.28}$$

Then these pairings define actual native currents $M_j(u,S)$ if and only if, for every fixed u, S and every cutoff stage, a continuous coefficient seminorm bound holds. Equivalently, one may require, for suitable compact $L_i \Subset \Omega_i$, integer $m_i \ge 0$, and constant A_i,

$$|B_j(u,S;Q_i\eta)| \le A_i p_{L_i,m_i}(\eta). \tag{C.1.29}$$

All these choices may depend on u, S, i. The raw current $R_j(u,S)$ is then closed. To iterate, require separately $R_j(u,S) \in \mathcal{C}_{j+1}$.

For such currents, the exact adjacent symmetry identity is equivalent to the following equality on every *$\alpha \in \mathcal{E}^{r-j-2,r-j-2}$:*

$$B_{j+1}(u,R_j(v,S);d'd''\alpha) = B_{j+1}(v,R_j(u,S);d'd''\alpha). \tag{C.1.30}$$

Testing only a terminal measure, selected radial functions, or one order of multiplication does not supply this criterion.

A sufficient, stronger certificate for (C.1.29) is a family of finite signed Radon measures $\nu_{S,\alpha}$, linear in S,α, supported in $\operatorname{supp}\alpha$*, compatible with restriction, and satisfying*

$$S(h\alpha) = \int h\, d\nu_{S,\alpha} \quad (h \text{ ordinary smooth}), \qquad \int |u|\, d|\nu_{S,Q_i\eta}| \le A_i p_{L_i,m_i}(\eta).$$

In that case $B_j(u,S;\alpha)=\int u\,d\nu_{S,\alpha}$ *works.*

For a limit through such measures on a fixed compact set C*, the following is a sufficient tested convergence condition:* $u_a\to u$ *uniformly on* C*,* $\nu_a\to\nu$ *weakly against* every *continuous function on* C*, and* $\sup_a|\nu_a|(C)<\infty$*. Then*

$$\int_C u_a\,d\nu_a\longrightarrow\int_C u\,d\nu. \tag{C.1.31}$$

To obtain a native current from a family of limits, require in addition linearity, locality and a bound (C.1.29) *uniform in* a *on each fixed stage. To pass symmetry from approximants, verify convergence of* both *ordered pairings in* (C.1.30) *on every indicated test.*

Proof. For fixed u,S, the scalar functional $\alpha\mapsto B_j(u,S;\alpha)$ is continuous exactly when each composition with Q_i is continuous, by the final topology of ordinary test topology. A continuous scalar functional on the ambient coefficient space is bounded by a finite maximum of defining seminorms. Taking the union of their compact sets and the maximum of their derivative orders gives (C.1.29), after absorbing finitely many constants. The converse follows directly from that inequality. Thus it is an exact continuity criterion, not a demand for an unnecessarily stronger variation norm on all intermediate currents.

The differential check in the native conventions makes $d'd''M_j(u,S)$ a current. The identities $(d')^2=(d'')^2=0$ and $d'd''=-d''d'$ show that it is closed; they do not imply membership in a stronger supplied class. The positive double-transpose sign gives

$$R_{j+1}(u,R_j(v,S))(\alpha)=B_{j+1}(u,R_j(v,S);d'd''\alpha).$$

Equality of currents is equality on all tests, proving the stated equivalence. The measure certificate gives finiteness, smooth normalization, trilinearity and locality, while its absolute-integral bound implies (C.1.29).

For the convergence assertion use the explicit estimate

$$\left|\int_C u_a\,d\nu_a-\int_C u\,d\nu\right|\le\|u_a-u\|_C\,|\nu_a|(C)+\left|\int_C u\,d(\nu_a-\nu)\right|.$$

Its first term tends to zero by the uniform variation bound; its second does so by the stated continuous-test weak convergence. This proof works for a sequence or a net with the given uniform bound. For current-valued limits,

the additional fixed-stage bound passes to the pointwise limit and proves continuity by finality; the stated linearity and locality assumptions pass the appropriate identities. If both ordered scalar pairings converge, their equality for every approximant passes to their two limits. Without those two convergence assertions there is no argument identifying the limits with the desired products. □

Supported scalar measures for positive tests

Native scope and signs. Let K be complete for its specified real-valued non-Archimedean absolute value. The analytic arguments allow trivial valuation and generalized radii. Let X be good, Hausdorff, and pure of analytic dimension $n \geq 2$, and work on ordinary opens $U \subseteq \mathrm{Int}(X/K)$. Use the ordinary moment sheaf of ordinary smooth germ sheaf and the topology $\tau_{\mathrm{cut}} = \tau_{\mathrm{ord}}$ of ordinary test topology. For $0 \leq p \leq n$, write

$$\mathcal{E}^{p,p}(U) = \mathcal{A}_c^{p,p}(U), \qquad \mathcal{D}_{p,p}(U) = \mathcal{E}^{p,p}(U)'.$$

A cutoff stage is $Q_i\eta = \mathrm{ext}_0(\chi t_f^*\eta)$, with V affinoid, f a tuple of units, $t_f = -\log|f|$, an ambient open $\Omega \supset t_f(V)$, and $C_i = \operatorname{supp}\chi \Subset \mathrm{Int}_{\mathrm{top}}(V, U)$. Put

$$p_{L,m}(\eta) = \max_{I,J,\,|a|\leq m} \sup_L |\partial^a \eta_{I,J}|.$$

All constants and refinements in a stage estimate are fixed before η. A scalar linear functional is continuous exactly when its compositions with all cutoff stages are continuous.

All one-form generators anticommute; the positive top generator on a real d-plane is $\bigwedge_{k=1}^{d}(d'x_k \wedge d''x_k)$. Currents have bidimension (r, s) and transpose signs $(-1)^{r+s+1}$ for both differentials. Thus

$$(d'd''T)(\alpha) = T(d'd''\alpha). \tag{C.1.32}$$

The exact frozen theorem current operations supplies continuous test differentiation, fixed smooth multiplication, open zero extension, the transpose signs, support locality and finite-partition gluing of currents. Its scope is the ordinary topology above. Its fixed-stage mechanism differentiates coefficients with one extra derivative, or adjoins the fixed multiplier moments, and chooses compact partitions before variable coefficients. No varying-stage uniform bound, nonsmooth multiplier, or arbitrary current product is part of that input.

A real (p, p)-form will be called nonnegative on p-planes if its restriction to every p-plane inside every actual tangent plane in a common moment refinement has nonnegative coefficient in the indicated positive generator. Tangential equality and pullback make this criterion independent of representatives. Only this explicit criterion, including its lineality, is used below; no equivalence of external positivity conventions is assumed. For $p = 0$ it means a nonnegative scalar.

Theorem C.1.67 (A scalar-measure construction with explicit domination)**.** *Let $S : \mathcal{E}^{p,p}(U) \to \mathbb{R}$ be linear and nonnegative on every compact form nonnegative on p-planes. Then S is a native current. For every $\alpha \in \mathcal{E}^{p,p}(U)$ there is a unique finite signed Radon measure $\nu_{S,\alpha}$ with compact support in* $\operatorname{supp}\alpha$*, such that*

$$\int h\, d\nu_{S,\alpha} = S(h\alpha) \quad \text{for every ordinary smooth scalar } h. \tag{C.1.33}$$

It is linear in α, positive when α is nonnegative on p-planes, local under ordinary open restriction, and supported in $\operatorname{supp} S \cap \operatorname{supp}\alpha$*.*

For each cutoff stage there are a fixed compact form θ_i nonnegative on p-planes and a constant $c_i \geq 0$ such that

$$|\nu_{S,Q_i\eta}| \leq c_i p_{t_f(V),0}(\eta)\nu_{S,\theta_i}. \tag{C.1.34}$$

The assertions extend linearly and canonically to a linear functional whose ordinary local restrictions are finite signed sums of such S. In that case the right side is replaced locally by the sum of the absolute coefficients times the corresponding positive measures.

For such an S and any continuous real v, the formula

$$(vS)(\alpha) = \int v\, d\nu_{S,\alpha}$$

defines a native current, independently of its signed presentation, with support contained in $\operatorname{supp} S \cap \operatorname{supp} v$*. This conclusion is derived from the stated sign and domination hypotheses; order zero alone is not a premise sufficient for it.*

Proof. Fix a stage with N moment coordinates. By compact partition, choose $0 \leq \rho \leq 1$ compactly supported in $\operatorname{Int}_{\mathrm{top}}(V,U)$ and equal to one near C_i. Put $M = \sup|\chi|$ and

$$\Theta_p = \frac{1}{p!}\left(\sum_{k=1}^{N} d'x_k \wedge d''x_k\right)^p, \qquad \theta_i = M\,\operatorname{ext}_0(\rho t_f^* \Theta_p).$$

For $p = 0$ put $\Theta_0 = 1$; for $N < p$ the stage is zero. On a projected decomposable p-vector z, Θ_p has coefficient $|z|^2$ and an arbitrary representative η has coefficient $z^{\mathrm{t}} A_\eta z$ in the positive convention. The antisymmetric part contributes zero. A finite matrix bound gives, on every actual joint refinement, including rank drop,

$$c_i p_{t_f(V),0}(\eta)\theta_i \pm Q_i\eta \;\geq 0 \quad \text{on } p\text{-planes}. \tag{C.1.35}$$

The scalar cutoffs cause no difficulty: $\rho = 1$ on C_i, $|\chi| \le M$, and $Q_i\eta$ vanishes off C_i. Positivity of S gives $|S(Q_i\eta)| \le c_i S(\theta_i) p_{t_f(V),0}(\eta)$. Finality in ordinary test topology proves continuity.

Every compact form α is a finite sum of cutoff-stage images, by compact partition and the ordinary sheaf. Applying (C.1.35) to these fixed summands gives a compact form θ nonnegative on p-planes with $\theta \pm \alpha \ge 0$. Let $C = \operatorname{supp}\theta \cup \operatorname{supp}\alpha$. For every ordinary smooth h, the forms $\|h\|_C\theta \pm h\alpha$ are nonnegative on p-planes. Therefore

$$|S(h\alpha)| \le S(\theta)\|h\|_C. \tag{C.1.36}$$

This is a bound by one scalar supremum on a fixed compact set, stronger than an abstract ambient-stage order-zero statement.

We give the measure argument explicitly. Restrictions of ordinary smooth scalars are uniformly dense in $C(C,\mathbb{R})$: cover C by finitely many opens on which a given continuous function oscillates by less than δ, and combine sample values with the nonnegative finite partition from compact partition. For a nonnegative target the approximants may be chosen nonnegative. Thus (C.1.36) extends $h \mapsto S(h\alpha)$ uniquely to a bounded real linear functional Λ on $C(C)$.

Here is the elementary representation construction, so no abstract measure assertion is being inferred from the word "current." For a positive bounded functional P on $C(C)$ define

$$a(O) = \sup\{P(f) : 0 \le f \le 1,\ \operatorname{supp} f \subset O\}, \qquad a^*(E) = \inf_{O \supset E \text{ open}} a(O).$$

Continuous compact cutoffs and finite partitions on C are obtained by restricting the native cutoffs just used. Partitions on the compact support of f prove countable subadditivity of a on opens; disjoint opens give the reverse finite inequality by summing disjointly supported f. Hence a^* is an outer measure. To check that an open O is measurable, choose $V \supset E$ with $a(V) \le a^*(E)+\delta$ and $0 \le g \le 1$ supported in $V \cap O$, with $P(g) \ge a(V \cap O) - \delta$. Write $F = \operatorname{supp} g$. Tests supported in $V \setminus F$ have disjoint support from g, so

$$a(V \setminus F) \le a(V) - P(g), \qquad a^*(E \cap O) + a^*(E \setminus O) \le a^*(E) + 2\delta.$$

Let δ decrease to zero. The reverse inequality is subadditivity. The sets satisfying this splitting identity form a sigma-algebra: for disjoint such sets, iterate the identity finitely, then use the supremum of the finite sums and

outer subadditivity for the countable union. The same argument proves countable additivity on that sigma-algebra. Thus a^* restricts to a finite Borel measure μ on C.

If f is an admissible test for $a(O)$, then $P(f) \le \mu(\operatorname{supp} f)$ by taking the infimum over open neighborhoods of its support. It follows that $\mu(O) = a(O)$ is the supremum of $\mu(F)$ over compact $F \subset O$. Outer regularity is built into a^*; inner regularity on all Borel sets follows by complements and finiteness. Hence μ is Radon. To verify $P(u) = \int u \, d\mu$ for continuous $u \ge 0$, use lower step sums $\delta \sum_{k=1}^{m} \mu\{u > k\delta\}$ when $u \le m\delta$. For the upper estimate use the continuous functions $v_k = \min(1, \max(0, (u - k\delta)/\delta))$ with $u = \delta \sum_{k=0}^{m-1} v_k$. The resulting upper and lower bounds differ from the corresponding integral by at most $2\delta\mu(C)$. Let $\delta \downarrow 0$. Linearity gives the representation, and compact cutoffs give uniqueness.

For a bounded real Λ, put $\Lambda^+(u) = \sup_{0 \le v \le u} \Lambda(v)$ for $u \ge 0$. This is bounded, positive and additive: split $v \le u_1 + u_2$ into $\min(v, u_1)$ and its remainder for one inequality, and add near maximizing choices for the other. Extend linearly; both Λ^+ and $\Lambda^+ - \Lambda$ are positive. Their Radon representations give a signed representation of Λ. Positive uniqueness implies signed uniqueness. Extending by zero from C gives (C.1.33) on U.

Tests supported outside $\operatorname{supp} \alpha$, or in an open where S vanishes, have zero scalar pairing. Smooth density and Radon regularity on compact subsets of such opens prove the claimed support. The same uniqueness on a compact union of supports proves linearity, locality and independence from C or θ. If $\alpha \ge 0$ on p-planes, nonnegative smooth scalar tests give a positive measure. Apply this positivity to (C.1.35); the measure inequalities imply (C.1.34). Indeed $-a\lambda \le \nu \le a\lambda$ implies $|\nu| \le a\lambda$ by summing over finite Borel partitions.

Finite signed sums inherit scalar measures, the variation bound, and uniqueness. For local signed presentations, choose a fixed finite partition near each compact test support; summing the measures for the partitioned tests gives the same representation and hence the same measure on overlaps. For continuous v, compactness and (C.1.34) give on each stage

$$|(vS)(Q_i\eta)| \le c_i \sup_{C_i} |v| \, \nu_{S,\theta_i}(U) p_{t_f(V),0}(\eta)$$

in the positive case, and the corresponding finite sum in the signed case. A fixed local partition gives the same kind of bound. This proves native continuity, and locality proves the stated support. □

Algebraic unit lattices and intrinsic chart refinements

Throughout the algebraic unit and localization results below, K is an algebraically closed field and A is a nonzero finitely generated integral K-algebra. Put $U = \operatorname{Spec} A$ and $F = \operatorname{Frac} A$. Neither a valuation nor normality of A is assumed. A lattice means a free abelian group of finite rank. An inclusion of lattices is *saturated* if its quotient has no torsion.

Theorem C.1.68 (Boundary construction of the actual unit lattice)**.** *The group*

$$M_A = A^\times / K^\times$$

is a lattice. More precisely, there is a normal integral proper K-variety Y with function field F, a dense open $V = \operatorname{Spec} B \subset Y$ where B is the normalization of A in F, and a finite set S of codimension-one points of $Y \setminus V$, such that

$$M_A \longrightarrow \mathbb{Z}^S, \qquad [u] \longmapsto (\operatorname{ord}_D(u))_{D \in S} \tag{1}$$

is injective. No saturation of a group generated by chosen coordinates is used in this construction.

Proof links. The final finite-freeness step uses the subgroup lemma.

Proof. Choose generators $a_1, \dots, a_m$ of A. To construct a projective closure explicitly, take the homogeneous kernel of

$$K[X_0, \dots, X_m] \longrightarrow A[T], \qquad X_0 \longmapsto T, \quad X_i \longmapsto a_i T.$$

The image is an integral graded algebra. Its Proj is an integral closed subscheme $\overline{U}$ of $\mathbf{P}^m_K$ whose $X_0 \neq 0$ chart is U; that chart is dense. Projectivity gives properness by Stacks 01WC.

Normalize $\overline{U}$. By Stacks 0BXR, the normalization $\nu : Y \to \overline{U}$ is finite and birational, with Y a normal integral variety. It is proper: a finite ring map is integral by the determinant argument applied to multiplication on a finite generating module, so its associated finite morphism is universally closed by Stacks 01WM; it is finite type and separated because its affine diagonal is induced by a surjective multiplication map. Composition with $\overline{U} \to \operatorname{Spec} K$ is proper by Stacks 01W3. The inverse image V of U is the affine normalization $\operatorname{Spec} B$. Here normalization restricts to an affine open by

taking the integral closure in F; localization commutes with this operation by clearing the denominators of a monic integral equation.

All these schemes are Noetherian by Stacks 00FN. The closed set $Y \setminus V$ has finitely many irreducible components. Any codimension-one point in it is the generic point of one of those components, since Y is integral and the complement misses its generic point. Thus S is finite. At a codimension-one point D, the normal Noetherian local ring $\mathcal{O}_{Y,D}$ is a discrete valuation ring by Stacks 00PD, and we use its order normalized by $\operatorname{ord}_D(\pi_D) = 1$. Every unit of A is a unit on V, so its order vanishes at every codimension-one point outside S. Constants have order zero everywhere. This defines (1).

If $[u]$ maps to zero, then u and u^{-1} belong to every codimension-one local ring of Y. On every affine open of Y, Stacks 031T(2) identifies its normal coordinate ring with the intersection of its height-one localizations inside F. Thus u and u^{-1} are regular everywhere on Y.

A regular function f on this proper integral Y is constant. Indeed, the associated map $Y \to \mathbf{A}^1_K \subset \mathbf{P}^1_K$ is proper by Stacks 01W6, since $\mathbf{P}^1_K$ is separated. Its image is a nonempty closed irreducible subset of $\mathbf{P}^1_K$ missing infinity, hence one closed point. Since K is algebraically closed it is a K-point, and reducedness of Y implies f equals that scalar as a regular function. Applying this to u proves injectivity. Lemma C.1.26 now proves finite freeness. □

Proposition C.1.69 (Exact boundary image and conductor descent)**.** *For the Y, V, B, S of Theorem C.1.68, set*

$$E_S = \{f \in F^\times : \operatorname{ord}_D(f) = 0 \text{ for every codimension-one } D \notin S\},$$
$$P_S = \{(\operatorname{ord}_D f)_{D \in S} : f \in E_S\} \subset \mathbb{Z}^S.$$

Then $E_S = B^\times$ and $B^\times/K^\times \simeq P_S$. The exact image of M_A is

$$L_A = \{(\operatorname{ord}_D f)_{D \in S} : f \in B^\times,\ f, f^{-1} \in A\}. \tag{2}$$

If $A \neq B$, let $I = \{a \in A : aB \subset A\}$ be the conductor. It is a nonzero common ideal of A and B, and (2) can equivalently be specified by

$$f \in B^\times, \qquad \bar{f} \in (A/I)^\times \subset (B/I)^\times. \tag{3}$$

For $A = B$, the descent condition is vacuous and $L_A = P_S$.

Proof links. The boundary and the constant-kernel calculation use the same proper model.

Proof. The height-one points of V are exactly the height-one points of Y lying in V, hence those outside S. Apply Stacks 031T(2) to B, both to f and to f^{-1}. This proves $E_S = B^\times$. The kernel of the order map is $K^\times$ by the same properness argument as above. Formula (2) follows because a function and its inverse descend to A precisely when the function is a unit of A.

Since B is finite over A and contained in F, a common nonzero denominator of finite A-module generators of B belongs to I. If $a \in I$ and $b \in B$, then $ab \in A$ and $(ab)B \subset A$, so I is also an ideal of B. There is an equality of subrings of B,

$$A = B \times_{B/I} A/I.$$

Indeed, a residue class of $b \in B$ lies in A/I if and only if b differs from an element of A by an element of $I \subset A$. For $f \in B^\times$, condition (3) therefore puts both f and f^{-1} in A, and the converse is immediate. Multiplication by a constant does not change this condition, so it is well-defined on boundary vectors. □

Proposition C.1.70 (Intrinsic torus and factorization)**.** *Choose a basis of M_A and lifts of its elements to $A^\times$. Extending multiplicatively gives a section $s_A : M_A \to A^\times$, a torus*

$$T_A = \operatorname{Spec} K[M_A], \qquad N_A = \operatorname{Hom}_{\mathbb{Z}}(M_A, \mathbb{Z}),$$

and a morphism $\varphi_A : U \to T_A$. Changing the lifts translates this morphism by a point of $T_A(K)$. Every algebraic moment morphism $U \to \mathbb{G}_m^r$ factors through φ_A by an affine homomorphism of tori, meaning a torus homomorphism followed by a constant translation. The morphism φ_A is a closed immersion if and only if A is generated as a K-algebra by its units; this is equivalent to U being very affine.

For a K-algebra map $A \to C$ between integral finite-type K-algebras, the induced map $M_A \to M_C$ gives an affine torus map $T_C \to T_A$ compatible with the moment morphisms. No injectivity of this lattice map is asserted for an arbitrary map $A \to C$.

Proof links. The construction starts with the finite free algebraic unit lattice for each integral algebra.

Proof. Finite freeness supplies the section: lift a basis and use the unique integral expression of any lattice element. The resulting map $K[M_A] \to A$ sends its basis character χ^m to $s_A(m)$. For another section s'_A, the ratio $s'_A/s_A : M_A \to K^\times$ is a character-valued constant, that is, a point of $T_A(K)$; this gives the translation assertion.

An algebraic moment morphism is a finite tuple $u_i \in A^\times$. Each u_i is uniquely a constant times a monomial in the chosen basis lifts. This proves its factorization. The image of $K[M_A] \to A$ is the subalgebra generated by all units of A, so the map is surjective exactly under the stated generation condition, equivalently the morphism is a closed immersion. A closed embedding into a finite-dimensional torus implies generation by the coordinate units and their inverses. Conversely, if all units generate A, finite generation of A lets one select finitely many units generating it and gives a closed embedding into a torus.

A K-algebra map preserves units and constants. Its induced lattice map and the chosen sections express every pulled-back basis lift as a constant times a monomial in the target basis lifts. These expressions define the asserted affine homomorphism and prove the compatibility on coordinate rings. □

Theorem C.1.71 (Exact stability, with a normality condition for saturation)**.** *Let $A \subset C \subset F$ be a finitely generated K-subalgebra of F containing A. Then $M_C = C^\times/K^\times$ is a lattice, and there is an exact sequence*

$$0 \longrightarrow M_A \longrightarrow M_C \longrightarrow C^\times/A^\times \longrightarrow 0. \tag{4}$$

If A is normal, the first inclusion is saturated. This applies in particular to $C = A_h$ for $h \in A \setminus \{0\}$ and to

$$C = A[q_1^{\pm 1}, \dots, q_s^{\pm 1}], \qquad q_i \in F^\times. \tag{5}$$

If A is generated by units, so is the ring in (5), including A_h as the case $q_1 = h$. Thus these rings are very affine. In (5) the morphism $\operatorname{Spec} C \to U$ is not asserted to be an open immersion. When one inverts finitely many nonzero numerators and denominators $a_i, b_i \in A$, the ring is the genuine principal-open localization A_h, where $h = \prod_i a_i b_i$.

Proof links. The exact sequence starts from the actual finite free unit groups.

Proof. The ring C is an integral finite-type K-algebra, so Theorem C.1.68 applies to it. The inclusion of rings induces an injection of units, and it

induces an injection modulo constants because the constant field in both quotients is the same embedded K. Taking these successive group quotients gives (4).

Suppose now that A is normal and that $n[g] \in M_A$ for $g \in C^\times$ and $n > 0$. Then $g^n = cu$ for some $c \in K^\times$ and $u \in A^\times$. Both g and g^{-1} are integral over A, by the monic equations $X^n - cu$ and $X^n - (cu)^{-1}$. They lie in F, so normality puts both in A. Therefore $[g] \in M_A$, which is exactly saturation. The generation assertion follows directly by adjoining the specified units and their inverses. The final identification follows because making each nonzero a_i, b_i invertible is equivalent to inverting their product. □

Proposition C.1.72 (One boundary model for a principal localization)**.** *For $0 \neq h \in A$, retain the model Y of Theorem C.1.68. Put $V_h = \operatorname{Spec} B_h \subset V$, and let S_h be the codimension-one points of $Y \setminus V_h$. Then B_h is the normalization of A_h, $S \subset S_h$ is finite, and the exact lattice M_{A_h} is obtained by the construction of Proposition C.1.69 on this same Y, using S_h. The conductor of $A_h \subset B_h$ is I_h. Thus the inclusion $M_A \to M_{A_h}$ is realized by extending boundary vectors by zero on $S_h \setminus S$, with the respective conductor descent conditions retained.*

If A is normal, restriction of orders to the new boundary points gives the additional exact sequence

$$0 \longrightarrow M_A \longrightarrow M_{A_h} \longrightarrow \mathbb{Z}^{S_h \setminus S}, \qquad [f] \longmapsto (\operatorname{ord}_D f)_{D \in S_h \setminus S}.$$

There is no assertion of surjectivity onto the final group.

Proof links. The first paragraph uses the same boundary model and its conductor test. The final paragraph uses the known inclusion of unit groups.

Proof. Integral closure commutes with localization by clearing denominators in a monic equation, so the normalization is B_h. The same finiteness argument for the codimension-one boundary of a dense open in Y gives finiteness of S_h. Apply Proposition C.1.69 to V_h; properness, the function field and the normalized orders are unchanged.

Clearly I_h is contained in the conductor of $A_h \subset B_h$. Conversely, choose finite A-module generators $b_1, \dots, b_q$ of B. If a/h^m belongs to that conductor, then each ab_j lies in A_h. A common power h^N clears all these denominators, so $h^N aB \subset A$ and $h^N a \in I$. Therefore $a/h^m \in I_h$. This proves the conductor

identity. If the localized rings agree, the descent condition is simply vacuous. Units of A have zero orders at the additional points because those points lie in V, proving the extension-by-zero description of their boundary vectors.

For the last sequence assume $A = B$. A unit f of A_h with zero orders on $S_h \setminus S$ has zero order at every height-one point of V: the remaining points lie in V_h, where f is already a unit. By Stacks 031T(2), both f and f^{-1} then belong to A. This proves exactness at M_{A_h}, and injectivity at the first arrow was proved in Theorem C.1.71. □

Actual joint moment relations and intrinsic chart refinements

Fix a complete, algebraically closed, nontrivially valued non-Archimedean field K, with its specified real absolute value and natural logarithm. Let X be an integral separated scheme of finite type over K. The dimension is arbitrary, including zero. All sheaves below are on the ordinary topology of X^{an}, which is good and Hausdorff. Every use of the unit lattice is algebraic.

Lemma C.1.73 (The diagonal relation)**.** *Suppose f and g are two equal-length moment tuples on one compact affinoid C and $|f_i| = |g_i|$ everywhere on C. For every ambient smooth superform α defined near their common moment image, the two pullbacks of α to the actual joint image $t_{(f,g)}(C)$ agree tangentially on every cell and face. The assertion remains true after adjoining any finite tuple of further moment coordinates.*

Proof. The actual joint image lies in the diagonal $\{(u, u)\}$. On this diagonal, the two coordinate projections agree on points and on tangent vectors. Their pullbacks therefore agree in both exterior factors of a superform. Every cell tangent of the joint image lies in the diagonal tangent. Adjoining coordinates preserves the equality of the first two projections. Finite actual-image subdivisions are available by NAG-002358. Thus the assertion applies to the finite-image germ relations of NAG-002424. □

Proposition C.1.74 (Finite analytic relations survive replacement)**.** *For the simultaneous replacement in Proposition C.1.51, every finite ordinary moment-germ relation has the same value after replacing the analytic coordinates by the algebraic coordinates. After passing to a given compatible intrinsic chart contained in the witness neighborhood, a zero relation belongs to the full smooth part of GK's universal kernel.*

Proof links. The first paragraph uses one simultaneous replacement on the full compact witness. The intrinsic-chart step uses factorization through the actual algebraic unit lattice. For the last step, the given compatible chart and tests have actual tropical supports, finite pure polyhedral structures and positive top-dimensional weights, as in the smooth-kernel lemma. The application is the implication from tangential vanishing to membership in the smooth universal kernel.

Proof. Use the single C for the complete tuple of coordinates and apply Lemma C.1.73. A relation tangentially zero on the original actual joint image is therefore zero on the replaced joint image. On the explicit very affine embedding, the replaced tuple is given by monomials and constants in the selected unit coordinates. The preimage V of the strict box is contained in the original witness. Pullback by the resulting integral affine map preserves tangential vanishing on each refined cell.

For a given intrinsic chart, the selected units factor through its torus by their classes in $\mathcal{O}(U)^\times/K^\times$; shrinking its real open set by the inverse image of the strict box gives a chart still contained in V. The same argument applies to this affine pullback. Lemma C.1.52 then gives vanishing under every compatible algebraic test. Two choices of approximation are compared by putting their tuples and the original tuple on one smaller ordinary witness and applying the same diagonal argument. The resulting assertion is local and hence a statement about germ relations. □

The simultaneous replacement construction starts with one compact witness for the entire finite tuple. For finitely many analytic units on an ordinary neighborhood of x, including all coordinates of finitely many witnessed germ relations, there are

$$x \in V \subset C \subset U^{\mathrm{an}}, \qquad C \subset W,$$

where C is a compact Laurent affinoid domain, V is an ordinary open neighborhood of x, and U is a very affine Zariski open, together with $g_i \in \mathcal{O}(U)^\times$ satisfying

$$|f_i(z)| = |g_i(z)| \quad (z \in C). \tag{C.1.37}$$

Here V is the inverse image of an open real box under an explicit closed algebraic unit embedding of U.

For precision, the reviewed construction uses translated algebra generators y_j nonzero at x and the actual Banach algebra

$$B = K\{r^{-1}T, sS\}/(I(T), T_jS_j - 1)_j, \qquad C = \mathcal{M}(B).$$

The image of $A[(\prod_j y_j)^{-1}]$ is dense in B by truncation of a lift in the displayed Tate algebra. A single error bound

$$\|g_i - f_i\| < \varepsilon < \min_i \|f_i^{-1}\|^{-1}$$

forces (C.1.37) everywhere on C. The nonzero numerator polynomials of the g_i are inverted in A to obtain U. The strict box defines V and puts it in the analytic interior of this presentation of C over K. Thus the same actual domain contains all relations before any comparison is made. This is the application of the reviewed R1 argument, not a new assertion of algebraic equality $f_i = g_i$.

Proposition C.1.75 (Intrinsic realization and local common refinements)**.** *The preceding V is an intrinsic chart for the actual algebraic lattice M_U. Every selected approximant is a constant times a character of T_U, and* (C.1.37) *holds on the entire original C. Intrinsic charts form a basis of ordinary neighborhoods in X^{an} and admit common intrinsic refinements near every point of a finite intersection.*

Proof links. The compact witness comes from uniform norm preservation and simultaneous replacement.

Proof. Apply `F7U44R1-L1` to the integral finite-type coordinate ring of U, and `F7U44R1-T1` to its selected units. Their tropicalizations are integral affine functions of t_U. In particular the explicit unit embedding ψ of R1 factors through φ_U by an affine torus map, with tropical affine map F. If $V = \psi_{\mathrm{trop}}^{-1}(\Omega_0)$, then

$$V = t_U^{-1}\big(F^{-1}(\Omega_0)\big).$$

The inverse image is real open. This does not shrink or change C and does not change the approximants.

Applying R1 to the empty tuple inside any prescribed ordinary neighborhood constructs a chart V there. For common refinements of charts (V_j, U_j) at x, choose an affine Zariski neighborhood of the scheme point underlying x contained in $\bigcap_j U_j$. Apply R1 to the ordinary neighborhood $\bigcap_j V_j$ within

this affine analytification. Its output U' lies in every U_j and its V' lies in every V_j. Restriction of algebraic units gives the compatible maps $M_{U_j} \to M_{U'}$ and hence affine torus maps by F7U44R1-T1. Their tropical maps are the required refinement maps. This construction also refines any prescribed ordinary neighborhood of x.

All unit groups here are $\mathcal{O}(U)^\times/K^\times$ or the corresponding groups on genuine algebraic localizations. The stability used is F7U44R1-L3; no normality or saturation assertion is required. In particular neither a coordinate-generated subgroup nor the unit group of the completed algebra B is substituted for M_U. □

A graph closure and a common semistable model

On the affine T-chart write $A = O[T]$. For a centre c and radius r, write $\zeta_{c,r}$ for the Gauss point of the $T - c$ coordinate with radius r.

Proposition C.1.76 (Normalization does not repair the generic graph)**.** *Let k be any field, $O = k[[\pi]]$, and $K = k((\pi))$, with its usual complete discrete absolute value. On $\mathbf{P}^1_O$, with affine coordinate T, set*

$$\mathcal{X}_1 = \mathrm{Bl}_{(T,\pi^2)}\,\mathbf{P}^1_O, \qquad \mathcal{X}_2 = \mathrm{Bl}_{(T-\pi,\pi^2)}\,\mathbf{P}^1_O, \tag{4}$$

extending each ideal by the unit ideal near infinity. These are projective semistable models of $\mathbf{P}^1_K$. The schematic closure $\mathcal{G}$ of their generic identity graph has an open neighbourhood of the pair of special nodes equal to $\operatorname{Spec} R$*, with*

$$R = \frac{O[T,u,v]}{(Tu-\pi^2,\ (T-\pi)v-\pi^2,\ uv+\pi u-\pi v)}. \tag{5}$$

The domain R is normal, but

$$R/\pi R = k[T,u,v]/(Tu, Tv, uv). \tag{6}$$

At the origin this special fibre has three geometric branches and is not nodal. The normalization of $\mathcal{G}$ is therefore not a semistable model.

Proof. The actual charts of the first blowup are $O[T,u]/(Tu-\pi^2)$, with $u = \pi^2/T$, and $O[z]$, with $T = \pi^2 z$. These are the blowup subrings $A[\pi^2/T]$ and $A[T/\pi^2]$. The first embeds in $K[T,T^{-1}]$ using its normal-form monomials $1, T^i, u^j$ for $i,j > 0$. Both charts are flat and finitely presented, with smooth generic fibres. Their special fibres form two projective lines meeting at the split node $Tu = \pi^2$. Replace T by $T - \pi$ for the second model. Both ideals are units where their first generators are units, so the extension near infinity is valid. Projectivity follows from Stacks Tag 02NS and Stacks Tag 0C4P.

On the product of the node charts, the generic diagonal has ring

$$K[T,T^{-1},(T-\pi)^{-1}], \qquad u = \pi^2/T, \quad v = \pi^2/(T-\pi).$$

The coordinate ring of its schematic closure is the image of the product chart ring in this domain. The relations (5) vanish there. They reduce every mixed monomial to an O-linear combination of

$$1, \quad T^i, \quad u^j, \quad v^h \qquad (i,j,h \geq 1), \tag{7}$$

since $Tu = \pi^2$, $Tv = \pi v + \pi^2$ and $uv = \pi v - \pi u$ decrease total degree in T, u, v. The elements (7) are linearly independent in $K(T)$: the u-terms have sole poles at 0, the v-terms at π, and the polynomial part is regular at both. Comparing principal parts at these distinct points eliminates all u- and v-coefficients, and then the polynomial coefficients. Thus (5) is exactly the image ring, a domain free over O on (7). Reduction gives (6).

Put $\mathfrak{n} = (\pi, T, u, v)$. After inverting π we have the displayed smooth K-algebra. At a prime containing π but not T, the local ring is a localization of $O[T, T^{-1}, (T-\pi)^{-1}]$. At a prime containing π but not u, the elements $u, u - \pi$ are units, and

$$T = \pi^2/u, \qquad v = -\pi u/(u - \pi).$$

The local ring is a localization of $O[u, u^{-1}, (u-\pi)^{-1}]$. For a prime containing π but not v, use

$$T = \pi + \pi^2/v, \qquad u = \pi v/(v + \pi).$$

Every local ring outside $\mathfrak{n}$ is therefore regular, by regularity of localized polynomial rings over a DVR (or Stacks Tag 07NF).

At $\mathfrak{n}$, the element π is a nonzerodivisor. In (6), $T + u + v$ is a nonzerodivisor: that ring injects into $k[T] \times k[u] \times k[v]$, and multiplication restricts to multiplication by T, u, v in the respective factors. Thus $\pi, T + u + v$ is a regular sequence in $R_{\mathfrak{n}}$. Its depth is at least two. The strict chain of primes

$$(0) \subsetneq (\pi, u, v) \subsetneq \mathfrak{n}$$

shows that $\mathfrak{n}$ has height at least two: $R/(\pi, u, v) = k[T]$. Every height-one prime is outside $\mathfrak{n}$, where regularity was proved. Regular local rings are Cohen–Macaulay by Stacks Tag 00NQ. The Noetherian ring R therefore satisfies R_1 and S_2, so is normal by Stacks Tag 031S.

Over an algebraic closure of k, the three axes in (6) remain distinct. The special local ring at the origin has dimension one and embedding dimension three, so is neither smooth nor an ordinary double point. Normalization is the identity on the normal open $\operatorname{Spec} R$ and cannot remove this three-branch point. □

Proposition C.1.77 (The component missing from the graph)**.** *For (4), a projective semistable common model is obtained by first blowing up (T, π), and then, in the chart $T = \pi z$, blowing up the two disjoint special-point ideals (z, π) and $(z - 1, \pi)$, extended by the unit ideal elsewhere. The resulting $\mathcal{Z}$ has component vertices*

$$\zeta_{0,1}, \quad w = \zeta_{0,|\pi|} = \zeta_{\pi,|\pi|}, \quad \zeta_{0,|\pi|^2}, \quad \zeta_{\pi,|\pi|^2}.$$

The component at w is a geometric projective line attached to the other three components at $0, 1, \infty$. The map $\mathcal{Z} \to \mathcal{G}$ contracts that entire component to the origin of (6).

Proof. Blowing up (h, π) at a smooth point with local parameter h has charts $O[h, t]/(ht - \pi)$ and $O[z]$, with $h = \pi z$. It is projective, flat, finitely presented and semistable, with one new projective-line component. After the first blowup the next two centres are distinct smooth points $z = 0, 1$ of its exceptional line; the old component attaches at infinity. These ideals agree with the unit ideal off their supporting points, so define actual global blowups. Their coordinates give the stated Gauss radii.

In the z-chart the ideals in (4) pull back to $\pi(z, \pi)$ and $\pi(z - 1, \pi)$, which are invertible after the two subsequent blowups. The other first-blowup chart is $O[T, r]/(Tr - \pi)$. On $D(1 - r)$ both ideals are (T), because

$$(T - \pi, \pi^2) = T(1 - r, Tr^2).$$

The open $D(r)$ lies in the z-chart, and $D(r) \cup D(1 - r)$ covers this other chart. Hence both pullback ideals are globally invertible, generated locally by nonzerodivisors since $\mathcal{Z}$ is integral. The blowup universal property Stacks Tag 0806 supplies the two generic-identity maps. Their pair factors through $\mathcal{G}$, because the generic fibre is schematically dense in the flat integral source.

At the generic point of w, z has nonconstant residue and

$$T = \pi z, \quad T - \pi = \pi(z - 1), \quad u = \pi/z, \quad v = \pi/(z - 1)$$

all reduce to zero. The image is the origin of (6). Its inverse image is closed and contains the generic point of that component, hence contains the entire component. □

Tame Kummer descent for supplied models

We retain the exact coefficient class of the passing theorem. Let K be complete and nontrivially real-valued, with valuation ring O, value group Γ, and residue field k. Let $e \geq 2$ be invertible in O, and let $\zeta \in O$ be an e-th root whose order and residual order are both e. Suppose

$$L = K(s), \qquad s^e = c \in K^\times, \qquad \gamma = v(s) > 0, \qquad i\gamma \notin \Gamma \quad (0 < i < e). \tag{K}$$

Write $O' = L^\circ$ for the actual valuation ring, $\mathfrak{m}'$ for its maximal ideal, and $G = \langle \sigma \rangle$, with $\sigma(s) = \zeta s$. The passing coefficient calculation gives

$$O' = \bigoplus_{i=0}^{e-1} I_i s^i, \qquad I_i = \{a \in K : v(a) + i\gamma \geq 0\}, \tag{3}$$

and identifies its residue field with k. No module finiteness of O' over O is assumed.

Let B' be a flat O'-algebra with a semilinear G-action inducing this coefficient action. Set

$$B = (B')^G, \qquad S = O'[B] \subset B', \qquad C = B'/S. \tag{4}$$

The quotient C is an additive S-module. It is not being regarded as a B'-module. The passing theorem identifies S with the image of the injective multiplication map

$$\mu : O' \otimes_O B \longrightarrow B'. \tag{5}$$

Theorem C.1.78 (Residual identity suffices in the nondiscrete class)**.** *Assume (K) and the stated flatness and semilinear action on B'. If the additive quotient $C = B'/O'[(B')^G]$ is a finitely generated $S = O'[(B')^G]$-module, then the following are equivalent:*

1. *G acts identically on the full special-fibre algebra $B'/\mathfrak{m}'B'$;*
2. *the given semilinear algebra has effective descent over O;*
3. *the multiplication map (5) is an isomorphism;*
4. *for every $0 \leq i < e$,*

$$s^{-i}\{b \in B' : \sigma(b) = \zeta^i b\} = I_i (B')^G \quad \text{inside } K \otimes_O (B')^G. \tag{6}$$

The finiteness assumption on C holds whenever B' is of finite type over O'. In particular, the equivalence applies to every flat finitely presented nodal affine chart in (K). For such a chart the invariant algebra B is flat, finitely presented and nodal over O, and (5) gives its effective descent with the prescribed action. No split-branch, diagonal-coordinate, or discrete-value-group hypothesis is added.

Proof. The zero algebra is immediate, so assume $B' \neq 0$. Flatness then makes $O' \to B'$ injective. The equivalence of conditions 2, 3 and 4, and the implication $2 \Rightarrow 1$, are the exact passing result C.1.53. We prove $1 \Rightarrow 3$ under the specified finite S-module assumption.

First $C \otimes_{O'} L = 0$. Here is the generic calculation using the same exact input, without any integral torsor identity. The Fourier projectors give $B' = \bigoplus_i M_i$, with $M_i = \{b : \sigma(b) = \zeta^i b\}$. The localization statement in the passing theorem gives

$$s^{-i} M_i \subset B_K, \qquad B_K = K \otimes_O B.$$

For $m \in M_i$, write $s^{-i} m = b/d$ with $b \in B$, $d \in O \setminus \{0\}$. Then $m = s^i b/d$ lies in $S \otimes_{O'} L$, because $s^i \in O' \subset S$. Summing the character components shows

$$S \otimes_{O'} L = B' \otimes_{O'} L.$$

Localization is exact, so $C \otimes_{O'} L = 0$.

Next, residual identity gives $C = \mathfrak{m}' C$. For every $z \in B'$, the average

$$P_0(z) = \frac{1}{e} \sum_{g \in G} g(z)$$

belongs to $B \subset S$. Since $z - g(z) \in \mathfrak{m}' B'$ for every g, we have $z - P_0(z) \in \mathfrak{m}' B'$. Consequently

$$B' = S + \mathfrak{m}' B', \qquad C = \mathfrak{m}' C.$$

The ring S contains the coefficient ring O', so these are precisely the module and scalar actions needed in Lemma C.1.32. Apply that lemma with $R = O'$, $F = L$ to obtain $C = 0$. Thus $S = B'$, proving surjectivity of (5); its injectivity is already supplied by the passing criterion. This proves condition 3.

If B' is of finite type over O', choose a finite set of algebra generators. Lemma C.1.33 applies with $R' = O'$ and gives the required finite S-module C. There is no claim that B' or C is finite over O'. For B' finitely presented

and nodal, the flatness, finite presentation and nodality of B follow from the persistence part of C.1.53, now that the actual base-change map is an isomorphism. □

We work with the exact tame Kummer class of the passing C.1.53. Thus K is complete and nontrivially real-valued, $O = K^\circ$, $e \geq 2$ is invertible in O, and $\zeta \in O$ and its reduction both have order e. We assume

$$L = K(s), \quad s^e = c \in K^\times, \quad \gamma = v(s) > 0, \quad i\gamma \notin v(K^\times) \quad (0 < i < e). \tag{K}$$

The ring $O' = L^\circ$ is the actual valuation ring, $\mathfrak{m}'$ is its maximal ideal, and $G = \langle\sigma\rangle$, $\sigma(s) = \zeta s$. The residue field of O' is $k = \widetilde{K}$, on which G acts trivially. The extension $O \to O'$ is faithfully flat and affine; it need not be finite.

A semilinear action on an O'-scheme Y' means an O-scheme action inducing the specified action on $\operatorname{Spec} O'$. An effective descent is an O-scheme Y with a G-equivariant isomorphism $Y \times_O O' \simeq Y'$, where G acts on the coefficient factor on the left. Full residual identity means that the induced action on the entire scheme $Y'_k = Y' \times_{O'} k$ is the identity.

Lemma C.1.79 (Fixed special points and generic finite orbits)**.** *Let Y' be a separated O'-scheme, locally of finite presentation, with a semilinear G-action. Suppose that every point of Y'_k is fixed by G. Assume also that Y'_L is of finite type over L and has dimension at most one. Then Y' has a cover by G-invariant affine open subschemes. If Y' is quasi-compact, the cover can be chosen finite.*

Alternatively, properness of $Y' \to \operatorname{Spec} O'$ may replace the hypothesis on the generic fibre. Every finite intersection of the affine opens just obtained is affine, invariant, and of finite presentation over O'.

Proof. Choose $0 \neq \pi \in \mathfrak{m}$. Rank one gives $O'[1/\pi] = L$ and $\sqrt{\pi O'} = \mathfrak{m}'$: any positive real valuation eventually dominates any other after multiplication by a positive integer. Hence the generic fibre is the open $D(\pi) \subset Y'$, and its complement is the underlying special fibre.

Let $x \in Y'_k$, and choose an affine open $V \subset Y'$ containing x. Every translate gV contains x, because the point is fixed. The intersection

$$U_x = \bigcap_{g \in G} gV \tag{2}$$

is invariant and still contains x. It is affine by Stacks Tag 01KP(1)(a), since Y' is separated over the affine base $\operatorname{Spec} O'$.

For $x \in Y'_L$, its orbit is a finite subset of the separated finite-type L-scheme Y'_L. By Stacks Tag 0A25, this scheme is a locally closed subscheme of some projective space over L. Therefore Stacks Tag 01ZY places the entire finite orbit in an affine open $V \subset Y'_L$. This is an affine open of Y', since Y'_L is open. Formula (2) again gives an invariant affine neighborhood of x. This covers every point of Y'. Quasi-compactness supplies a finite subcover when required.

For the alternative proper case, let U be the union of the invariant affine neighborhoods constructed at special-fibre points. The closed complement $Z = Y' \setminus U$, with its reduced closed subscheme structure, is proper over O'. Its image is closed and misses the closed point of $\operatorname{Spec} O'$. Every nonempty closed subset of a local spectrum contains its closed point, so Z is empty. A finite subcover again exists by properness.

Finally, finite intersections remain invariant and affine by Stacks Tag 01KP. Their structural morphisms are locally of finite presentation, and a morphism between affine schemes is quasi-compact and quasi-separated. They are therefore of finite presentation. □

Proof inputs. C.1.53.

Proposition C.1.80 (Affine overlaps descend as open immersions)**.** *Let Y' be separated, flat and locally of finite presentation over O', with a semilinear G-action which is the identity on Y'_k. Let $U'_1, \dots, U'_r$ be invariant affine opens. For every nonempty subset $I \subset \{1, \dots, r\}$, set*

$$U'_I = \bigcap_{i \in I} U'_i, \qquad A'_I = \Gamma(U'_I, \mathcal{O}_{Y'}), \qquad A_I = (A'_I)^G, \qquad U_I = \operatorname{Spec} A_I. \tag{3}$$

Empty intersections are allowed as schemes, with coordinate ring zero. Then:

1. *U_I is flat and finitely presented over O, and multiplication identifies $(U_I)_{O'}$ equivariantly with U'_I. If Y' is nodal of relative dimension one, then U_I/O is nodal of relative dimension one.*
2. *If $I \subset J$, restriction defines an open immersion $j_{J,I} : U_J \hookrightarrow U_I$. Its base change is exactly the given inclusion $U'_J \hookrightarrow U'_I$.*
3. *If $\varnothing \neq H \subset I \cap J$, the canonical map is an isomorphism*

$$A_I \otimes_{A_H} A_J \xrightarrow{\sim} A_{I \cup J}. \tag{4}$$

These identifications respect every further restriction. Thus pairwise and triple intersections downstairs are the descents of the corresponding actual intersections upstairs.

Proof. Separatedness makes every U'_I affine by Stacks Tag 01KP. Its restricted structural morphism is flat and locally of finite presentation. Since its source and target are affine, it is also quasi-compact and quasi-separated, and hence finitely presented. The restricted action has full residual identity. Apply C.1.78 to obtain

$$\mu_I : O' \otimes_O A_I \simeq A'_I. \tag{5}$$

The same result supplies flatness, finite presentation and, when applicable, nodality downstairs.

Restriction of functions is G-equivariant and hence maps A_I to A_J. The multiplication maps (5) commute with these restrictions: both composites send $a' \otimes b$ to $a'\, b|_{U'_J}$. Consequently the base change of the actual morphism $j_{J,I}$ is the specified open immersion. By Stacks Tag 02L3, open immersion is fpqc local on the target. The relevant target cover is

$$(U_I)_{O'} \longrightarrow U_I,$$

the base change of the faithfully flat affine morphism $\operatorname{Spec} O' \to \operatorname{Spec} O$. Thus $j_{J,I}$ is an open immersion. This application does not identify $O' \otimes_O O'$ with a product indexed by G.

The map in (4) is induced by multiplying the two restriction maps. After tensoring over O with O', it becomes

$$A'_I \otimes_{A'_H} A'_J \longrightarrow A'_{I \cup J}.$$

This is an isomorphism because U'_I and U'_J are affine open subschemes of U'_H, and their fibre product is their intersection. Faithful flatness over O now makes (4) an isomorphism: tensoring is exact and detects zero kernels and cokernels. All maps were formed from restriction and multiplication, so their compositions have the asserted compatibility. □

Proof inputs. C.1.53.

Theorem C.1.81 (Effective descent of a supplied separated nodal curve)**.** *Assume (K). Let $Y' \to \operatorname{Spec} O'$ be a separated, flat, finitely presented scheme which is at-worst-nodal of relative dimension one, equipped with a semilinear G-action. The following are equivalent:*

1. *G acts identically on the entire special fibre Y'_k.*
2. *There is a separated, flat, finitely presented nodal O-scheme Y of relative dimension one and a G-equivariant isomorphism*

$$Y \times_O O' \simeq Y'. \tag{6}$$

The descent with identification (6) is unique up to a unique isomorphism compatible with that identification. It is obtained from the invariant coordinate rings of a finite invariant affine cover, with the invariant overlap rings in (3). If Y' is proper over O', then Y is proper over O.

Proof. Assume condition 1. The generic fibre of Y' is a separated finite-type L-scheme of dimension one. Lemma C.1.79 gives a finite invariant affine cover $Y' = \bigcup_i U'_i$. Apply Proposition C.1.80 and write $U_i = U_{\{i\}}$, $U_{ij} = U_{\{i,j\}}$.

Each U_{ij} embeds openly in both U_i and U_j. Use these embeddings to identify their images. Formula (4) identifies, inside U_i, the intersection of the images of U_{ij} and U_{ik} with $U_{\{i,j,k\}}$. The transition maps on this intersection satisfy the cocycle condition: their coordinate maps are the same restrictions to $A_{\{i,j,k\}}$. Thus these are genuine open-gluing data. By Stacks Tag 01JB they glue to a locally ringed space Y. Since its open pieces U_i are affine schemes, Y is a scheme. Their O-structure maps glue as well.

The isomorphisms (5) agree on every overlap. They therefore glue to (6), and it is G-equivariant because each μ_I is equivariant. In particular the construction uses the full given algebraic scheme and its action.

For completeness, separatedness can be checked directly, without an assertion about quotients preserving it. On the pair of charts U_i, U_j, consider

$$A_i \otimes_O A_j \longrightarrow A_{ij}. \tag{7}$$

After tensoring with O', this is the restriction map $A'_i \otimes_{O'} A'_j \to A'_{ij}$, which is surjective because Y'/O' is separated, by Stacks Tag 01KP. Faithful flatness makes (7) surjective. Hence the diagonal of Y/O is a closed immersion on every affine open $U_i \times_O U_j$ of its target, so Y/O is separated. Flatness

and the nodal relative-dimension-one property hold on the charts by Proposition C.1.80. Each chart is finitely presented over O; the finite cover makes Y quasi-compact, and separatedness makes it quasi-separated. Thus Y/O is finitely presented.

The construction is independent of the invariant affine cover. For two such covers, their pairwise intersections give a common invariant affine refinement. Proposition C.1.80 identifies its invariant rings and open embeddings on both sides. The resulting opens cover each descended chart: they do so after base change, and that base change is surjective. They therefore produce a canonical isomorphism between the gluings. For any other effective descent Z/O with a specified equivariant identification $Z_{O'} \simeq Y'$, pull back an affine cover of Z. These are invariant affine opens of Y'. Their invariant rings recover the original coordinate rings of Z: this is the weight-zero recovery in C.1.53 for an effective presentation. The same common-refinement argument identifies Z with Y, compatibly with (6). Uniqueness follows because equality of maps can be checked after a faithfully flat base change, the faithful part of Stacks Tag 02W0. Here only faithfulness is used; a semilinear action has not been presumed to be an integral fpqc descent datum.

If Y' is proper, (6) and Stacks Tag 02L1 imply that Y/O is proper. Conversely, any effective presentation (6) has special fibre $Y \times_O k$. The action on this scheme is the identity because the coefficient action on k is trivial. This proves condition 1. □

Retain the coefficient class of C.1.53. Let K be complete and nontrivially real-valued, with valuation ring O, value group Γ, and residue field k. Let $e \geq 2$ be invertible in O, and let $\zeta \in O$ have order e, with residue also of order e. Assume

$$L = K(s), \qquad s^e = c \in K^\times, \qquad \gamma = v(s) > 0, \qquad i\gamma \notin \Gamma \quad (0 < i < e). \tag{K}$$

Write $O' = L^\circ$, $\mathfrak{m}'$ for its maximal ideal, and $G = \langle \sigma \rangle$, where $\sigma(s) = \zeta s$. The cited criterion gives a faithfully flat map $O \to O'$, identifies both residue fields with k, and gives identity coefficient action on k. In particular, its character-zero summand is $(O')^G = O$. The value group need not be discrete, and O' is the actual valuation ring; it need not be finite as an O-module.

Proposition C.1.82 (Residual identity for finite coefficient modules)**.** *Assume (K). Let B' be a flat finite-type O'-algebra with a semilinear G-action which is the identity on $B'/\mathfrak{m}'B'$. Set $B = (B')^G$. Let M' be a finitely generated B'-module, flat over O', with a compatible semilinear action, meaning $g(bm) = g(b)g(m)$. Put $M = (M')^G$. The following conditions are equivalent:*

1. *G acts identically on $M'/\mathfrak{m}'M'$.*
2. *The natural multiplication map is an equivariant isomorphism*

$$B' \otimes_B M \longrightarrow M'. \tag{1}$$

Here $B' \simeq O' \otimes_O B$ by C.1.78, so (1) is also the map $O' \otimes_O M \to M'$, with coefficient action on the left. If these conditions hold and M' is finite projective of constant rank r over B', then M is finite projective of rank r over B. In particular this applies to rank one.

Proof. Assume condition 1. Form the commutative square-zero algebra

$$E' = B' \oplus M', \qquad (b, m)(d, n) = (bd, bn + dm). \tag{2}$$

It is flat over O', since both summands are flat. It is a finite-type O'-algebra: take finitely many algebra generators of B' and finitely many B'-module generators of M'. These elements, placed in their respective summands, generate E' as an algebra. This does not assert finite generation of M' over O'.

The given actions define a semilinear algebra action on E', and the full residual algebra action is the identity because

$$E'/\mathfrak{m}'E' = (B'/\mathfrak{m}'B') \oplus (M'/\mathfrak{m}'M')$$

with the same square-zero multiplication. Moreover, $(E')^G = B \oplus M$. Apply the finite-type assertion of C.1.78 to E'. Its canonical multiplication isomorphism is

$$O' \otimes_O (B \oplus M) \xrightarrow{\sim} B' \oplus M'. \tag{3}$$

It preserves both summands. On the first it is the known algebra isomorphism, and on the second it is $O' \otimes_O M \to M'$. Thus the second map is an isomorphism. The algebra identification $B' = O' \otimes_O B$ rewrites it as (1). Equivariance follows from the multiplication formula and the fact that M is fixed. The square-zero algebra is generally not nodal; this use is legitimate because the antecedent proves effectiveness for every flat finite-type algebra, with no nodality or reducedness assumption.

Conversely, under (1) the reduction of M' is $k \otimes_O M$, on which the coefficient action is the identity. This proves condition 1.

The map $B \to B'$ is faithfully flat, being the base change of $O \to O'$. If M' is finite projective, Stacks Tag 058S applied to (1) makes M finite projective. For each prime $\mathfrak{p} \subset B$, choose a prime of B' above it. The dimension of the fibre of M at $\mathfrak{p}$ is unchanged by extending to the corresponding residue field upstairs; it is therefore r. This proves the rank assertion. □

Proof inputs. C.1.53.

Proposition C.1.83 (Line bundles and relative ampleness)**.** *Assume (K). Let Y be a flat, locally finitely presented O-scheme, put $Y' = Y \times_O O'$, and let $p : Y' \to Y$ be the projection, with its coefficient G-action. Let $\mathcal{L}'$ be a G-linearized invertible sheaf on Y'. The following conditions are equivalent:*

1. *The restricted action on $\mathcal{L}'|_{Y'_k}$ is the identity.*
2. *The sheaf $\mathcal{L} = (p_*\mathcal{L}')^G$ is invertible, and evaluation gives a G-equivariant isomorphism*
$$p^*\mathcal{L} \simeq \mathcal{L}'. \tag{4}$$

This descent is unique up to a unique isomorphism compatible with (4). If the conditions hold, $\mathcal{L}$ is relatively ample over O if and only if $\mathcal{L}'$ is relatively ample over O'.

Proof. Assume condition 1. For any affine open $V = \operatorname{Spec} B$ of Y, its inverse image is the invariant affine $V' = \operatorname{Spec} B'$, where $B' = O' \otimes_O B$. The algebra B' is flat and finitely presented over O'. Its coefficient action has full residual identity, and $(B')^G = B$ by the character-zero recovery in C.1.53 for an effective presentation.

By the affine equivalence Stacks Tag 01IB and the finite-projective characterization Stacks Tag 00NX, the module $M' = \Gamma(V', \mathcal{L}')$ is finite projective of rank one over B'. It is flat over O', since it is a direct summand of a finite free B'-module and B' is O'-flat. Its residual action is the identity: reduction of sections on this affine identifies it with the sections of $\mathcal{L}'|_{V'_k}$, by Stacks Tag 01I9. Proposition C.1.82 therefore gives a finite projective rank-one B-module $M = (M')^G$ and the equivariant isomorphism (1).

These affine modules describe the asserted invariant sheaf. Indeed, for $f \in B$, the averaging projector

$$P_0 = \frac{1}{e} \sum_{g \in G} g$$

is B-linear and commutes with localization at f. Its image is the invariant module, both before and after localization. Hence

$$(M'_f)^G = M_f. \tag{5}$$

On the principal-open basis of V, formula (5) identifies $(p_*\mathcal{L}')^G|_V$ with $\widetilde{M}$. Thus the invariant sheaf is quasi-coherent and invertible. The local multiplication maps (1) are the restrictions of the canonical evaluation map (4), so they glue and make (4) an equivariant isomorphism. No independent assumption of an integral fpqc descent datum has been made.

For any other invertible sheaf $\mathcal{D}$ on Y with an equivariant identification $p^*\mathcal{D} \simeq \mathcal{L}'$, local trivializations of $\mathcal{D}$, together with $(O' \otimes_O B)^G = B$, identify $\mathcal{D} \simeq (p_*p^*\mathcal{D})^G$. Taking invariants of the specified identification gives its unique compatible isomorphism with $\mathcal{L}$. Conversely, (4) gives identity on the special fibre because the coefficient action on k is the identity.

Finally, $\operatorname{Spec} O' \to \operatorname{Spec} O$ is a faithfully flat affine morphism, hence an fpqc cover. Once the actual invertible sheaf $\mathcal{L}$ and (4) have been constructed, Stacks Tag 0D2P applies to this cover and proves the equivalence of relative ampleness. Its hypotheses require neither a Noetherian base nor a finite extension of valuation rings. □

A symmetric insertion and the arithmetic of its midpoint

Let K be a complete non-Archimedean field with a specified nontrivial real-valued absolute value. Write

$$O = K^\circ, \qquad k = \widetilde{K}, \qquad v(c) = -\log|c|, \qquad \Gamma = v(K^\times) \subset \mathbb{R}.$$

Let C/K be a smooth projective geometrically connected curve. A model means a projective flat finitely presented nodal O-curve with generic fibre identified with C and geometrically connected, geometrically reduced special

fibre, as in 4.45.3. A marking D, when present, is a fixed finite etale O-scheme embedded in the relative smooth locus. All model morphisms below induce the identity on C.

Fix an actual model $\mathcal{X}$. Choose a finite unramified Galois residue lift L/K splitting its nodes. Put $l = \widetilde{L}$ and $G = \mathrm{Gal}(L/K)$. Here *unramified* means the actual finite free etale coefficient extension of 4.43.1; in particular $v(L^\times) = \Gamma$. The splitting field and rational pointed etale nodal charts exist by 4.18.2.

For each node e of $\mathcal{X}_l$, choose an ordering of its two branches and a pointed chart $x_e y_e = a_e$, with $0 < |a_e| < 1$. Put $\ell_e = v(a_e)$. By 4.39.1 and 4.39.3, its entire tube is the standard open annulus

$$|a_e| < |x_e| < 1, \qquad s = v(x_e) \in (0, \ell_e).$$

The coordinate s increases from the chosen first end to the second. These are two distinct *branch ends* even if their component vertices coincide.

Use an algebraically closed complete isometric comparison field $\Omega \supset L$ with residue field $\overline{k}$, as in 4.45.1, and write $p : C_\Omega^{\mathrm{an}} \to C^{\mathrm{an}}$. The geometric component vertices of a model are exactly $p^{-1}(V(\mathcal{X}))$, by 4.45.2. Write $\zeta_e(r)$ for the Gauss point of radius r in the selected annular tube over Ω.

Lemma C.1.84 (An original-ring symmetric insertion)**.** *Let q be a closed node of $\mathcal{X}_s$, and let ℓ be the common length of its split geometric tubes. For $\delta \in \Gamma$ with $0 < \delta \le \ell/2$, there is a projective semistable modification of $\mathcal{X}$, an isomorphism away from q, inserting precisely $\delta, \ell - \delta$ in each geometric tube over q. A coincident pair is counted once. The modification preserves D and all old vertices and is the blowup of an explicit finite-type ideal on $\mathcal{X}$.*

Proof. Choose $\lambda \in K$ with $v(\lambda) = \delta$. On a Zariski neighbourhood U of q omitting the other special nodes, set

$$\mathcal{I}_U = (\lambda) + \mathrm{Fitt}_1\, \Omega_{U/O}.$$

The differential module is finitely presented, so its Fitting ideal is of finite type. At a smooth point that module is locally free of rank one, and its first Fitting ideal is the unit ideal. On the generic fibre λ is invertible. Thus $\mathcal{I}_U$ equals the unit ideal on $U \setminus \{q\}$ and glues with that ideal on $\mathcal{X} \setminus \{q\}$. We have constructed a quasi-coherent finite-type ideal $\mathcal{I}_q$ on the original model. It contains (λ); for any fixed $0 \neq \pi \in K^{\circ\circ}$, some power of π belongs to (λ), since the valuation has rank one.

Extend to $O' = L^\circ$. Differentials and Fitting ideals commute with coefficient extension and the indicated etale charts (Stacks tags Stacks Tag 04BX, Stacks Tag 0C3D, Stacks Tag 0C3E). The ideal in every selected chart is (λ, x_e, y_e). Blowup commutes with these flat base changes by Stacks Tag 0805. The accepted 4.27.1 applies because $c_e = a_e/\lambda^2 \in O'$. Its three actual torsion-free charts are

$$O'[u,z]/(uz - c_e), \qquad O'[x,w]/(xw - \lambda), \qquad O'[y,w']/(yw' - \lambda).$$

We reuse that calculation, including its gluing and component count. It inserts two smooth geometric projective lines if $2\delta < \ell$, and one if $2\delta = \ell$, at exactly the asserted radii. They form a chain between the two old branch ends.

Shrink each auxiliary pointed etale neighbourhood so its fibre over each selected node in either target is exactly the specified rational point. These charts cover the exceptional fibre. With the unchanged complement, they prove flatness and local finite presentation as in 4.27.2, using Stacks Tag 036K and Stacks Tag 036N. Nodality descends through the finite faithfully flat coefficient extension by Stacks Tag 0C5E. The actual global blowup is projective by Stacks Tag 02NS; composition over the affine base is projective by Stacks Tag 0C4P. Quasi-compactness, separatedness and local finite presentation give finite presentation. Replacing each geometric edge by a connected chain preserves geometric connectedness and reducedness. The generic fibre is unchanged, and the smooth marking is disjoint from the centre.

This constructs the integral model before using geometric vertex invariance. The Fitting ideal is defined even at a nonsplit node and when both branches belong to one global component. □

Proof inputs. 4.18.2, 4.39.1, 4.39.3, 4.43.1.

Proposition C.1.85 (An invariant midpoint over a dense value group)**.** *There is a complete nontrivially real-valued field K, with algebraically closed residue field of characteristic zero and dense value group $\Gamma = \mathbb{Z}[1/3]$, and a split projective semistable model $\mathcal{X}$ of $\mathbb{P}^1_K$, for which the following holds. Its geometric skeleton is an interval of length 1. Adding its midpoint gives a semistable geometric vertex set fixed by every isometric K-automorphism of $\Omega = \widehat{K}$, but no semistable original-O model has that geometric vertex set. The midpoint is realized after the ramified quadratic extension $K(\sqrt{t})/K$.*

Proof. Fix an algebraically closed field k of characteristic zero. Take compatible Laurent-series fields

$$F_n = k((t^{1/3^n})), \qquad F_n \hookrightarrow F_{n+1}, \qquad v(t^{1/3^n}) = 3^{-n},$$

and let K be the completion of $F = \bigcup_{n\geq 0} F_n$. For nonzero $a \in K$, choose $f \in F$ with $|a - f| < |a|$; then $|a| = |f|$. Thus completion introduces no new nonzero values and $v(K^\times) = \mathbb{Z}[1/3]$, which is dense in $\mathbb{R}$. For $a \in K^\circ$, approximation with error less than 1 identifies its residue with a residue from some F_n°. Hence the residue field is k.

On $\mathbb{P}^1_O$, with affine coordinate T, blow up the ideal (T, t), extended as the unit ideal outside its support. The two affine charts over the T-line are

$$\operatorname{Spec} O[T, u]/(Tu - t), \qquad \operatorname{Spec} O[z], \quad T = tz.$$

Their standard monomial bases make these rings free over O, hence flat; the displayed presentations are finite. The first is a nodal chart and the second is smooth. Together with the unchanged infinity chart they give a projective semistable model $\mathcal{X}$, by Stacks Tag 02NS and Stacks Tag 0C4P, with special fibre two copies of $\mathbb{P}^1_k$ meeting at one split node. Its geometric vertices have $v(T) = 0, 1$, and the node tube is $|t| < |T| < 1$, of length 1.

Choose $b \in \Omega$ with $b^2 = t$, and put $L = K(b)$. Since $1/2 \notin \Gamma$, $b \notin K$ and $[L : K] = 2$. The two terms in $a + cb$, for $a, c \in K$, have distinct valuations when nonzero, since $\Gamma \cap (\Gamma + 1/2) = \varnothing$. Thus $|a + cb| = \max(|a|, |c||b|)$; completeness follows coefficientwise from completeness of K. Since $v(b) = 1/2$, the extension is ramified. Lemma C.1.84, using the accepted charts 4.27.1, at $\delta = 1/2$ on $\mathcal{X}_{L^\circ}$ inserts exactly the midpoint. Consequently its base change to Ω° realizes the three-element semistable geometric vertex set

$$\{\zeta(1),\ \zeta(|t|^{1/2}),\ \zeta(|t|)\}.$$

Each of these Gauss seminorms is fixed by every isometric K-automorphism of Ω: its radius is fixed and its formula on $\Omega[T]$ uses only the absolute values of the coefficients.

If an original semistable model realized this set, then 4.45.2 would make the image w of the midpoint a component vertex satisfying $v(\mathcal{H}(w)^\times) = \Gamma$. But T is a nonzero element of $\mathcal{H}(w)$ with $v(T(w)) = 1/2$, a contradiction. Thus invariance, even with already split branches and residue field, is insufficient. The use of L° above is a ramified construction, not an etale descent step. □

Proposition C.1.86 (A tame valuation-ring extension that is not finite)**.** *Use the audited field*

$$K = \bigcup_{r\geq 0} \widehat{k((t^{1/3^r}))}, \qquad \operatorname{char}(k) = 0, \quad k \text{ algebraically closed}, \qquad v(t) = 1, \quad \Gamma = \mathbb{Z}[1/3],$$

and $L = K(b)$, $b^2 = t$. *For* $O = K^\circ$, $O' = L^\circ$,

$$O' = O \oplus Mb, \qquad M = \{c \in K : v(c) > -1/2\}. \tag{13}$$

The O*-module* M*, and therefore* O'*, is not finitely generated. In particular* $O[b] \neq O'$*, although* L/K *is tame quadratic with unchanged residue field.*

Proof. The audited midpoint proof gives the degree, completeness, value group, residue field, and orthogonal equality $v(a+cb) = \min(v(a), v(c)+1/2)$. Hence (13) follows. The weak inequality for c is strict because $-1/2 \notin \Gamma$.

A nonzero O-submodule of K generated by finitely many elements is principal: choose a generator of least valuation, and divide every other generator by it in O. But the value set $\Gamma \cap (-1/2, \infty)$ of M has no least element, since Γ is dense. Thus M is not finitely generated. Projection onto the second summand in (13) is O-linear; finiteness of O' would imply finiteness of M.

Finally $O[b] = O \oplus Ob$, whereas $t^{-1/3}b \in O'$ has value $1/6 > 0$ and its coefficient $t^{-1/3}$ does not belong to O. This proves the strict inequality of the rings. The degree equals the value index two, the residue field is unchanged, and its characteristic is zero, giving the stated tameness. □

Proof inputs. C.1.85.

Coordinate zero spaces and fixed-test cutoffs

Let K be complete for its specified non-Archimedean absolute value, which may be trivial. All dimensions below are analytic. For a function f on an ordinary open U, the conditions S1–S3 are the following.

S1. Every ordinary local ring of U satisfies S_1.

S2. Multiplication by f is injective on $\mathcal{O}_{U_G}$. Thus "regular" means an actual non-zero-divisor, not merely a nonzero function on one component.

S3. The actual zero space $D = V(f) \subset U$, with its quotient structure, is empty or pure of analytic dimension $n-1$.

Proposition C.1.87 (An arbitrary-dimensional class with checked purity; F8SA-M)**.** *On the strict n-polydisc $V = \mathcal{M}(K\langle T_1, \dots, T_n\rangle)$, let $f = u\prod_{j=1}^{r} T_j^{m_j}$, where u is an analytic unit, $1 \le r \le n$, and m_j are positive integers. Then S1–S3 hold on V. The irreducible components of its actual zero space are the coordinate hyperplanes, and its module length at the generic prime (T_j) is m_j.*

Proof. The polydisc algebra is a domain, and its ordinary local rings and all actual affinoid-domain algebras are regular by NAG-001760; in particular they satisfy S_1. Multiplication by f is injective, also after domain restriction by the flatness of NAG-001832. A prime containing the displayed product contains one T_j. Each (T_j) is prime, its quotient is a strict $(n-1)$-polydisc algebra, and these distinct coordinate primes are incomparable. They are therefore exactly the minimal primes over (f). Their analytic dimensions are $n-1$ by NAG-001657/NAG-001664. This verifies S3 without an unqualified prime-union rule in a mixed-component ring.

At (T_j), the other coordinates and u are units. The maximal ideal is generated by the non-zero-divisor T_j; successive powers in the quotient by $T_j^{m_j}$ have exactly m_j residue-field factors. The length is thus m_j. □

Cutoffs under prescribed support exclusion

Lemma C.1.88 (A fixed-test substitute; F8SC-L)**.** *Let X be good Hausdorff and pure of dimension n, let f be regular analytic, and let $\eta \in \mathcal{A}_c^{n-1,n-1}(X)$, with compact support K_0 in $\mathrm{Int}(X/K)$. Let B be a closed analytic set such that $X \setminus B$ satisfies S_1. Assume*

$$\dim(D \cap B) \le n-2, \qquad \operatorname{supp}\eta \cap (D \cap B) = \varnothing, \tag{4.2}$$

where $D = \{f = 0\}$; for $n = 1$, require $D \cap B = \varnothing$. Let W be an ordinary open neighbourhood of $K_0 \cap D$ on which f is pure of relative dimension $n-1$. There is a smooth cutoff χ, equal to one near D, such that $\chi\eta$ has compact support in $W \setminus B$, and $(1-\chi)\eta$ has compact support in $X \setminus D$.

Proof. The compact set $K_0 \cap B$ is disjoint from D, as is $K_0 \setminus W$. On either nonempty set the continuous function $|f|$ has a positive minimum. Choose $r > 0$ below both minima, ignoring an empty set. Choose a smooth function of $\log|f|$ equal to one for sufficiently small $|f|$, and zero for $|f| \ge r' < r$. Extend it by one across D. This is an ordinary smooth scalar: it is constant near D, and off D it uses the unit f. Its two products with η have the asserted compact supports. □

The proof uses compact smooth cutoffs and the ordinary sheaf of smooth moment forms.

Fixed-stage tests and matched tangential topologies

Let X be good and Hausdorff over a complete non-Archimedean field with its given absolute value, which can be trivial. Use the ordinary compact test space $\mathcal{E}^{p,q}(X) = \mathcal{A}_c^{p,q}(X)$ and the cutoff and ordinary coefficient presentations of Definition 8.15.3 and Theorem 8.15.4.

Proposition C.1.89 (Sequences in a fixed coefficient presentation)**.** *For a linear functional $T : \mathcal{E}^{p,q}(X) \to \mathbb{R}$, the following are equivalent:*

(i) T is continuous for either topology of Theorem 8.15.4.

(ii) For every s and every sequence $\eta^{(k)} \in H_s$ converging to zero in all coefficient C^∞ seminorms, $T(R_s\eta^{(k)}) \to 0$.

This is a criterion for scalar functionals. It does not characterize all convergent sequences in the full final test space.

Proof. Continuity implies (ii). For the converse, choose compact exhaustions of the finitely many Ω_j. Maxima of coefficient derivatives through order m on the first m compact sets give an increasing countable family P_m defining the topology of H_s. If the linear functional TR_s were not continuous, then for every m the neighbourhood $\{P_m < 1/m\}$ would contain v_m with $|TR_s(v_m)| \geq 1$. Indeed, a bound by one on any neighbourhood, followed by scalar dilation, would imply continuity. But $P_l(v_m) < 1/m$ for $m \geq l$, so $v_m \to 0$, contrary to (ii). Thus each TR_s is continuous, and the final seminorm definition and Theorem 8.15.4 imply (i). □

Proposition C.1.90 (Separation for functions)**.** *The space $(\mathcal{E}^{0,0}(X), \tau_{\mathrm{cut}})$ is Hausdorff.*

Proof. For $x \in X$, evaluation on a cutoff stage is either zero or $\chi(x)\eta(t_f(x))$. It is continuous in the ambient coefficient space. Thus $\alpha \mapsto |\alpha(x)|$ is one of the defining continuous seminorms. By `v037:forms:smoothcutoff`, ordinary scalar sections embed in continuous functions, so these seminorms separate distinct sections. Given a nonzero difference, disjoint intervals around its two values pull back to disjoint neighbourhoods. This proves Hausdorffness. □

Matched coefficient spaces and compact face sectors

Write U for a good Hausdorff analytic space over a complete non-Archimedean field, with arbitrary valuation. For an application with interior tests, take U to be an ordinary open subset of the true analytic interior of the ambient space. Put $E = \mathcal{A}_c^{p,q}(U)$, with the frozen ordinary moment sheaf and actual ordinary compact supports. The two final topologies of NAG-002472 are equal by NAG-002473; denote their common value by τ_a. A cutoff generator has the form

$$Q_i : E^{p,q}(\Omega_i) \longrightarrow E, \qquad Q_i\eta = \mathrm{ext}_0(\chi_i t_{f_i}^* \eta), \qquad t_{f_i} = -\log|f_i|.$$

Here V_i is affinoid, f_i is a unit tuple, Ω_i contains $t_{f_i}(V_i)$, and $\operatorname{supp}\chi_i$ is compact in $\mathrm{Int}_{\mathrm{top}}(V_i, U)$. The coefficient space has all compact C^∞ seminorms. A seminorm on E is τ_a-continuous exactly when all its composites with Q_i are continuous. The images of the Q_i span E. We now define a matched intrinsic model, so that no external sheaf identification is hidden. For a finite compact polyhedral set $P \subset \Omega \subset \mathbb{R}^N$, let

$$C(P) = E^{p,q}(\Omega)/N_P,$$

where N_P consists of forms whose tangential restrictions to all faces vanish. The underlying vector space consists of ambiently smooth restrictions. Its *intrinsic* topology is generated by the suprema $r_{\sigma,m}$ of tangential coefficient derivatives through order m on the compact faces σ, in fixed affine tangent bases. Using all compact subfaces gives the same model after the corresponding restrictions. This definition does not add arbitrary piecewise smooth forms that lack an ambient representative.

For a finite ordinary presentation s, set $P_j = t_{f_j}(V_j)$ and use these $C(P_j)$. We require the usual native nullity implication: zero tangential restriction on P_j pulls back to the zero ordinary section. Let $J_s \subset \prod_j C(P_j)$ consist of the tuples whose pullbacks agree on ordinary open overlaps and vanish off the fixed compact support $K_s \subset \bigcup_j \mathrm{Int}_{\mathrm{top}}(V_j, U)$. Give J_s the intrinsic subspace topology. Its gluing map is G_s. Let τ_t be the final locally convex topology for these G_s. The ambient preimage of J_s is exactly the frozen space H_s. Thus both topologies in this comparison are on the same native test space, with the same compact supports and overlap relations.

Proposition C.1.91 (The exact local-to-final comparison)**.** *For the matched stages above, $\tau_t \subseteq \tau_a$. Choose an increasing cofinal sequence of ambient seminorms p_m and put*

$$q_m([\eta]) = \inf_{\nu \in N_P} p_m(\eta + \nu).$$

If, on every coefficient space used in a generating family, for each m there are finitely many intrinsic seminorms r_l and a constant C_m with

$$q_m(a) \le C_m \max_{l \le s_m} r_l(a), \tag{C.1.38}$$

then $\tau_t = \tau_a$ for that generating family. Constants and derivative orders may depend on the presentation. No uniform estimate over all presentations is needed for this equality of final topologies.

Proof. Tangential restriction and differentiation are fixed linear combinations of ambient coefficient derivatives. They annihilate N_P and give continuous maps from ambient coefficients to $C(P)$ with its intrinsic topology; this is the exact direction of NAG-002476. Consequently $H_s \to J_s \to (E, \tau_t)$ is continuous. The final property of τ_a gives the asserted inclusion.

The q_m generate the quotient locally convex topology. Thus (C.1.38), together with the preceding direction, makes that quotient topology equal to the intrinsic one. The finite product quotient map π onto $\prod_j C(P_j)$ is open. Its restriction from $H_s = \pi^{-1}(J_s)$ onto J_s is still open: the image of $O \cap \pi^{-1}(J_s)$ is $\pi(O) \cap J_s$ for every open O. The continuous gluing map on H_s therefore descends continuously from J_s to (E, τ_a). Applying its final property to all J_s gives $\tau_a \subseteq \tau_t$. □

Proposition C.1.92 (Extension away from polyhedral junctions)**.** *Let $P \subset \Omega$ be a finite compact polyhedral complex. Choose finitely many maximal faces σ and compact subsets $K_\sigma \subset \operatorname{relint}(\sigma)$, and put $K = \bigcup_\sigma K_\sigma$. Let $C_K(P) \subset C(P)$ consist of the forms supported in K, and give its ambient preimage the coefficient subspace topology. There is a linear extension*

$$S : C_K(P) \longrightarrow E^{p,q}(\Omega), \qquad [Sa] = a,$$

with compact support in a fixed neighbourhood of K and, for every ambient compact L and every m, a bound

$$p_{L,m}(Sa) \le C_{L,m} \max_{\sigma} r_{\sigma,m}(a). \tag{C.1.39}$$

Hence the quotient topology on this support sector equals its intrinsic topology. The same conclusion holds for final spaces generated by compatible tuples of these sectors.

Proof. Write L_σ for the affine span of σ, choose a fixed affine projection π_σ onto it and complementary normal coordinates. The tangential coefficients of $a|_\sigma$ are smooth on $\operatorname{relint}(\sigma)$ and vanish off K_σ. Extending them by zero to L_σ is smooth, since K_σ stays away from the relative boundary. Extend the tangential covectors by π_σ^*.

The distance from K_σ to the other maximal faces and to the complement of Ω is positive. Choose a normal smooth cutoff ζ_σ, equal to one near zero, with sufficiently small fixed support, and form

$$S_\sigma a = \zeta_\sigma \, \pi_\sigma^*(a|_{L_\sigma}).$$

Its support lies in a fixed compact tube over K_σ; shrink the normal cutoff so that this tube misses every other maximal face and stays in Ω. Define $S = \sum_\sigma S_\sigma$. On P this is exactly a, including the lower-dimensional faces, where a vanishes. For a zero-dimensional face the same construction is the constant coefficient times a bump; inadmissible bidegrees are zero.

The product and chain rules express each derivative of order at most m using derivatives of $a|_{L_\sigma}$ of order at most m. All cutoff derivatives and all covector/projection matrices are fixed. Their finitely many constants give (C.1.39). The section S gives the reverse quotient bound on this sector; the forward bound was already proved. For compatible tuples, apply the sections componentwise. Their pullbacks have not changed, so all ordinary overlap and support constraints remain satisfied. The two continuous factorizations give the asserted final-topology comparison. □

The comparison uses the final topology on matched stages.

Finite algebra and length formulas

Proposition C.1.93 (Finite locally free intersection lengths)**.** *Let $(A, \mathfrak{m}, k)$ be a Noetherian local ring and let B be a finite locally free A-algebra of constant rank $n \geq 1$. Let $a_1, \dots, a_r$ be an A-regular sequence, and put $I = (a_1, \dots, a_r)$. Assume A/I is nonzero and has finite length. Then the sequence remains regular on B, and*

$$\sum_{\mathfrak{q}|\mathfrak{m}} [\kappa(\mathfrak{q}) : k] \operatorname{length}_{B_{\mathfrak{q}}}(B_{\mathfrak{q}}/IB_{\mathfrak{q}}) = n \operatorname{length}_A(A/I). \tag{C.1.40}$$

Every maximal ideal of B is included. Residue degrees are full degrees, including inseparable degrees; the quotient algebras are not reduced before taking lengths.

Proof. Since A is local, the finite locally free module B is free of rank n. Tensoring the injections defining regularity with this flat module, and then with its successive free quotients over $A/(a_1, \dots, a_i)$, proves regularity on B. The final quotient is nonzero since it is, as an A-module, $(A/I)^n$. In particular

$$\operatorname{length}_A(B/IB) = n \operatorname{length}_A(A/I). \tag{C.1.41}$$

The finite algebra $C = B/IB$ has finite A-length and hence finite length over itself, since its ideals are also A-submodules. Tag 00JB therefore makes it Artinian and identifies it with the product of its finitely many localizations $C_{\mathfrak{q}}$ at the maximal ideals of B above $\mathfrak{m}$. Each composition factor of $C_{\mathfrak{q}}$ as a $B_{\mathfrak{q}}$-module is $\kappa(\mathfrak{q})$. Viewed as an A-module this field is annihilated by $\mathfrak{m}$ and has length $[\kappa(\mathfrak{q}) : k]$, its vector-space dimension over k. Additivity of length along each composition series and then the finite product gives the left side of (C.1.40) as $\operatorname{length}_A(C)$. Equation (C.1.41) proves the result. □

Let L/K be a finite field extension and let $n = [L : K]$.

Corollary C.1.94 (Two scalar conventions for finite intersection algebras)**.** *If C is any finite-dimensional K-algebra, then*

$$\dim_L(C \otimes_K L) = \dim_K C, \qquad \dim_K(C \otimes_K L) = n \dim_K C.$$

For any finite-dimensional algebra D over a field H,

$$\dim_H D = \sum_j \operatorname{length}_{D_j}(D_j)\, [D_j/\mathfrak{m}_j : H], \qquad D = \prod_j D_j.$$

Proof. A K-basis of C becomes an L-basis after tensoring. Restriction of scalars then multiplies the dimension by n. For the last formula, use a composition series in each Artinian local factor; every simple factor is its residue field. This is the same length calculation as in Proposition C.1.93. □

Lemma C.1.95 (A finite algebra over a DVR)**.** *Let $(A, (\pi), k)$ be a DVR, and let B be a commutative finite free A-algebra of rank $n \geq 1$. If $b \in B$ is a non-zero-divisor, then $D = \det_A(m_b)$ is nonzero, B/bB has finite A-length, and*

$$\operatorname{ord}_A D = \operatorname{length}_A(B/bB) = \sum_{\mathfrak{q} \in \operatorname{Max} B} [\kappa(\mathfrak{q}) : k] \operatorname{length}_{B_{\mathfrak{q}}}(B_{\mathfrak{q}}/bB_{\mathfrak{q}}). \quad \text{(C.1.42)}$$

All maximal ideals of B lie above (π). Terms with b a unit are zero. Full residue-field degrees and unreduced quotient rings are used. The assertion does not require B to be a domain or reduced, or any residue extension to be separable.

Proof. Choose an A-basis of B, and let T be the matrix of m_b. Its kernel is zero. Over $\operatorname{Frac} A$, a nonzero kernel vector could be multiplied by one nonzero common denominator to give a nonzero kernel vector in A^n. Thus T is invertible over that field and $D \neq 0$.

Here is the required matrix reduction over A. Choose a nonzero entry of smallest order and move it to the upper-left corner by row and column permutations. Multiply its row by a unit to make this entry π^a. It divides every matrix entry. Elementary row operations therefore clear its column; elementary column operations then clear its row. These operations are invertible over A. The remaining square block has nonzero determinant, so induction reduces T to a diagonal matrix $\operatorname{diag}(\pi^{a_1}, \dots, \pi^{a_n})$ with $a_i \geq 0$. It follows that

$$B/bB \simeq \bigoplus_i A/(\pi^{a_i}), \qquad \operatorname{ord}_A D = \sum_i a_i.$$

The successive powers of π give a composition series of length a_i for $A/(\pi^{a_i})$. Length is additive in a short exact sequence: intersect a chain with the submodule and project it to the quotient for one inequality, and concatenate a submodule chain with inverse images of a quotient chain for the other. This proves the first equality and finite length.

A finite algebra is integral: on its finite generating module, the adjugate of the matrix of multiplication gives a monic equation for each element. If $\mathfrak{q}$

is maximal in B, integrality makes its contraction maximal in A. Indeed, if a field is integral over a subdomain, then that subdomain is a field: a monic equation for the inverse of a nonzero element, multiplied by a suitable power of the element, puts its inverse in the subdomain. Therefore $\mathfrak{q} \cap A = (\pi)$, and $\kappa(\mathfrak{q})/k$ is finite.

The ring $C = B/bB$ has finite length over itself, since every chain of its ideals is a chain of its A-submodules. Tag 00JB decomposes C into its finitely many Artinian local factors. In a $B_{\mathfrak{q}}$-composition series for $C_{\mathfrak{q}}$, every simple factor is $\kappa(\mathfrak{q})$. Its A-length is its full k-dimension: the action factors through k, so its A-submodules are precisely its k-subspaces. Adding the lengths of all factors gives the second equality in (C.1.42). If $C = 0$, the sum is zero and the same equality holds. Neither step removes nilpotents or counts embeddings instead of field dimensions. □

Common normal models and the supported projection interface

Let R be a complete DVR with uniformizer π, fraction field K, and residue field k. A model of a fixed normal integral proper K-variety X is a proper flat finite-type R-scheme $\mathcal{X}$ with a specified isomorphism $\mathcal{X}_K \simeq X$. Write $d = \dim X$; the applications of interest have $d \geq 2$. Maps of models must respect these actual identifications. The special fibre may be nonreduced. We impose no projectivity or normality on the initial models.

We use the affine construction of normalization: for an integral scheme with function field F, normalize $\operatorname{Spec} A$ by the integral closure $\overline{A} \subset F$ and glue. Integral closure commutes with localization. Indeed, if z is integral over $A[1/t]$, multiplying z by a sufficiently high power of t clears all coefficients of its monic equation and makes that multiple integral over A. The same argument works for an arbitrary multiplicative set. Consequently normalization is an isomorphism on any normal open. A normal integral scheme mapping birationally to an integral scheme factors uniquely through its normalization: each integral element in the common function field is regular in every normal local ring upstairs, and these sections glue.

Properness is preserved by composition, base change and closed immersion, by Stacks, Tag 01W3, Stacks, Tag 01W4 and Stacks, Tag 01W5. A morphism from a proper S-scheme to a separated S-scheme is proper by Stacks, Tag 01W6. Finite morphisms are proper: they are affine, separated and of finite type, and are universally closed by Stacks, Tag 01WM. These facts concern schemes and do not invoke formal-model domination.

Theorem C.1.96 (The normalized diagonal gives a common model)**.** *Let $\mathcal{X}_1, \dots, \mathcal{X}_m$ be a finite nonempty family of models of X. Each $\mathcal{X}_i$ is integral. In $P = \prod_{i=1}^m \mathcal{X}_i$ over R, let C be the scheme-theoretic closure of the generic diagonal $X \hookrightarrow P_K$. Then C is integral and proper flat of finite type over R, with $C_K = X$. Its normalization $\nu : \mathcal{M} \to C$ is finite, and $\mathcal{M}$ is a normal integral proper flat finite-type model of X. The maps*

$$p_i : \mathcal{M} \longrightarrow \mathcal{X}_i$$

are proper birational maps inducing the identity on X. The normalization map is finite; the maps p_i need not be finite.

The same construction provides a common normal refinement of any finite collection of normal models already mapping to a fixed model; the new maps commute with those maps to the fixed model.

Proof. On a nonempty affine open $\operatorname{Spec} A \subset \mathcal{X}_i$, flatness makes $A \to A[1/\pi]$ injective. Its target is the coordinate ring of a nonempty affine open of the integral variety X. It is nonempty because $A[1/\pi] = 0$ would make 1 into π-torsion. Thus A is a domain. Every nonempty open meets X, so X is dense and its irreducibility makes the entire model irreducible. The model is therefore integral, even though its special fibre need not be reduced.

The diagonal is closed in P_K because X is separated. Its scheme-theoretic closure is locally cut out by the kernel of the map to its generic function field $K(X)$ on the affines which meet the closure. That kernel is prime. These kernels are coherent since P is Noetherian, and they restrict to the diagonal ideal after inverting π. Hence C is integral with the stated generic fibre. It is a closed subscheme of the proper finite-type scheme P, hence proper and finite type. Each of its affine rings contains R and is a domain, so is torsion-free over R and is flat by Stacks, Tag 0539.

The complete DVR is Noetherian and complete local. By the exact parts (2) and (5) of Stacks, Tag 0335, every finite-type R-algebra is Nagata. Thus C is Nagata, and Stacks, Tag 035S makes its normalization finite. Its affine rings are integral closures inside $K(X)$, so $\mathcal{M}$ is integral and normal. It is proper and finite type, and is flat by the same torsion-free argument. Since $C_K = X$ is normal, normalization is unchanged on this open; hence $\mathcal{M}_K = X$. The projections p_i are proper and are the identity on the dense open X, which proves birationality.

For the refinement assertion apply the same construction to the models in question. Two resulting morphisms to the fixed separated model agree on the dense generic fibre. They agree everywhere: the inverse image of its diagonal is a closed subscheme containing that dense open, and an integral scheme has no nonzero ideal vanishing on a dense open. This proves commutation, not a least-model assertion. □

Theorem C.1.97 (Divisor and special-fibre pushforward from the common model)**.** *Let $p : \mathcal{M} \to \mathcal{T}$ be one of the maps of Theorem C.1.96, or any proper birational map from a normal model to a model of the same X, inducing the identity on X. For each codimension-one point v of $\mathcal{T}$, the prime divisors of $\mathcal{M}$ mapping onto $\overline{\{v\}}$ correspond exactly to the branches $\mathfrak{q}_j$ of the finite*

normalization of $\mathcal{O}_{\mathcal{T},v}$. Their local DVRs and residue fields are those branch DVRs and fields, embedded in the common function field.

Consequently, for every rational Cartier section σ of a line bundle on $\mathcal{T}$,

$$p_* \operatorname{div}(p^*\sigma) = \operatorname{div}(\sigma) \quad \text{as coherent divisor cycles on } \mathcal{T}. \tag{C.1.43}$$

For the special fibres, of pure dimension d,

$$p_*[\mathcal{M}_k]_d = [\mathcal{T}_k]_d, \qquad b_V = \sum_{E \mapsto V} [\kappa(E) : \kappa(V)] b_E. \tag{C.1.44}$$

Every other prime divisor upstairs is vertical and has image of codimension at least two, so contributes zero to these cycle pushforwards. If $\mathcal{T}$ is normal, the branch over each prime divisor is unique, its residue degree is one, and its DVR and b_V are unchanged. In that case p is an isomorphism over an open containing all codimension-one points of $\mathcal{T}$. These formulas apply both to $\nu : \mathcal{M} \to C$ and to every projection p_i in Theorem C.1.96.

Proof. The target normalization $n : \mathcal{T}^\nu \to \mathcal{T}$ is finite by the same Nagata argument. Normality of $\mathcal{M}$ gives a factorization $p = n \circ q$. The map q is proper by Stacks, Tag 01W6, applied over $\mathcal{T}$, since $\mathcal{T}^\nu$ is separated over $\mathcal{T}$ and p is proper. It is birational. Localization of the integral closure at v is exactly the finite algebra B in Lemma C.1.18. Its maximal ideals give the codimension-one points of $\mathcal{T}^\nu$ over v. The morphism q is an isomorphism near every such point by Stacks, Tag 0BFP(2): the target is Noetherian, the source is reduced, and the relevant normal height-one local ring is a DVR. This proves the precise branch correspondence, including equality of the embedded local rings. It does not assert that p is finite.

At each v, choose a local frame for the given line. The coefficient of the left side of (C.1.43) is the branch sum in (C.1.11), because the pulled-back rational function is the same element of the common function field. That sum is exactly the coherent coefficient downstairs. All other source divisors are contracted in codimension-one cycle pushforward. They cannot be horizontal because the generic-fibre morphism is an isomorphism.

The special fibres are pure d-dimensional by Stacks, Tag 00QK, applied to the integral affine coordinate algebras containing R. Their generic multiplicities are the lengths of the local quotients by π. Apply (C.1.12) with $t = \pi$ at each V to obtain (C.1.44). A contracted special component has image dimension less than d: its image is contained in the special fibre and

contains none of its generic component points. Thus its cycle pushforward is zero. Normality of $\mathcal{T}$ reduces its finite local normalization to its own DVR, giving the final assertions directly from Stacks, Tag 0BFP. □

A *Cartier datum on a prescribed closed support* Z consists of an invertible sheaf $\mathcal{L}$ on an integral scheme and a nonzero rational section σ which is a regular generating section off Z. Equivalently its Cartier divisor D is zero off Z. A *signed presentation on* Z is a pair of effective Cartier divisors A, B with $D = A - B$ as Cartier divisors and $|A| \cup |B| \subset Z$. Equivalently it consists of two line bundles with nonzero global sections, an actual identification of their ratio with $(\mathcal{L}, \sigma)$, and the same support condition. This is stronger than equality of ordinary Chow classes.

Call a proper birational map of models *generic-identity* when it is the identity on the specified X. The next result constructs presentations; it does not assume the pending supported-calculus operations or prove descent of those operations on Chow groups.

Theorem C.1.98 (Exact generic criterion for acquiring presentations)**.** *Let $\mathcal{M}$ be a normal model of X, and let $(\mathcal{L}_i, \sigma_i; Z_i)$ be finitely many Cartier data on it. There exists a normal model $\mathcal{M}'$ and a proper generic-identity map $q : \mathcal{M}' \to \mathcal{M}$ such that every pulled-back datum admits a signed presentation on $q^{-1}Z_i$ if and only if every generic Cartier datum admits a signed presentation on $Z_i \cap X$. When these equivalent conditions hold, q can be constructed by finitely many blowups of nonzero coherent ideals, followed by finite normalization. It is an isomorphism off $\bigcup_i Z_i$. Each individual presentation retains its own prescribed inverse-image support.*

In particular the condition holds if signed presentations are already supplied on another model and pulled back to $\mathcal{M}$. It also holds for every collection of rational Cartier data when X is locally factorial. No factoriality of $\mathcal{M}$ or $\mathcal{M}'$ follows or is required.

Proof. Necessity follows by restriction to X: the map is the identity there, and each effective Cartier factor remains effective Cartier because its nonzero section stays nonzero on the integral generic fibre.

For sufficiency first consider one datum, with divisor D and a generic presentation $D|_X = A_K - B_K$ on $Z \cap X$. Let $\mathcal{I}_+$ and $\mathcal{I}_-$ be the ideals of the scheme-theoretic closures of A_K and B_K in $\mathcal{M}$. They are coherent nonzero ideals, are invertible on X, and are the unit ideal off Z. For example,

on $\operatorname{Spec} A \subset \mathcal{M}$ the closure ideal is the contraction of its ideal in $A[1/\pi]$; Noetherianity gives finite generation and localization gives gluing.

Blow up $\mathcal{I}_+$ and then the extended ideal $\mathcal{I}_-$. These blowups are projective and proper by Stacks, Tag 02NS and Stacks, Tag 01WC. Their affine charts for an ideal $I = (a_1, \dots, a_s)$ are $A[I/a_j] \subset \operatorname{Frac}(A)$, for nonzero a_j. On such a chart the extended ideal is (a_j), an invertible ideal generated by a non-zero-divisor. Thus the blowups are integral, make the indicated ideals invertible, and are isomorphisms wherever those ideals were invertible. In particular they leave X and $\mathcal{M} \setminus Z$ unchanged. Write $u : Y \to \mathcal{M}$ for the composite, and let A_0, B_0 be the effective Cartier divisors of the two extended ideals. Their supports lie in $u^{-1}Z$, and their generic restrictions are A_K, B_K.

The Cartier divisor

$$V = u^*D - (A_0 - B_0)$$

is zero on the generic fibre and off $u^{-1}Z$. As subsheaves of the constant sheaf of rational functions on the integral Y, form the coherent nonzero ideal

$$\mathcal{J} = \mathcal{O}_Y(-V) \cap \mathcal{O}_Y.$$

Coherence follows locally by clearing one denominator and intersecting two finitely generated modules over a Noetherian ring. It is the unit ideal on X and off $u^{-1}Z$. Blow up $\mathcal{J}$, with map $v : Y' \to Y$, and write $\mathcal{J}\mathcal{O}_{Y'} = \mathcal{O}_{Y'}(-E)$. The inclusion $\mathcal{J} \subset \mathcal{O}_Y(-V)$ gives a nonzero map between invertible sheaves

$$\mathcal{O}_{Y'}(-E) \longrightarrow \mathcal{O}_{Y'}(-v^*V).$$

Its section has an effective Cartier divisor F satisfying $E - v^*V = F$. This can also be checked in a local frame: if $\mathcal{O}_Y(-V) = f\mathcal{O}_Y$ and $\mathcal{J}\mathcal{O}_{Y'} = (h)$, then h/f is regular and $F = \operatorname{div}(h/f)$. Both E and F vanish off $(uv)^{-1}Z$. Thus

$$(uv)^*D = (v^*A_0 + E) - (v^*B_0 + F)$$

is the required signed presentation. This third blowup leaves the generic fibre unchanged because $\mathcal{J}|_X = \mathcal{O}_X$.

For finitely many data repeat these steps, pulling earlier effective Cartier factors along subsequent dominant maps. Their sections remain nonzero, and their supports remain inside the respective inverse images of Z_i. All stages are integral proper finite-type schemes over R, with generic fibre X, and are flat by Stacks, Tag 0539. Normalize the final stage. Its normalization is finite by Theorem C.1.96's Nagata argument, is the identity over normal

X, and preserves all effective Cartier factors under its dominant pullback. Outside $\bigcup_i Z_i$ the previous stages were the original normal $\mathcal{M}$, so normalization changes nothing there either. This gives q and all the asserted support properties.

An existing presentation pulls back to any common integral model, with its actual line and section identities. No factoriality is needed for this step. Finally on a locally factorial integral Noetherian X, decompose the finite Weil cycle of a Cartier divisor into its positive and negative parts. Local unique factorization makes both parts effective Cartier: their local equations differ by units on overlaps. Their difference is the original Cartier divisor, and their supports lie in its support. This proves the last sufficient condition, independently of any pending intersection claim. □

Proposition C.1.99 (A principal divisor with no presentation on its support)**.** *Over any field K, let*

$$X = \{ad - bc = 0\} \subset \mathbf{P}^4_K, \qquad [a : b : c : d : t], \qquad o = [0 : 0 : 0 : 0 : 1].$$

This is a normal integral proper threefold. Put

$$P_0 = \{a = b = 0\}, \qquad P_1 = \{c = d = 0\}, \qquad Z = P_0 \cup P_1.$$

The rational section $f = a/c$ of $\mathcal{O}_X$ has Cartier divisor with Weil cycle $P_0 - P_1$ and is a regular unit off Z. It has no signed presentation on Z, even in a neighbourhood of o. Hence no proper generic-identity modification of any normal DVR model carrying this datum can acquire such a presentation on the inverse image of the prescribed support. In particular this obstruction applies to the constant equation $ad - bc = 0$ over a complete DVR.

Proof. On the chart $t = 1$ the coordinate algebra is $A = K[a, b, c, d]/(ad - bc)$. It identifies with the weight-zero subring of $B = K[u_0, u_1, v_0, v_1]$, where u_0, u_1 have weight 1, v_0, v_1 have weight -1, and

$$a = u_0 v_0, \quad b = u_0 v_1, \quad c = u_1 v_0, \quad d = u_1 v_1.$$

Every weight-zero monomial is a product of these four generators. Their only relation is the displayed determinant: after inverting a one solves $d = bc/a$, and a, b, c are algebraically independent under this substitution. The determinant polynomial is prime by its primitive linear form in d and unique factorization, so this localization is injective.

The polynomial ring B is normal by Stacks, Tag 0BC1 and Stacks, Tag 0AFV. If $z \in \operatorname{Frac}(A)$ is integral over A, it is integral over B, so belongs to B. Under the weight substitution with an independent Laurent variable, z is fixed because it is a fraction of weight-zero elements. Comparing Laurent powers shows that its polynomial expression has weight zero, hence lies in A. Thus A is normal. Its localizations are normal by Stacks, Tag 00GY. The remaining projective charts, where one of a, b, c, d is nonzero, solve for a variable and are polynomial three-dimensional charts. This proves normality and integrality of X; projectivity gives properness.

The hyperplane sections satisfy $\operatorname{div}(a) = P_0 + Q$ and $\operatorname{div}(c) = P_1 + Q$, where $Q = \{a = c = 0\}$. Each coefficient is one, as is seen by solving the determinant equation at the corresponding generic point. Their difference is $P_0 - P_1$. Off Z, the two rows are nonzero; where a/c is not directly a unit, it equals b/d, which is a unit there. Thus the support is exactly as claimed. The presentation using the two hyperplane sections adds Q, which is not contained in Z, and is not an allowed presentation.

We prove the obstruction without a class-group computation. Over the affine chart $t = 1$, consider the incidence variety

$$Y = \{((a, b, c, d), [u_0 : u_1]) : au_1 = cu_0,\ bu_1 = du_0\} \longrightarrow \operatorname{Spec} A.$$

It is closed in $\operatorname{Spec} A \times \mathbf{P}^1$ and hence proper over $\operatorname{Spec} A$. Its two charts are

$$(a, b, z), \quad c = za,\ d = zb; \qquad (c, d, w), \quad a = wc,\ b = wd.$$

They are affine three-spaces. The map is an isomorphism off the origin, since a nonzero rank-one matrix determines its column line. Its exceptional fibre is the zero section $C \simeq \mathbf{P}^1$, which has codimension two. In particular there is no exceptional prime divisor. The strict transforms F_0, F_1 of P_0, P_1 are fibres of $Y \to \mathbf{P}^1$, over $[0 : 1]$ and $[1 : 0]$.

Suppose an effective Cartier divisor H near o is supported in $P_0 \cup P_1$, with multiplicities $m, n \geq 0$. Shrink to an affine neighbourhood of o on which H is principal. Its pullback to Y over that neighbourhood has divisor $mF_0 + nF_1$: off C this follows from the isomorphism, and no prime divisor is contained in C. Equality of these Cartier divisors follows on the local UFD charts. The associated line bundle restricts to the trivial line on C, because it was pulled back from a principal divisor. But the restriction of $\mathcal{O}_Y(mF_0 + nF_1)$ is $\mathcal{O}_{\mathbf{P}^1}(m + n)$. In the standard two affine trivializations its transition function is z^{m+n}. A trivialization of the line on each affine chart can change this

only by invertible polynomials, which are constants. Thus triviality forces $m + n = 0$, and hence $m = n = 0$. Both effective factors of a hypothetical signed presentation would therefore have zero coefficients at P_0, P_1 near o, contradicting the coefficients $1, -1$ of $\operatorname{div}(f)$.

The same weight-zero argument over the UFD R shows that the constant affine cone is normal over R; the other charts are polynomial rings over R. This gives a normal proper model, flat by torsion-freeness. The ratio a/c is a unit outside the two corresponding closed row planes, so defines the prescribed model datum. Any proposed generic-identity presentation would restrict to the impossible presentation on X, by Theorem C.1.98. □

Let K be complete and nontrivially discretely valued, with valuation ring R, residue field k, uniformizer π, and the fixed number $\lambda = -\log|\pi| > 0$. Let X be an integral proper K-variety of dimension $d \geq 2$. A model in this note is proper, flat, integral and normal over R, of finite type, with generic fibre identified with X. Retain explicitly the ordinary DVR local rings at all height-one points used below. Its special components have dimension d.

For a proper model $\mathcal{T}$ and closed support S, suppose there are groups $C_r(\mathcal{T}; S)$ of r-dimensional cycles modulo equivalences *retaining that support*. Suppose model pseudo-divisors D act by operators $D\cdot : C_r(\mathcal{T}; S) \to C_{r-1}(\mathcal{T}; S \cap |D|)$. For the objects used, require the following four properties:

1. The operators are additive and commute; the first operation on an integral model is its Cartier divisor cycle when that is defined.
2. Proper pushforward retains the prescribed supports and satisfies $p_*(p^*D\cdot \alpha) = D \cdot p_*\alpha$.
3. On vertical cycles, D acts by the ordinary first Chern operation of its model line, even if its chosen section restricts identically to zero. Moreover $\operatorname{div}(\pi) \cdot [\mathcal{T}] = \sum_V b_V[V]$.
4. Vertical zero-cycles have degree over k, with actual local lengths and full residue-field degrees, and this degree is preserved by proper pushforward.

These are interface hypotheses. In particular, the second property is the supported algebraic projection formula, not F6's analytic theorem.

For a special component V, write b_V for the order of π at its ordinary height-one DVR, hence for its full fibre multiplicity. For the complementary d model lines, the model-measure mass in the following formula is the sum

of the weighted mixed component degrees divided by the complementary product of root exponents. The closing blowup sentence recalls a separate historical illustration.

Proposition C.1.100 (Common domination and the uniformizer test)**.** *Assume the four interface properties for all cycles and operations below. Let $p : \mathcal{Y} \to \mathcal{X}$ be a proper common-generic-fibre domination with $p_*[\mathcal{Y}] = [\mathcal{X}]$. Let D_i be model pseudo-divisors with lines extending $L_i^{\otimes e_i}$ and specified sections $s_i^{\otimes e_i}$, $0 \le i \le d$. Suppose only that*

$$\bigcap_{i=0}^{d} |D_i| \cap X = \varnothing. \tag{C.1.45}$$

No pairwise or intermediate proper intersection is required. With $E_0 = \prod_{i=0}^{d} e_i$, define the supported model value by

$$J_{\mathcal{X}}(D_0, \dots, D_d) = \frac{\lambda}{E_0} \deg_k(D_0 \cdots D_d \cdot [\mathcal{X}]).$$

Then it is symmetric and

$$J_{\mathcal{Y}}(p^*D_0, \dots, p^*D_d) = J_{\mathcal{X}}(D_0, \dots, D_d). \tag{C.1.46}$$

Hence two model presentations have equal values if their divisor data pull back compatibly to a common domination satisfying the same properties. This requires the actual pulled-back lines, sections and supports, not just their generic line-bundle classes.

Replacing s_i by πs_i at a fixed metric gives

$$\Delta J = +\frac{\lambda}{\prod_{j \ne i} e_j} \sum_V b_V \deg_{(\mathcal{L}_j|_V)_{j \ne i}, k}(V). \tag{C.1.47}$$

This equals $+\lambda$ times the corresponding model-measure mass. It is $+\lambda$ times the generic degree only when the relevant specialization-of-degree identity has also been established.

Proof. The support after all $d+1$ operations lies in $\bigcap_i |D_i|$. By (C.1.45) this is vertical, so the degree in the definition is available, even when the total support has positive dimension. The operations produce a zero-dimensional class there. Their commutativity proves symmetry. Iterating the second property gives

$$p_*\big(p^*D_0 \cdots p^*D_d \cdot [\mathcal{Y}]\big) = D_0 \cdots D_d \cdot p_*[\mathcal{Y}] = D_0 \cdots D_d \cdot [\mathcal{X}].$$

The retained vertical degree and identical root exponents prove (C.1.46). Applying this equality to each side of a common domination proves the next assertion. This proof does not manufacture the supported operators or their projection formula.

The model divisor changes by $e_i \operatorname{div}(\pi)$ when s_i is multiplied by π. Additivity, commutativity and the third property turn the change in the final class into

$$e_i \sum_V b_V \left(\prod_{j \neq i} c_1(\mathcal{L}_j|_V) \right) [V].$$

Taking its degree and dividing by E_0/λ proves (C.1.47). The generic support condition is unchanged; the model support is enlarged by the special fibre when needed. On a model with only the standard projective component and degrees m_j, this gives $+\lambda \prod_{j \neq i} m_j$, as required by the point normalization. The blowup computation gives the same mass for pulled-back data, so it is also a common-model regression test. □

Intersections on prescribed supports over a DVR

Let R be a DVR, $S = \operatorname{Spec} R$, η its generic point, and k its residue field. For analytic assertions assume that R is the valuation ring of a complete nontrivially discretely valued field K with its fixed absolute value. Use the dimension function $\delta(\eta) = 1$, $\delta(s) = 0$ at the closed point. A DVR is Noetherian and Cohen–Macaulay: its uniformizer is a regular sequence of length one, and its only other localization is its fraction field. Thus Stacks, Tag 00NM gives the universally catenary hypothesis of Stacks, Tag 02QL. On a finite-type S-scheme, dimensions below are δ-dimensions. In particular, a horizontal integral model of relative dimension d has dimension $d + 1$, and a vertical integral k-scheme has its usual dimension.

For a closed subset T of a finite-type S-scheme $\mathcal{X}$ set

$$C_r(\mathcal{X}; T) = \mathrm{CH}_r(T_{\mathrm{red}}).$$

Rational equivalences use integral subschemes *inside* T. This group is not defined as the image in $\mathrm{CH}_r(\mathcal{X})$. Reduction identifies Chow groups: integral subschemes, their rational functions, and their divisor relations are unchanged. This observation does not replace the fundamental cycle of a nonreduced scheme by that of its reduction; its generic lengths remain coefficients of the cycle. We freely use a scheme-theoretic intersection to construct a cycle and the canonical reduction identification to place its class in the group on its closed support.

Proper pushforward uses the full function-field degree on an integral cycle whose image has the same dimension, and zero when the image has smaller dimension (Stacks, Tag 02R4). It descends to Chow groups by Stacks, Tag 02S2. Its composition law follows on prime cycles from the tower law for field degrees; a dimension decrease remains a decrease under further pushforward. All field degrees include their inseparable parts. If T is vertical and proper over R, then T_{red} is proper over k. Its zero-cycle degree is pushforward to $\operatorname{Spec} k$ (Stacks, Tag 0AZ1); on closed points it is $\sum n_x[\kappa(x) : k]$ (Stacks, Tag 0AZ2). Hence proper pushforward preserves this degree while retaining the prescribed vertical support.

For an invertible sheaf $\mathcal{L}$ and a global section s on $\mathcal{X}$, let $D = Z(s)$. A section here is allowed to be zero or a zero-divisor; “global section” does not mean a regular section in the non-zero-divisor sense. Apply the Gysin

construction of Stacks, Tag 02T8 on T_{red} and then identify its target with the reduced support. Write the resulting operation as

$$G_{(\mathcal{L},s),T} : C_r(\mathcal{X}; T) \longrightarrow C_{r-1}(\mathcal{X}; T \cap |D|).$$

Theorem C.1.101 (Supported Gysin operations on Chow groups)**.** *The maps $G_{(\mathcal{L},s),T}$ are well-defined on Chow groups and satisfy all the following assertions.*

1. *For an integral $W \subset T$, if $s|_W$ is nonzero, the result is the divisor cycle of $s|_W$, with its actual local lengths. If $s|_W = 0$, it is the image of $c_1(\mathcal{L}|_W) \cap [W]$ in the stated target, not an instruction to discard W.*
2. *Let $p : \mathcal{Y} \to \mathcal{X}$ be proper, let $T' \subset \mathcal{Y}$ and $T \subset \mathcal{X}$ be closed with $p(T') \subset T$, and pull back the actual line and section. Then*

$$p_* G_{(p^*\mathcal{L},p^*s),T'}(\alpha) = G_{(\mathcal{L},s),T}(p_*\alpha) \quad \text{in } C_{r-1}(\mathcal{X}; T \cap |D|). \tag{C.1.48}$$

   This includes naturality under enlargement of the prescribed support.
3. *Two such operations commute in the group on $T \cap |Z(s)| \cap |Z(t)|$. No proper-intersection hypothesis is needed.*
4. *For $(\mathcal{M}, t)$ a second pair, set $B = |Z(s)| \cup |Z(t)|$. After pushing the three targets into $T \cap B$,*

$$G_{(\mathcal{L}\otimes\mathcal{M},s\otimes t),T} = G_{(\mathcal{L},s),T} + G_{(\mathcal{M},t),T}. \tag{C.1.49}$$

   After pushing into T, the operation is $c_1(\mathcal{L}|_T) \cap -$.

Proof. The definition gives (1), and Stacks, Tag 02TO proves descent through rational equivalence. Apply Stacks, Tag 02TA to the proper map $T'_{\mathrm{red}} \to T_{\mathrm{red}}$ and the restricted line and section. Its target is the zero scheme of the restricted section on T, so its pushforward identity is exactly (C.1.48) after reduction. Applying this also to closed immersions proves the support-enlargement statement. It does not pass through the image of $\mathrm{CH}(T)$ in the ambient Chow group.

For clarity, the proper-pushforward calculation retains the factor $[K(W') : K(p(W'))]$ when dimensions agree. If an integral W' is contracted, choose a rational section of the relevant line on its integral image W. Its pullback divisor is supported over a proper closed subset of W. Every component then

has image dimension less than $\dim_\delta W' - 1$, and its cycle pushforward is zero. This also handles the contained-component Chern term by its divisor representative. Thus dimension-decreasing images do not create an unrecorded coefficient.

Apply Stacks, Tag 0B73 on T_{red}. The rational equivalence in its proof lies on the intersection of both zero schemes; in particular its target is precisely the support in (3). Reduction and the naturality just proved identify the successive targets used here with those of that lemma.

To prove (4), work on an integral cycle $[W]$. If neither restricted section is zero, divisors of their tensor product add as cycles. Locally this is $\mathrm{ord}(fg) = \mathrm{ord}(f) + \mathrm{ord}(g)$; at a one-dimensional local domain one can see the length equality from $0 \to A/(f) \xrightarrow{g} A/(fg) \to A/(g) \to 0$. If one or both sections vanish identically on W, then $W \subset B$. The product contributes $c_1((\mathcal{L} \otimes \mathcal{M})|_W)[W]$; each nonzero restricted section represents its own first Chern class on W. Additivity of that class, Stacks, Tag 02SP, proves equality already in $\mathrm{CH}(W)$, and hence in the required target. Linearity proves (C.1.49). Finally Stacks, Tag 02T9 identifies the push into T with the first Chern operation. □

A *signed presentation on Z* of an invertible sheaf $\mathcal{L}$ with a nonzero rational section σ on an integral $\mathcal{X}$ consists of two pairs $(\mathcal{L}^+, s^+)$, $(\mathcal{L}^-, s^-)$ with nonzero global sections, an isomorphism $\mathcal{L} \simeq \mathcal{L}^+ \otimes (\mathcal{L}^-)^{-1}$ taking σ to s^+/s^-, and $|Z(s^+)| \cup |Z(s^-)| \subset Z$. For every T, define

$$I_{(\mathcal{L},\sigma;Z),T} = G_{(\mathcal{L}^+,s^+),T} - G_{(\mathcal{L}^-,s^-),T} : C_r(\mathcal{X};T) \longrightarrow C_{r-1}(\mathcal{X};T \cap Z), \quad \text{(C.1.50)}$$

using the closed-immersion pushforwards to this common target.

Proposition C.1.102 (Independence with no extra support)**.** *The operation* (C.1.50) *is independent of the signed presentation on the* same prescribed *Z. It is additive under tensor product with union of supports, commutes with other such operations on their intersection of supports, and satisfies* (C.1.48) *for pulled-back presentations. These assertions remain meaningful when a pulled-back factor section vanishes identically. Its image in $C_{r-1}(\mathcal{X};T)$ is the first Chern operation of $\mathcal{L}|_T$.*

Every rational Cartier section on a locally factorial integral Noetherian $\mathcal{X}$ has a signed presentation on exactly the support of its divisor. Thus the result applies, in particular, to arbitrary rational Cartier sections on locally factorial proper DVR models. On other integral models the existence of the stated presentation is a hypothesis, not a conclusion obtained by enlarging Z.

Proof. Suppose $(A,a)/(B,b)$ and $(A',a')/(B',b')$ present the same $(\mathcal{L},\sigma)$. The specified line identifications give $A\otimes B'\simeq A'\otimes B$, and the global sections $a\otimes b'$ and $a'\otimes b$ agree: they agree at the generic point, and an invertible sheaf on an integral scheme has no section supported off that point. Equation (C.1.49), with all targets pushed to $T\cap Z$, gives $G_a+G_{b'}=G_{a'}+G_b$. Subtraction proves independence. The equality of these global sections persists under every pullback, even if both pull back to zero. Consequently the same calculation proves independence for pulled-back presentations on arbitrary source schemes.

Tensor additivity follows from (C.1.49). Proper compatibility follows by subtracting the two identities (C.1.48). For commutation, expand into four compositions and use Theorem C.1.101(3), then push to the common intersection of the prescribed supports. Naturality for the intermediate closed immersions justifies this last step. The Chern assertion follows by subtraction and Stacks, Tag 02SP.

For existence in the locally factorial case, write the Cartier divisor as the finite Weil sum $D=\sum n_P P$. Let $D^+=\sum \max(n_P,0)P$ and $D^-=\sum \max(-n_P,0)P$. At each point, unique factorization makes each of these effective sums principal. These local equations glue as effective Cartier divisors: on an overlap their quotient has zero exponent at every prime factor of each local UFD, and so is a unit. Their canonical sections of $\mathcal{O}(D^+)$ and $\mathcal{O}(D^-)$ have union of zero supports $|D|$. The usual local identification of $\mathcal{O}(D)$ with $\mathcal{L}$ carries their ratio to σ. These are the required data. This argument does not replace a prescribed support by the support of an auxiliary ample divisor. □

Let R be a complete DVR, with uniformizer π, fraction field K, and residue field k. Equip K with a nontrivial non-Archimedean absolute value whose valuation ring is R. Put $\lambda=-\log|\pi|>0$. Let X be a normal integral proper K-variety of dimension $d\geq 2$. A model is a proper flat finite-type R-scheme with a specified identification of its generic fibre with X. Maps called generic-identity respect these identifications. Such models are integral by Theorem C.1.96; their special fibres may be nonreduced.

A root model presentation of a metric h on a line bundle L is $(\mathcal{T},\mathcal{L},e,\alpha)$, with $e\geq 1$ and $\alpha:\mathcal{L}|_X\xrightarrow{\sim}L^{\otimes e}$ specified. If s is a nonzero rational section of L, its model section is $\sigma=\alpha^{-1}(s^{\otimes e})$. The identification α is part of the datum. An abstract isomorphism of the underlying line bundles does not replace it.

Fix line bundles L_i, root algebraic model metrics h_i, nonzero rational sections s_i, and prescribed closed subsets $S_i \subset X$, for $0 \le i \le d$. Require that s_i is a regular generator off S_i and

$$\bigcap_{i=0}^{d} S_i = \varnothing. \tag{C.1.51}$$

A computing datum consists of an integral model $\mathcal{T}$, extensions $\mathcal{A}_i|_X \simeq L_i^{\otimes e_i}$ inducing h_i, and signed presentations of their model sections on closed sets $Z_i \subset \mathcal{T}$ such that $Z_i \cap X = S_i$. Every factor zero support must lie in its own Z_i. A support is not replaced by the image of its Chow group in the Chow group of $\mathcal{T}$.

Use the dimension function of the supported-calculus packet: $\delta(\operatorname{Spec} K) = 1$ and $\delta(\operatorname{Spec} k) = 0$. Thus $[\mathcal{T}]$ has dimension $d+1$. For a closed support Z put $C_r(\mathcal{T}; Z) = \mathrm{CH}_r(Z_{\mathrm{red}})$. Write I_i for the signed operation supplied by Theorem C.1.101 and Proposition C.1.102. Then

$$\beta_{\mathcal{T}} = I_0 \cdots I_d[\mathcal{T}] \in \mathrm{CH}_0(T_{\mathrm{red}}), \qquad T = \bigcap_i Z_i.$$

By (C.1.51), T_{red} is vertical and proper over k, even if it has positive dimension. Define

$$J_{\mathcal{T}} = \frac{\lambda}{\prod_{i=0}^{d} e_i} \deg_k(\beta_{\mathcal{T}}). \tag{C.1.52}$$

Degree is proper pushforward to $\operatorname{Spec} k$: a closed point contributes its full residue degree, including its inseparable part. The original coherent and divisor lengths stay in the cycle coefficients. There is no extra factorial and no normalization of λ to one.

Lemma C.1.103 (The supported comparison rules needed here)**.** *For computing data, the following changes leave* (C.1.52) *unchanged:*

1. *pullback of the actual data along a proper generic-identity map of integral models, using the inverse-image supports;*
2. *replacement of* $(\mathcal{A}_i, \sigma_i, e_i)$ *by* $(\mathcal{A}_i^{\otimes m_i}, \sigma_i^{\otimes m_i}, m_i e_i)$*, with* $m_i \ge 1$*;*
3. *replacement of signed presentations on one common support;*
4. *enlargement of model supports, provided their total generic intersection is still empty.*

In (1), before degree one has equality in $\mathrm{CH}_0(T_{\mathrm{red}})$ *under the proper map of the final supports. The source need not be normal.*

Proof. Let $q : \mathcal{Y} \to \mathcal{T}$ be as in (1). Repeated supported projection gives

$$q_*\big(I_{q^*0} \cdots I_{q^*d}[\mathcal{Y}]\big) = I_0 \cdots I_d q_*[\mathcal{Y}] = I_0 \cdots I_d[\mathcal{T}].$$

The last equality uses the actual function-field degree one. At every step the target is the prescribed intersection, and the final map is between proper vertical supports. Its zero-cycle pushforward preserves degree over k, including residue degrees. This proves (1).

Signed tensor additivity on the same support gives $I_{\sigma_i^{m_i}} = m_i I_{\sigma_i}$. The factors $\prod_i m_i$ in the numerator and denominator of (C.1.52) cancel, proving (2).

For (3), present one datum as $(A, a)/(B, b)$ and $(A', a')/(B', b')$. The actual line identities and equality of their rational ratios give the global equality $a \otimes b' = a' \otimes b$ on the integral model. Supported Gysin additivity therefore gives

$$G_a + G_{b'} = G_{a'} + G_b$$

in the group on the common prescribed support, and subtraction identifies the signed operations. Naturality for each intermediate closed support permits their iteration with all other operations. The comparison precedes degree; it is not merely equality of ambient Chow classes. Finally the same naturality proves (4). The larger final support is still proper over k, so its inclusion also preserves degree. □

Proposition C.1.104 (A support-sensitive counterexample in every dimension)**.** *Let* $\mathcal{X} = \mathbf{P}^d_R$*,* $d \geq 2$*,* $V = \mathcal{X}_k$*, and take* $(\mathcal{L}, s) = (\mathcal{O}(1), \pi Z_0)$*. With prescribed support* $T = V$*,*

$$G_{(\mathcal{L},s),V}[V] = c_1(\mathcal{O}_V(1)) \cap [V] \neq 0 \quad \text{in } \mathrm{CH}_{d-1}(V).$$

After another $d-1$ *hyperplane operations its degree is one. Thus an operation that discards a component when its restricted section is zero fails the required vertical Chern compatibility.*

More strongly, let $D = Z(\pi Z_0)$*, with closed support* $V \cup H_0$*, where* $H_0 = \{Z_0 = 0\}$*. The same nonzero class maps to zero in* $\mathrm{CH}_{d-1}(D)$*. Knowing only its image in the ambient zero scheme therefore does not determine the operation on the original support* V*.*

Proof. The restricted section is identically zero on V, so the definition gives the first Chern class. Its representative $V \cap H_0$ followed by $d-1$ other coordinate hyperplanes is one rational point with local quotient length one. Successive coordinate quotients compute its degree as one, proving nonvanishing on V. Inside D, the horizontal integral $H_0 \simeq \mathbf{P}_R^{d-1}$ is an allowed scheme for rational equivalence. Its rational function π has divisor $V \cap H_0$ with coefficient one. The image of our class is consequently zero in $\mathrm{CH}_{d-1}(D)$. Inside V that horizontal rational-equivalence relation is unavailable. This is why the operation must be constructed on each T, not recovered from an ambient image after the first intersection. □

For a proper d-dimensional integral k-scheme W and invertible sheaves $M_1, \dots, M_d$, use the mixed degree

$$\delta(W; M_1, \dots, M_d) = \deg_k\big(c_1(M_1) \cdots c_1(M_d) \cap [W]\big).$$

By Stacks, Tag 0BFI this agrees with the usual numerical mixed intersection, with no extra factorial. No ampleness or nefness is required in this mixed formula.

Theorem C.1.105 (Projection for algebraic component degrees)**.** *Let $q : W \to V$ be a proper morphism of proper integral k-schemes, with $\dim W = d$ and $\dim V \le d$, and let $M_1, \dots, M_d$ be invertible sheaves on V. If $\dim q(W) < d$, then*

$$\delta(W; q^*M_1, \dots, q^*M_d) = 0.$$

If q is dominant and $\dim V = d$, then

$$\delta(W; q^*M_1, \dots, q^*M_d) = [k(W) : k(V)]\delta(V; M_1, \dots, M_d). \tag{C.1.53}$$

Proof. Use the global pairs $(M_i, 0)$ on V. Their Gysin operations are exactly $c_1(M_i)$, since their zero schemes are all of V. Iterating (C.1.48) gives

$$q_*\big(c_1(q^*M_1) \cdots c_1(q^*M_d) \cap [W]\big) = c_1(M_1) \cdots c_1(M_d) \cap q_*[W].$$

In the contracted case $q_*[W] = 0$. In the dominant equal-dimensional case it is $[k(W) : k(V)][V]$, with the full field degree. Proper pushforward preserves degree over k, proving both formulas. □

Model metrics and intersections on prescribed supports

Use the complete DVR, model identifications and prescribed supports in Lemma C.1.103, with empty total generic intersection (C.1.51) and supported value (C.1.52).

For an analytic point x, use its valued residue field F_x and valuation ring F_x°. The morphism $\operatorname{Spec} F_x \to X$ has a unique extension to $\operatorname{Spec} F_x^\circ \to \mathcal{T}$ by Stacks, Tag 0BX5. A frame of the pulled-back model line is assigned norm one. For $v \in L(x)$, if $v^{\otimes e} = a\,\alpha(\ell)$ in such a frame, the root norm is $|a|^{1/e}$. A change of frame is a unit of F_x°, of absolute value one. This is the pointwise bounded-frame convention for the supplied algebraic model metrics. No new theorem about existence of arbitrary formal models or continuity of general metrics is assumed.

On a normal model $\mathcal{M}$, the local ring at the generic point of a special component E is an ordinary algebraic DVR. Set $b_E = \operatorname{ord}_E(\pi) > 0$. The corresponding analytic point ξ_E has generic scheme support and

$$|f(\xi_E)| = |\pi|^{\operatorname{ord}_E(f)/b_E} \quad (f \in K(X)^\times).$$

Here the normalized valuation extends $|\cdot|$ on K, and NAG-001707 realizes its restriction on affine K-algebras as an analytic point. The factor b_E is the multiplicity in the full scheme special fibre $\operatorname{div}(\pi)$, not the coefficient of its reduction.

The height-one assertion uses Lemma C.1.17; the minimal primes over the nonzero uniformizer have height one by Stacks, Tag 00KV(1). At ξ_E the restriction of the valuation ring $F_{\xi_E}^\circ$ to $K(X)$ is $\mathcal{O}_{\mathcal{M},\eta_E}$. The map from that ordinary local ring into $F_{\xi_E}^\circ$ is local, because a positive order has norm less than one. Thus the induced map $\operatorname{Spec} F_{\xi_E}^\circ \to \mathcal{M}$ has centre η_E. The uniqueness in Stacks, Tag 0BX5 identifies it with the centre used in the frame definition.

Theorem C.1.106 (Metric equality and compatible powered extensions)**.** *Root model norms are unchanged by generic-identity pullback. Consider two root model presentations $(\mathcal{T}, \mathcal{L}, e, \alpha)$ and $(\mathcal{T}', \mathcal{L}', e', \alpha')$ of L, with norms h, h'. Let $p : \mathcal{M} \to \mathcal{T}$ and $p' : \mathcal{M} \to \mathcal{T}'$ be any common normal model, and let n be a positive common multiple of e, e'. Put*

$$\mathcal{A} = p^*\mathcal{L}^{\otimes n/e}, \qquad \mathcal{B} = p'^*\mathcal{L}'^{\otimes n/e'}.$$

The generic identifications define $\theta_K : \mathcal{B}|_X \xrightarrow{\sim} \mathcal{A}|_X$ *and its rational section* τ *of* $\mathcal{A} \otimes \mathcal{B}^{-1}$*. The following are equivalent:*

1. $h = h'$ *on* L *at every analytic point of* X*;*
2. $h = h'$ *at the finitely many* ξ_E *for the special components of* $\mathcal{M}$*;*
3. θ_K *extends to a unique isomorphism* $\theta : \mathcal{B} \xrightarrow{\sim} \mathcal{A}$ *on* $\mathcal{M}$*.*

In this case θ *identifies the rational sections induced by* $s^{\otimes n}$ *for every nonzero rational* s *of* L*. The conclusion is a compatible isomorphism of actual extensions after pullback and tensor powers. It is not equality of prescribed closed supports.*

Proof. For a generic-identity map of models, composition of the centre on the source with that map is the centre on the target, by uniqueness in Stacks, Tag 0BX5. Pulling back the actual line gives the same lattice in the fibre over F_x; hence the same norm. This also proves pointwise compatibility with tensor powers and duals.

Clearly (1) implies (2). At a special component, a frame of $\mathcal{A} \otimes \mathcal{B}^{-1}$ and the local rational equation of τ give

$$-\log \|\tau(\xi_E)\| = \lambda \frac{\operatorname{ord}_E(\tau)}{b_E}.$$

The norm of τ is the ratio of the two nth-power norms. Thus (2) implies $\operatorname{ord}_E(\tau) = 0$ for every vertical prime divisor. At a horizontal height-one point, τ already generates the line on the generic fibre, so its order is zero there too.

The model is Noetherian by Stacks, Tag 01T6. In a local frame at any point y of $\mathcal{M}$, write $\tau = f$. Its local ring is a Noetherian normal domain; all its height-one localizations are the relevant model height-one DVRs. Both f and f^{-1} belong to all of them. Their intersection is the local ring by Stacks, Tag 031T(2). Hence f is a unit. These local extensions agree on the dense generic fibre and glue, proving (3) and uniqueness. This is the exact additional normal-ring input; the codimension-one vanishing alone was not silently treated as an isomorphism.

Finally an isomorphism in (3) identifies the pulled-back lattices at every analytic point. The frame rule proves (1). Its generic restriction is the specified identity on $L^{\otimes n}$, so it also identifies the stated rational sections. □

Write $D_i = \operatorname{div}(s_i)$. The generic power-presentation condition is:

$$\text{for some } r_i \geq 1, \quad r_i D_i = A_i - B_i, \qquad A_i, B_i \text{ effective Cartier}, \quad |A_i| \cup |B_i| \subset S_i. \tag{C.1.54}$$

All divisor equalities here are actual Cartier equalities, with the associated line and rational-section identifications.

Theorem C.1.107 (Exact acquisition criterion, allowing tensor powers)**.** *Computing data exist if and only if* (C.1.54) *holds for every i. More precisely, start with any finite supplied family of model presentations of the metrics and any model supports for their Cartier data whose generic restrictions are the S_i. After taking suitable positive tensor powers, there is a common normal generic-identity refinement carrying signed presentations on the respective inverse images of those supports. No additional support is needed in this refinement assertion.*

The condition holds for all rational Cartier data on their divisor supports when X is locally factorial. It also holds when every Weil divisor on X has a positive Cartier multiple, in particular for a normal $\mathbf{Q}$*-factorial X.*

Proof. Restriction of any computing presentation to the identified generic fibre gives (C.1.54) with $r_i = e_i$. Nonzero factor sections remain nonzero on that dense integral open. This proves necessity, including after any generic-identity refinement.

For sufficiency take a common normal model of the supplied model presentations. Choose the new exponent for each i to be a common multiple of its model exponents and r_i. The tensor-powered generic data have the required presentations on S_i. Apply precisely Theorem C.1.98 to the actual pulled-back lines, rational sections and inverse-image supports. It produces effective Cartier factors with no extra support and leaves X unchanged. The frame rule preserves the metrics. If no model supports were supplied, one may choose

$$Z_i = \overline{S_i}^{\mathcal{M}} \cup |\mathcal{M}_k|.$$

This is an explicit allowed support containing the entire special fibre, and the datum is a regular generator on its complement. It is an existence choice, not an enlargement of a previously restricted support.

For the last assertion, split the Weil cycle of D_i into its positive and negative parts. Under the stated hypothesis some common multiple makes both parts Cartier. In the locally $\mathbf{Q}$-factorial case, a finite open cover gives such

a common multiple. They are effective Cartier: in every normal local ring their local equations have nonnegative orders at all height-one points, hence are regular by Stacks, Tag 031T(2). The difference is the chosen multiple of D_i, since a rational local equation of order zero everywhere is a unit by the same argument as in Theorem C.1.106. This gives the required presentation. Local factoriality is the case with no powers needed. □

Theorem C.1.108 (Model independence on the prescribed generic supports)**.** *Fix the data of* (C.1.51) *and* (C.1.54)*. The value* (C.1.52) *is a well-defined element of* $\lambda\mathbf{Q}$*, independent of the computing model, all generic-identity refinements, model exponents, signed presentations, and model supports with the fixed generic restrictions* S_i*. It is also independent of the chosen model extensions inducing the same pointwise metrics* h_i*, with their specified generic identifications.*

The value is symmetric under simultaneous permutation of the inputs and supports. It is additive under tensor product in any input when the other inputs are fixed, using the union of the two generic supports and requiring the displayed total-intersection condition. If two systems of generic supports S_i, S_i' *both describe the same metric and rational-section data, their values agree whenever* $\bigcap_i (S_i \cup S_i') = \varnothing$ *and both systems satisfy* (C.1.54)*.*

Proof. Theorem C.1.107 makes the collection of computations nonempty. Compare two of them on a common normal model $\mathcal{N}$. For each input choose a common multiple n_i of their exponents and pull back and tensor-power the actual factor presentations. These steps preserve each value by Lemma C.1.103.

Theorem C.1.106 gives the unique compatible isomorphism between the two powered line extensions on $\mathcal{N}$. It identifies their rational sections, because both restrict to $s_i^{\otimes n_i}$. It does not identify their allowed supports. Instead set

$$W_i = q^{-1}Z_i \ \cup \ q'^{-1}Z_i', \qquad W = \bigcap_i W_i.$$

Here $W_i \cap X = S_i$, so W_{red} is proper over k. Both presentations are allowed on W_i. Push to these common supports, apply the cross-addition identity of Lemma C.1.103, and iterate the identified operations. The resulting zero-classes agree in $\mathrm{CH}_0(W_{\mathrm{red}})$. Taking degree there proves equality of the original values. This also proves independence of the chosen common refinement.

Symmetry is the supported commutation in the reviewed calculus. For tensor additivity choose simultaneous computing data and common exponents. Signed additivity on the union support makes the numerator additive; the common denominators give the assertion. The same comparison works for S_i, S_i' when their componentwise union still has empty total intersection. In each case it is this last condition that makes the final degree comparison legitimate. □

Proposition C.1.109 (Failures of weaker replacement statements)**.** *The following limitations already occur in the present dimensional scope.*

1. *Equal induced model metrics need not make the specified generic isomorphism extend on a nonnormal initial model, even when both underlying model lines are trivial.*
2. *Abstractly equal model extensions, without their generic identifications, can induce different metrics and different values in* (C.1.52)*.*
3. *Normality of X does not imply the generic power-presentation condition on its prescribed divisor support. The quadric example of Proposition C.1.99 fails it for every positive power.*

Proof. For (1) take $R = \mathbf{Q}[[\pi]]$, $K = \mathbf{Q}((\pi))$, $u^2 = 2$, $B = \mathbf{Q}(u)[[\pi]]$ and

$$A = R + \pi B = R \oplus R(\pi u) \simeq R[z]/(z^2 - 2\pi^2) \subset B.$$

This is a finite free integral R-algebra with $A[1/\pi] = K(u)$, and $u \notin A$ is integral over A. The model $\mathcal{T} = \mathbf{P}^d_A$ is proper flat of finite type over R; its normal integral generic variety is $\mathbf{P}^d_{K(u)}$. The special fibre is allowed to be nonreduced: $A/\pi A \simeq \mathbf{Q}[z]/(z^2)$.

Use two copies of $\mathcal{O}_\mathcal{T}$ as extensions of $\mathcal{O}_X$, with generic identifications $1 \mapsto 1$ and $1 \mapsto u$. At every analytic point $|u|^2 = |2| = 1$, so both induced norms of 1 are one. But the compatible generic isomorphism between these two model lines is multiplication by u in one direction. It cannot extend on an affine chart with ring $A[t_1, \dots, t_d]$, since u does not belong to that ring. On the normal model $\mathbf{P}^d_B$ it is a unit and does extend. Normality of this model follows from normality of the DVR B and Stacks, Tag 030A. Thus passing to a common normal model in Theorem C.1.106 is substantive.

For (2) work on $\mathbf{P}^d_R$. Take $L_0 = \mathcal{O}_X$, $s_0 = 1$, $e_0 = 1$, and the two trivial extensions with identifications $1 \mapsto 1$ and $1 \mapsto \pi^{-1}$. Their root norms of 1

are respectively 1 and $|\pi|$. For $1 \le i \le d$ take the standard extension of $\mathcal{O}_X(1)$ with section Z_i. Set $S_0 = \varnothing$ and $S_i = \{Z_i = 0\}$; the total generic intersection is empty. The first computation has model section $\sigma_0 = 1$ and value zero. In the second $\sigma_0 = \pi$. Its first intersection is the full special fibre. Intersecting with $Z_1, \dots, Z_d$ gives the k-rational point $[1 : 0 : \cdots : 0]$ with length one. The second value is therefore $+\lambda$. This verifies the sign without using the pending logarithmic induction theorem.

For (3) use the proper normal quadric $ad - bc = 0$ in $\mathbf{P}^4_K$ and $f = a/c$, with prescribed support $P_0 \cup P_1$, $P_0 = \{a = b = 0\}$, $P_1 = \{c = d = 0\}$. The reviewed obstruction proof establishes that every effective Cartier divisor supported on this union near the vertex has zero coefficients at both planes: its pullback to the displayed small resolution restricts as $\mathcal{O}_{\mathbf{P}^1}(m+n)$ on the exceptional curve, while a principal local divisor restricts trivially; $m, n \ge 0$ force $m = n = 0$. A signed presentation of $r\,\mathrm{div}(f)$ would thus have zero coefficients at both planes, contradicting $r, -r$ for every $r > 0$. □

Purely inseparable base change

In the following example use the supported operation of Theorem C.1.101 and the pulled-back presentations of Proposition C.1.102. Use the dimension function of Lemma C.1.103. All root exponents are one. The native scales are $\lambda_K = -\log c$ and $\lambda_L = -\log |u| = \lambda_K / p$.

Example C.1.110 (Reduction loses a factor)**.** Let $k = \mathbf{F}_p$, $K = k((t))$ and $L = k((u))$ with $u^p = t$. Keep $|t| = c$ with $0 < c < 1$, so $|u| = c^{1/p}$. Take $R = k[[t]]$, $R' = k[[u]]$, and regard $\mathcal{X} = \mathbf{P}^d_{k[[v]]}$ as an R-model via $t = v^p$, where $d \ge 2$. Grouping power-series exponents modulo p identifies $k[[v]]$ with the free R-module on $1, v, \dots, v^{p-1}$. Thus $\mathcal{X}$ is integral, proper and flat over R, and its generic fibre is normal integral over K.

Take exponent one throughout, $(\mathcal{L}_0, \sigma_0) = (\mathcal{O}, v)$ with vertical support, and use d coordinate hyperplane sections of $\mathcal{O}(1)$ for the other factors. Their intersection with $\mathrm{div}(v)$ is one k-point of length one, so $J_R(\mathcal{X}) = \lambda_K$. The full base change is

$$\mathcal{Y} = \mathbf{P}^d_{R'[v]/(v^p - u^p)} \simeq \mathbf{P}^d_{R'[\epsilon]/(\epsilon^p)}, \qquad v = u + \epsilon.$$

It has generic length p along its one reduced component. After the hyperplane operations the quotient by v is $R'/(u^p)$, of length p; multiplication by v is

injective because $v^p = u^p$ and the algebra is R'-free. Equivalently, compute on the full fundamental cycle $p[\mathbf{P}^d_{R'}]$. Thus

$$\deg_{k'} \beta_{\mathcal{Y}} = p, \qquad J_{R'}(\mathcal{Y}) = (\lambda_K/p)p = \lambda_K.$$

Replacing $\mathcal{Y}$ by its reduction before forming its fundamental cycle gives degree one and the incorrect value λ_K/p. Its reduction is a different scheme, not a permissible deletion of generic multiplicity.

For the supported-cycle computation, the sole reduced component upstairs is $\mathbf{P}^d_{R'}$, with coefficient p in the full input cycle. On that component the d coordinate hyperplanes cut out the section $\operatorname{Spec} R'$. Intersecting this section with $v = u$ gives the single $k' = k$ point of length one. Applying the supported operation linearly gives degree p in the actual vertical support. The direct quotient above records the same multiplicity.

Supplied model maps and supported induction

Let K be complete and nontrivially discretely valued, with valuation ring R, residue field k, uniformizer π, and the fixed number $\lambda = -\log|\pi| > 0$. Let X be an integral proper K-variety of dimension $d \geq 2$. A model in this note is proper, flat, integral and normal over R, of finite type, with generic fibre identified with X. Retain explicitly the ordinary DVR local rings at all height-one points used below. Its special components have dimension d.

For a vertical component V use the ordinary local ring $A_V = \mathcal{O}_{\mathcal{X},\eta_V}$ and write $b_V = \mathrm{ord}_V(\pi) > 0$.

A *displayed modification* is a proper morphism $p : \mathcal{Y} \to \mathcal{X}$ inducing the identity on X, together with an open $U \subseteq \mathcal{X}$ containing X and every height-one point of $\mathcal{X}$, such that $p^{-1}(U) \to U$ is an isomorphism. This open is part of the hypotheses. We do not infer it merely from the equality of generic fibres. The complement has codimension at least two. A component W of $\mathcal{Y}_k$ is called exceptional here if it does not dominate a component of $\mathcal{X}_k$.

Lemma C.1.111 (Ordinary divisor coefficients under a supplied modification)**.** *Let p be a displayed modification. For each prime divisor V of $\mathcal{X}$ there is exactly one prime divisor $\widetilde{V}$ of $\mathcal{Y}$ dominating it, and their ordinary local DVRs are identified inside $K(X)$. For a Cartier divisor D with rational section presentation,*

$$p_* \,\mathrm{cyc}(p^*D) = \mathrm{cyc}(D). \tag{C.1.55}$$

The pushforward uses full residue-field degrees on equal-dimensional images and zero on dimension-decreasing images. In particular, for special components, $b_{\widetilde{V}} = b_V$. Every exceptional special component has image of dimension at most $d-1$.

The codimension-one isomorphism hypothesis is checkable for a blowup of a finite-type ideal I with $I|_X = \mathcal{O}_X$: it holds wherever I is locally principal and nonzero, hence on an open containing every height-one point of the normal model. This assertion concerns the blowup itself; any additional normalization or domination needs its own compatibility check.

Proof. Over the generic point of a prime divisor V, the morphism is an isomorphism. Taking the closure of its inverse-image point gives $\widetilde{V}$ and identifies its local ring and residue field with those of V. No second divisor can dominate V, since it would also meet this isomorphic inverse image. Any other

prime divisor lies over the complement of U, so its image has smaller dimension. Properness makes that image closed. The coefficient of p^*D at $\widetilde{V}$ is the coefficient of D at V, because the same rational function is measured in the same DVR. Its pushforward degree is one, and the other coefficients push forward to zero. This proves (C.1.55). Applying the same ordinary DVR calculation to π gives $b_{\widetilde{V}} = b_V$.

At a height-one point v, I_v is a nonzero finitely generated ideal in a DVR and thus is principal, say (a). After shrinking a neighbourhood, a is a section of I and every chosen finite generator of I is a multiple of a; clearing the finitely many localization denominators proves this assertion on an open. On that open, the Rees algebra is $\bigoplus_{n\geq 0}(a^n)T^n \simeq A[t]$, since a is a non-zero-divisor. Its Proj is $\operatorname{Spec} A$. The union of these opens and the generic fibre gives the required U for the blowup. □

Finite measures with supplied atoms and centres

Assume the following actual analytic data on the common Hausdorff X^{an}. For every special component on either model the point ξ_V has generic scheme support, valuation $|f(\xi_V)| = |\pi|^{\operatorname{ord}_V(f)/b_V}$ on $K(X)$, and its indicated centre on that model. The points attached to distinct components of each model are distinct. The points for V and $\widetilde{V}$ agree, and the downstairs centres of the exceptional atoms lie outside U. Assume the two centres of each point are compatible under p and use the prescribed root frame rule on their actual reducing domains, with positive integral root exponents.

For lines $\mathcal{L}_i$ extending $L_i^{\otimes e_i}$, $1 \leq i \leq d$, write

$$E = \prod_{i=1}^{d} e_i, \qquad \delta_V = \deg_{\mathcal{L}_1|_V,\dots,\mathcal{L}_d|_V,k}(V), \qquad \mu_{\mathcal{X}} = \sum_V \frac{b_V \delta_V}{E}\delta_{\xi_V}. \quad \text{(C.1.56)}$$

This is the specified finite model measure, with the ordinary mixed component degree over k. All root exponents, nilpotent lengths and full residue-field degrees are retained. It can be signed. The root model metric has $\|s\| = |a|^{1/e}$ when $s^{\otimes e} = ae_{\mathcal{M}}$ in a model frame of $\mathcal{M}$.

Theorem C.1.112 (Component-degree criterion with supplied model atoms)**.** *Under the point, centre and frame hypotheses above, use $p : \mathcal{Y} \to \mathcal{X}$ and the pulled-back model lines $p^*\mathcal{L}_i$ with the same root exponents. Then the following are equivalent:*

1. *The two finite measures on the common* X^{an} *are equal.*
2. *Their component degrees satisfy*

$$\delta_{\widetilde{V}} = \delta_V \quad \text{for every } V, \qquad \delta_W = 0 \quad \text{for every exceptional } W. \tag{C.1.57}$$

Under this criterion all continuous tests, and all Borel tests finite on the common finite support, have equal integrals. In particular, if M *has a model* $\mathcal{M}$ *extending* $M^{\otimes e_0}$*, the pullback model metric is the same metric on* M*. Every nonzero rational section* s *satisfies*

$$\int -\log\|s\|\, d\mu_{\mathcal{Y}} = \int -\log\|s\|\, d\mu_{\mathcal{X}}. \tag{C.1.58}$$

The logarithm is used off its zero/pole support and may be extended arbitrarily across that null set for these atomic measures. Both are finite total-variation integrals. If $a_V = \mathrm{ord}_V(s^{\otimes e_0})$ *in a model frame, the common downstairs expression is*

$$\frac{\lambda}{e_0 E}\sum_V a_V \delta_V, \qquad -\log\|s(\xi_V)\| = \frac{\lambda a_V}{e_0 b_V}. \tag{C.1.59}$$

Replacing s *by* πs *changes it by* $+\lambda\mu_{\mathcal{X}}(X^{\mathrm{an}})$*.*

Proof. The strict-transform atoms agree by hypothesis, and their b's agree by Lemma C.1.111. An exceptional atom cannot equal one of these: its centre on $\mathcal{X}$ is in $\mathcal{X}\setminus U$, whereas the strict-transform atom has centre $\eta_V \in U$. Distinct components of $\mathcal{Y}$ also give distinct atoms. Comparing the coefficients of each Dirac mass in (C.1.56), and using $b_W > 0$, proves precisely the equivalence with (C.1.57). This argument allows signed degrees; no cancellation between distinct atoms is possible. Equality of the finite measures proves equality for every stated test.

A frame of $\mathcal{M}$ pulls back to a frame of $p^*\mathcal{M}$ at every point reducing over that frame. The coefficient of a generic section is the same rational function, evaluated at the same analytic point. The root metric formula therefore proves equality of these metrics on all of X^{an}. The prescribed centres are compatible under p, so the comparison uses the same reducing domains. Every atom has generic underlying scheme point, so a nonzero rational section is regular and nonvanishing there. The root norm gives the second formula in (C.1.59); multiplication by its mass $b_V\delta_V/E$ gives the first. This proves finiteness without any singular limiting argument. Finally a_V becomes $a_V + e_0 b_V$ for πs, giving the positive change $\lambda\sum_V b_V\delta_V/E$. □

Algebraic induction on prescribed supports

Use the dimension function and supported Gysin operations of Theorem C.1.101 and the signed operations of Proposition C.1.102. Use the mixed degree convention preceding Theorem C.1.105. The ordinary height-one DVRs are the rings of Lemma C.1.17. In an integral finite-type flat model, a minimal prime over the nonzero uniformizer has height one by Stacks, Tag 00KV(1).

Now let K be complete and nontrivially discretely valued with ring R, and put $\lambda = -\log|\pi| > 0$. Let $\mathcal{X}$ be an integral normal proper flat model of relative dimension $d \geq 2$. For $0 \leq i \leq d$, let $\mathcal{L}_i$ extend $L_i^{\otimes e_i}$, $e_i \geq 1$, and let $\sigma_i = s_i^{\otimes e_i}$ be a nonzero rational model section. Specify signed presentations on closed supports Z_i satisfying

$$\bigcap_{i=0}^{d} Z_i \cap X = \varnothing, \qquad X = \mathcal{X}_K. \tag{C.1.60}$$

Write I_i for the supported operations, $E = \prod_{i=0}^{d} e_i$, and $T = \bigcap_i Z_i$. Define

$$J_{\mathcal{X}} = \frac{\lambda}{E} \deg_k\big(I_0 \cdots I_d[\mathcal{X}]\big), \qquad I_0 \cdots I_d[\mathcal{X}] \in \mathrm{CH}_0(T_{\mathrm{red}}). \tag{C.1.61}$$

The value is defined on this model data. This construction also applies to the horizontal integral cycles occurring below, using the remaining pulled-back factor presentations, even when a factor vanishes identically.

Theorem C.1.113 (Supported projection and algebraic horizontal–vertical induction)**.** *The value* (C.1.61) *is independent of the permitted signed presentations and symmetric in all $d+1$ inputs. Let $p : \mathcal{Y} \to \mathcal{X}$ be a supplied proper dominant map of integral proper flat models of the same relative dimension, and put $N = [K(\mathcal{Y}) : K(\mathcal{X})]$. With the actual pulled-back factor data and supports on $\mathcal{Y}$, one has*

$$J_{\mathcal{Y}} = N J_{\mathcal{X}}. \tag{C.1.62}$$

Normality of $\mathcal{Y}$ is not needed for this supported equality.

At the ordinary height-one DVRs of $\mathcal{X}$, write

$$\mathrm{div}_{\mathcal{L}_0}(\sigma_0) = \sum_{H \text{ horizontal}} a_H[H] + \sum_{V \text{ vertical}} a_V[V].$$

Let J_H be the construction (C.1.61) on H using the remaining d pulled-back presentations and denominator $\prod_{i=1}^{d} e_i$. Put $\delta_V = \delta(V; \mathcal{L}_1|_V, \dots, \mathcal{L}_d|_V)$. Then

$$J_{\mathcal{X}} = \frac{1}{e_0} \sum_H a_H J_H + \frac{\lambda}{e_0 \prod_{i=1}^{d} e_i} \sum_V a_V \delta_V. \tag{C.1.63}$$

Thus the horizontal coefficients are exactly those of $\operatorname{div}(s_0)$ on the generic fibre. At fixed model lines, identifications and root exponents, replacing s_i by πs_i and enlarging its support by the special fibre when needed changes the supported value by

$$\Delta J = \frac{\lambda}{\prod_{j \neq i} e_j} \sum_V b_V \, \delta\big(V; (\mathcal{L}_j|_V)_{j \neq i}\big).$$

Only (C.1.60) is required; no pairwise proper intersection or generic nonvanishing on every intermediate cycle is imposed.

Proof. The operations produce a zero-class on T after $d+1$ steps. Condition (C.1.60) makes T_{red} a proper k-scheme, so its degree is defined even if T has positive dimension. Presentation independence and commutation prove the first assertions. For the supplied proper map, repeated supported projection gives

$$p_*(I_{p^*0} \cdots I_{p^*d}[\mathcal{Y}]) = I_0 \cdots I_d p_*[\mathcal{Y}] = N I_0 \cdots I_d[\mathcal{X}].$$

The supports remain the displayed inverse images; degree compatibility proves (C.1.62). This proves a statement about a supplied map and compatible data, not existence of a common model.

Apply I_0 first. Each factor section in its signed presentation is nonzero on $\mathcal{X}$. Its Gysin image of $[\mathcal{X}]$ is therefore its divisor cycle, and subtraction gives the displayed cycle of σ_0 on Z_0. A positive coefficient at a height-one point is the length of the quotient by a local equation in the ordinary DVR; differences give the signed coefficient. Apply the remaining operators to each component, using proper compatibility for its closed immersion. On a horizontal H, the remaining generic supports have empty total intersection: $H \subset Z_0$ and (C.1.60) applies. This contribution is $(a_H/e_0)J_H$. The value J_H uses the restricted factor presentations, not a purported restriction of a rational section that vanishes identically on H.

On a vertical V, push the remaining supported intersection class into $\mathrm{CH}_0(V)$. The support-forgetting first Chern assertion of Theorem C.1.101,

its signed extension in Proposition C.1.102, and proper compatibility show that the result is $c_1(\mathcal{L}_1|_V)\cdots c_1(\mathcal{L}_d|_V)[V]$. This push stays inside the proper vertical scheme V, so it preserves the relevant degree. It gives $a_V\delta_V$ and proves (C.1.63). Localization at π identifies the horizontal DVR with its generic-fibre DVR. Since $\sigma_0 = s_0^{e_0}$, its horizontal coefficient is e_0 times the coefficient of $\operatorname{div}(s_0)$.

Finally $s_i \mapsto \pi s_i$ changes the model divisor by $e_i \operatorname{div}(\pi)$ and may enlarge its support by the special fibre. Its first supported operation on $[\mathcal{X}]$ gives $e_i \sum_V b_V[V]$. Commutation and the same vertical calculation give

$$\Delta J = \frac{\lambda}{\prod_{j\neq i} e_j} \sum_V b_V \delta(V; (\mathcal{L}_j|_V)_{j\neq i}),$$

with positive sign. □

Local criteria for affinoid neighbourhoods and collars

Theorem C.1.114 (An ordinary affinoid neighbourhood gives affine reduction)**.** *If x has an ordinary affinoid neighbourhood in an analytic space U, the graded birational reduction of (U, x) is affine.*

Proof. Choose such a neighbourhood $V = \mathcal{M}(B)$. By reduction on actual analytic germs and ordinary affinoid neighbourhood invariance, $\mathcal{R}(U, x)$ is the reduction computed on V in the same graded completed residue field. Choose an actual admissible absolute weighted Tate presentation for B. The fixed absolute presentation makes its graded reduction finite over the image of the graded polynomial algebra. Its further evaluated image in the graded residue field is therefore a finitely generated graded algebra. Its valuation locus is affine by the definition of the reduction of the affinoid representative. □

Theorem C.1.115 (Absolute interior on an actual affinoid domain)**.** *For an affinoid domain D of an affinoid Y,*

$$\mathrm{Int}(D/K) = \mathrm{Int}_{\mathrm{top}}(D, Y) \cap \mathrm{Int}(Y/K).$$

Proof. The source-factor inclusion applied to $D \to Y \to \mathcal{M}(K)$ sends an absolutely interior point of D into $\mathrm{Int}(D/Y)$. The affinoid-domain criterion makes D an ordinary neighbourhood there. The ordinary local test then gives absolute interior in Y. Conversely the same domain criterion together with forward composition gives absolute interior in D. □

C.2 The exact whole-fibre boundary and capture condition

Fix a complete non-Archimedean field K with its specified real-valued absolute value, possibly trivial. All affinoids are generalized affinoids, with arbitrary positive real presentation radii. Finite maps are norm-admissible finite: their given Banach structures are equivalent to the canonical finite-module structures. All domains, fibres and modules below have their actual analytic structures; nilpotents are retained. Write $t_g = -\log|g|$ for a tuple of analytic units. For a closed rectangular box $P \subset \mathbb{R}^m$, $\mathbb{T}_P$ is the entire inverse image of P in the analytic m-torus. The point η_s is its weighted Gauss point at $s \in P$.

The frozen local finite criterion 2.49.1 already reconstructs Berkovich's ordinary-neighbourhood theorem. It does not assert that a neighbourhood of η_s contains the entire exact polytorus $\mathbb{T}_s$. The next criterion makes the missing quantifier explicit: every point of $t_g^{-1}(s)$, not just the points above η_s, must be controlled.

Theorem C.2.1 (Compact ambient separation and completion over a source)**.** *Let $Y = \mathcal{M}(A)$ be a generalized affinoid. Let $U, V \subset Y$ be affinoid domains, and let $g_i \in (A^\times)^{m_i}$, $1 \le i \le r < \infty$, be actual unit tuples. Put $q_i = t_{g_i}$, choose $s_i \in q_i(Y)$, and define*

$$K_i = q_i^{-1}(s_i), \qquad G = \mathrm{Int}(Y/K) \cap \mathrm{Int}_{\mathrm{top}}(U, Y) \cap \mathrm{Int}_{\mathrm{top}}(V, Y), \qquad B = Y \setminus G. \tag{1}$$

The following are equivalent.

1. *For every i, $s_i \notin q_i(B)$, or equivalently the* entire *K_i is contained in G.*
2. *There are full-dimensional closed rectangular boxes P_i, with $s_i \in \mathrm{int}(P_i)$, such that*

$$C_i = q_i^{-1}(P_i) \subset U \cap V, \qquad g_i : C_i \longrightarrow \mathbb{T}_{P_i} \quad \textit{is norm-admissible finite.} \tag{2}$$

   The inverse image defining C_i is taken in all of Y.
3. *Every K_i is contained in $\mathrm{Int}_{\mathrm{top}}(U, Y) \cap \mathrm{Int}_{\mathrm{top}}(V, Y)$, and the analytic map $g_i : Y \to (\mathbb{G}_m^{m_i})^{\mathrm{an}}$ is finite at* every point of *K_i in the ordinary-neighbourhood sense.*

When these conditions hold, the P_i may be chosen inside any prescribed real neighbourhoods of their centres, and one may require $C_i \subset G$. In particular,

$$(q_i|_U)^{-1}(P_i) = (q_i|_V)^{-1}(P_i) = q_i^{-1}(P_i) \tag{3}$$

as actual analytic domains. Over every analytic target point of $\mathbb{T}_{P_i}$, these identities retain the entire analytic fibres in Y, U, V, including all local factors. Compatible finite modules on U and V give the same complete module on these fibres.

There is a separate criterion when Y is only a domain in a larger intended source. More generally, let Ω be a good Hausdorff analytic space, let $Z \subset \Omega$ be an affinoid domain, and suppose that actual unit tuples on Ω restrict to norm-admissible finite saturated collars over boxes P_i^0 in Z, with $s_i \in \mathrm{int}(P_i^0)$. There exist smaller such boxes $P_i \subset P_i^0$ with

$$q_i^{-1}(P_i) \text{ in } \Omega = (q_i|_Z)^{-1}(P_i) \tag{4}$$

if and only if

$$s_i \notin \overline{q_i(\Omega \setminus Z)} \quad \text{for every } i. \tag{5}$$

The closure is taken in $\mathbb{R}^{m_i}$. *The equality in (4) is again an equality of analytic domains and entire fibre algebras, not just of selected Gauss lifts.*

Proof. The set G is ordinary open in the compact Hausdorff space Y. Indeed absolute interior is open, and the other two sets are topological interiors. Hence B and $q_i(B)$ are compact. The domain-interior and composition identities give, as subsets of Y,

$$G = \operatorname{Int}(U/K) \cap \operatorname{Int}(V/K). \tag{6}$$

Here 2.44.3 identifies relative interior of a domain with its topological interior, and C.1.115 is applied to $U \to Y \to \mathcal{M}(K)$ and to $V \to Y \to \mathcal{M}(K)$.

Assume condition 1. Since $K_i \subset \operatorname{Int}(Y/K)$, the frozen whole-moment-fibre theorem 5.38.4, applied to the tuple g_i, supplies a finite saturated box about s_i. Because the compact image $q_i(B)$ misses s_i, shrink that box to avoid $q_i(B)$ and to lie in the prescribed real neighbourhood. Finite base change preserves the canonical finite norm. Its whole inverse image C_i is contained in G. This can be done for all the finitely many i; the ambient source and the two intended domains stay fixed. This proves condition 2 and the stated simultaneous choices. The finiteness theorem itself is inherited, not reproved here.

Conversely assume condition 2 and let $y \in K_i$. The target point $g_i(y)$ lies in $\operatorname{Int}(\mathbb{T}_{P_i}/K)$: all its defining polyannulus bounds are strict because $s_i \in \operatorname{int}(P_i)$. A finite map is everywhere relatively interior by 2.33.18, so composition gives $y \in \operatorname{Int}(C_i/K)$. Since $C_i \subset U, V$, the domain restriction theorem makes C_i an affinoid domain of both. Applying the composition identity to $C_i \to U \to \mathcal{M}(K)$ and to $C_i \to V \to \mathcal{M}(K)$ places y in both $\operatorname{Int}(U/K)$ and $\operatorname{Int}(V/K)$. Equation (6) gives $y \in G$, proving condition 1. Thus merely placing K_i in the closed subsets U, V would not suffice; the necessary interior condition has been deduced from finiteness.

We verify the ordinary-local formulation as well. Choose a large closed polyannulus $\mathbb{T}_{R_i}$ so that all coordinate bounds strictly exceed the norms of g_i and g_i^{-1}, and the whole image $g_i(Y)$ is in its ordinary and absolute interior. It gives a bounded map $Y \to \mathbb{T}_{R_i}$. At a point where g_i is finite in the ordinary sense, the frozen local criterion and ordinary local testing give relative interiority for this affinoid map. Composing with $\mathbb{T}_{R_i} \to \mathcal{M}(K)$

gives absolute interiority in Y. Thus condition 3 implies 1. Under condition 2 the whole analytic fibre over any point with moment s_i is a fibre of the finite map $C_i \to \mathbb{T}_{P_i}$, and is therefore finite and discrete. In particular every point of K_i is isolated in its analytic fibre in Y. The already proved condition 1 gives absolute interiority, hence relative interiority over $\mathbb{T}_{R_i}$. The frozen local finite criterion gives ordinary local finiteness at every such point. This proves condition 3. No flatness hypothesis was used.

The set equalities (3) follow from $C_i \subset U \cap V$ and saturation in Y. The actual domain universal property and domain base change identify their analytic structures. Further base change to any analytic target point identifies the entire fibre algebras. For the module assertion, fix an actual isomorphism between the restrictions of the two finite modules to $U \cap V$. Restrict it to C_i, then to the fibre. Finite-module tensor comparison makes these the complete canonical modules, and every such finite-module isomorphism is bounded with bounded inverse. Nothing in these operations takes a reduction or discards a field or local Artinian factor.

Finally consider Ω and Z. If (5) holds, choose $P_i \subset \operatorname{int}(P_i^0)$ about s_i disjoint from $\overline{q_i(\Omega \setminus Z)}$. Every inverse-image point then belongs to Z, proving (4). The resulting map is finite by restriction of the given finite collar in Z. Conversely, (4) implies $P_i \cap q_i(\Omega \setminus Z) = \varnothing$. The open set $\operatorname{int}(P_i)$ contains s_i and is disjoint from that image, so s_i is outside its closure. Domain base change gives the analytic assertion as before. No compactness of $\Omega \setminus Z$ was assumed; this is exactly why the closure in (5) is retained. □

The ordinary neighbourhood step uses the local finite criterion and the ordinary local test on the larger torus chart.

Finite base extension of supported model intersections

Let K be complete for a specified nontrivial discretely valued non-Archimedean absolute value. Put

$$R = K^\circ, \qquad k = R/\mathfrak{m}_R, \qquad \lambda_K = -\log|\pi| > 0$$

for a uniformizer π of R. Let X be a normal integral proper K-variety of dimension $d \geq 2$, and let $\mathcal{X}$ be an integral proper flat finite-type R-model of X. The initial model need not be normal.

For $0 \leq i \leq d$, fix a line bundle L_i on X, a nonzero rational section s_i, and a closed set S_i off which s_i is a regular generator. Assume $\bigcap_i S_i = \varnothing$.

A computing datum consists of positive integers a_i, invertible sheaves $\mathcal{L}_i$, specified identifications $\mathcal{L}_i|_X \simeq L_i^{\otimes a_i}$, and signed presentations of the induced rational sections $\sigma_i = s_i^{\otimes a_i}$. Thus

$$(\mathcal{L}_i, \sigma_i) \simeq (\mathcal{L}_i^+, s_i^+) \otimes (\mathcal{L}_i^-, s_i^-)^{-1}, \qquad |Z(s_i^+)| \cup |Z(s_i^-)| \subset Z_i, \qquad Z_i \cap X = S_i,$$

where the factor sections are nonzero global sections. All line identifications and all supports are part of the data.

We use the supported projection formula (2) and the signed-presentation construction for the following operations.

$$C_r(\mathcal{X}; T) = \mathrm{CH}_r(T_{\mathrm{red}}), \qquad I_{i,T} : C_r(\mathcal{X}; T) \longrightarrow C_{r-1}(\mathcal{X}; T \cap Z_i).$$

The dimension convention assigns 1 to the generic point of $\operatorname{Spec} R$ and 0 to its closed point; thus $[\mathcal{X}]$ has dimension $d+1$. Set

$$A = \prod_{i=0}^{d} a_i, \qquad T = \bigcap_i Z_i, \qquad \beta_{\mathcal{X}} = I_0 \cdots I_d[\mathcal{X}] \in \mathrm{CH}_0(T_{\mathrm{red}}), \qquad J_R(\mathcal{X}) = \frac{\lambda_K}{A} \deg_k \beta_{\mathcal{X}}. \tag{C.2.1}$$

The support T_{red} is proper over k, although it need not be zero-dimensional. Degree uses the full residue-field degrees. Passing to a reduced support identifies the Chow groups; it never changes the coefficients of an input fundamental cycle.

A local model frame has norm one, and the specified line identification gives the a_i-th root of its coefficient norm. The proper centre is the unique extension from the fraction field of the relevant valuation ring. Stacks Tag 0BX5

Choose a finite extension as in the valuation-ring calculation. Keep the entire fibre product $\mathcal{Y} = \mathcal{X} \times_R R'$ with projection $q : \mathcal{Y} \to \mathcal{X}$. The schemes and all prescribed inverse-image supports carry their actual structures.

Lemma C.2.2 (Pullback of the data and of the root norms)**.** *The scheme $\mathcal{Y}$ is proper, flat and of finite type over R'; q is finite locally free of rank n. Its generic fibre is $X_L = X \times_K L$. The actual pulled-back lines, sections and identifications have the same exponents a_i. With $Z_i' = q^{-1}Z_i$ and $T' = q^{-1}T$, their supported operators I_i' define*

$$\beta_{\mathcal{Y}} = I_0' \cdots I_d'[\mathcal{Y}] \in \mathrm{CH}_0(T'_{\mathrm{red}}).$$

The support T'_{red} is proper over k'. Their pointwise root model norms are the pullbacks of the original norms, using the original extending absolute value.

Proof. On an affine chart B of $\mathcal{X}$ the fibre product has ring $B \otimes_R R'$, locally free of rank n over B by Lemma C.1.16. Properness and finite type persist by base change. Flatness over R' follows by tensoring an exact sequence of R'-modules with the flat R-module B. Localizing at ϖ gives $B \otimes_R L$; these identifications glue to the stated generic fibre.

Pullback preserves all specified line and cross-product identities, and the zero schemes of the factor sections pull back to their scheme-theoretic inverse images. This is exactly the arbitrary-source pullback scope of `f9sc:signed`, not a new assertion about arbitrary rational data on a nonreduced scheme. Every component of $\mathcal{Y}$ dominates $\mathcal{X}$ by Lemma C.1.38; hence it is horizontal and has dimension $d+1$. The total generic support is empty because it is the inverse image of $\bigcap_i S_i$. Thus the final reduced support is vertical and proper over k', and the supported operations give the stated zero-class.

For the norm statement let $y \in X_L^{\mathrm{an}}$ and $x = q(y)$. The valued residue field at y contains the valued residue field at x isometrically. The centre on $\mathcal{X}$ extended to the valuation ring at y, together with its map from R', gives the centre on $\mathcal{Y}$ by the fibre-product property. Uniqueness is the valuative criterion for properness, Tag 0BX5, as in the proper-centre argument. A local model frame pulls back to a frame. If a vector to the a_ith power has coefficient c in this frame, both norms are $|c|^{1/a_i}$. Units have norm one. This also handles the actual generic identifications and their tensor powers. □

The degree calculation uses this full pullback of the model and its data, and the full finite flat cycle.

Theorem C.2.3 (Finite base extension and numerical descent)**.** *For the full pulled-back computing datum,*

$$q_*\beta_{\mathcal{Y}} = n\beta_{\mathcal{X}} \quad \textit{in } \mathrm{CH}_0(T_{\mathrm{red}}), \qquad \deg_{k'} \beta_{\mathcal{Y}} = e \deg_k \beta_{\mathcal{X}}. \tag{C.2.2}$$

Consequently its native R'-normalized value is

$$J_{R'}(\mathcal{Y}) := \frac{\lambda_L}{A} \deg_{k'} \beta_{\mathcal{Y}} = J_R(\mathcal{X}). \tag{C.2.3}$$

If the same upstairs data are instead regarded over R, with the R-normalization, then

$$J_{\mathcal{Y}/R} := \frac{\lambda_K}{A} \deg_k \beta_{\mathcal{Y}} = nJ_{R'}(\mathcal{Y}) = nJ_R(\mathcal{X}). \tag{C.2.4}$$

These formulas hold for nonreduced $\mathcal{Y}$ and nonreduced X_L, respect finite extension towers, and are unchanged by tensor-power replacement of any root presentation.

Proof. View both models over R in order to apply proper projection. Their dimension functions agree with those over R': the generic and closed residue extensions are algebraic, so they add no transcendence degree. At every stage use the actual inverse-image intersection of supports. The proper map between these reduced supports is the restriction of q. Repeatedly applying `f9sc:refined`(2) to the two global factors and subtracting as in `f9sc:signed` gives

$$q_*(I'_0 \cdots I'_d[\mathcal{Y}]) = I_0 \cdots I_d(q_*[\mathcal{Y}]) = nI_0 \cdots I_d[\mathcal{X}],$$

where the last equality is Lemma C.1.38. This proves the first identity in (C.2.2) on the prescribed support. Neither a flat-pullback identity for Chow groups nor a proper-intersection hypothesis has been used.

For any zero-cycle class γ on the proper k'-scheme T'_{red}, the tower law at each closed point gives

$$\deg_k(q_*\gamma) = \deg_k \gamma = f \deg_{k'} \gamma.$$

Here the first degree treats T'_{red} as a k-scheme; proper pushforward and degree are the frozen conventions Tag 02S2, Tag 0AZ2. Thus $f \deg_{k'} \beta_{\mathcal{Y}} = n \deg_k \beta_{\mathcal{X}}$. By Lemma C.1.16, $n/f = e$ and $\lambda_L = \lambda_K/e$, which prove (C.2.3). Using the original base k and λ_K instead gives (C.2.4). The factor n in that formula is not a factor in the native value.

Replacing $(\mathcal{L}_i, \sigma_i, a_i)$ by $(\mathcal{L}_i^{\otimes b_i}, \sigma_i^{\otimes b_i}, b_i a_i)$ multiplies its signed operation by b_i, by the inherited tensor additivity on the same support. The product of these integers cancels the denominator. In a finite tower the full base-change models associate, the fundamental-cycle transfer ranks multiply, and both ramification and residue degrees multiply. Applying the identities twice therefore gives the direct identities. □

Finite analytic descent and direct images

Fix a complete field K with its specified real-valued non-Archimedean absolute value. Trivial valuation and generalized affinoid radii are allowed. Spaces in this supplement are good and Hausdorff. Coherent modules live on the analytic G-site. A line bundle means a coherent module which is free of rank one on ordinary open neighbourhoods. The symbol q^* on coherent modules denotes ordinary tensor pullback; it is not a derived functor.

For a norm-admissible finite morphism $q : Y \to X$, the full inverse image of $V = \mathcal{M}(A)$ is $\mathcal{M}(B)$, where B is finite over A with its canonical finite-module norm. If N is finite over B, compose controlled finite free presentations $A^a \twoheadrightarrow B$ and $B^b \twoheadrightarrow N$. Their lifting bounds compare the iterated quotient norm with the canonical finite-A-module norm. Thus restriction of scalars also preserves the canonical topology on N. Every tensor used below between finite modules has its canonical topology. The comparison with the completed analytic tensor is provided by NAG-001565 and NAG-001702. Algebraic finiteness with an unrelated Banach norm would not suffice.

Let L/K be a finite field extension and let $n = [L : K]$. Give L the unique extending absolute value, without rescaling it. Write $p : Y = X_L \to X$. In every direct image and every descent fibre product below, Y is regarded as a K-analytic space. This use of restriction of constants keeps the same Banach algebra; it is not the Weil restriction functor.

Lemma C.2.4 (The finite tensor bridge)**.** *For a generalized K-affinoid algebra A, put $B = A\widehat{\otimes}_K L$. There are natural algebra identifications*

$$B = A \otimes_K L, \qquad \underbrace{B\widehat{\otimes}_A \cdots \widehat{\otimes}_A B}_{r \text{ factors}} = A \otimes_K L^{\otimes_K r} \quad (r \geq 1). \tag{C.2.5}$$

Every algebra on the right has its canonical finite-A-module topology. In particular $A \to B$ is faithfully flat and finite free of rank n. For a finite A-module M, $B \otimes_A M = M \otimes_K L$ is the actual analytic pullback. These identifications commute with affinoid restrictions.

Direct inputs: NAG-001450, NAG-001561, NAG-001565, NAG-001685, NAG-001689, NAG-001701, NAG-001702.

Proof. Choose a K-basis of L containing 1. The finite-dimensional norm theorem makes its coordinate maps bounded in both directions. Tensoring

these maps with A identifies $A\widehat{\otimes}_K L$ with the complete space A^n, with equivalent norms. The maps are inverse on elementary tensors and hence on their completions. Their multiplication is the ordinary tensor multiplication. The scalar-presentation theorem gives the native L-affinoid structure, and the finite-algebra theorem gives the K-affinoid structure with the same Banach topology. A bounded K-seminorm on B restricts to the specified absolute value on L by uniqueness. Thus the two spectra have the same points and evaluation topology. All sheaves and fibre products in this supplement are taken on the finite K-analytic model just constructed.

Finite base change now identifies the completed tensors over A with ordinary tensors, proving (C.2.5) by iteration. The same finite-module comparison applies to M. A free A-module of positive rank is faithfully flat: tensoring an A-module with B gives its n-fold direct sum. The formulas and their inverses commute with the maps $A \to A_V$, which proves restriction compatibility. □

Full inverse images of ordinary affinoid neighbourhoods in X are affinoid by finite base change. Their interiors contain the inverse images of the downstairs interiors, so Y is good. Points with distinct images are separated by the Hausdorff property of X. Two distinct points above the same x lie in the open inverse image of the interior of one affinoid neighbourhood of x. This open set is a subspace of a Hausdorff affinoid inverse image and separates the points. Thus Y is Hausdorff as well.

The lemma is only the finite coefficient bridge needed for descent. No Gauss-field degree or native integral comparison is derived here. In particular the double space for descent is

$$Y^{[2]} = Y \times_X Y, \qquad \mathcal{O}(Y^{[2]}|_V) = A \otimes_K (L \otimes_K L),$$

not a product formed by replacing $L \otimes_K L$ by L. Write $q_1, q_2 : Y^{[2]} \to Y$ for its two projections.

Definition C.2.5. A coherent descent datum is a coherent module $\mathcal{F}$ on Y_G and an isomorphism $\delta : q_1^*\mathcal{F} \xrightarrow{\sim} q_2^*\mathcal{F}$ whose pullbacks to $Y^{[3]} = Y \times_X Y \times_X Y$ satisfy $\delta_{23}\delta_{12} = \delta_{13}$. Morphisms commute with δ. The isomorphism and its cocycle are identities of modules on the full, possibly nonreduced, fibre products.

Theorem C.2.6 (Effective coherent and line-bundle descent)**.** *Pullback along p gives an equivalence between $\mathrm{Coh}(X_G)$ and coherent descent data on Y/X. It restricts to an equivalence of line bundles with descent data. The descent construction commutes with affinoid restriction and tensor products.*

Direct inputs: Lemma C.2.4, NAG-001561, NAG-001624, NAG-001752, NAG-001753, and the already registered STACKS-023N(1).

Proof. First work on $V = \mathcal{M}(A)$. Let N represent $\mathcal{F}$ on $\mathcal{M}(B)$. Lemma C.2.4 converts the analytic datum into an ordinary $B \otimes_A B$-linear isomorphism

$$\varphi : N \otimes_A B \xrightarrow{\sim} B \otimes_A N$$

with the ordinary triple-tensor cocycle. The exact effectiveness statement of Stacks Tag 023N(1) applies because $A \to B$ is faithfully flat. It provides an effective A-module.

For completeness, identify the inverse and morphisms rather than using the parts of Tag 023N whose proofs are omitted there. Set

$$M = \{z \in N : \varphi(z \otimes 1) = 1 \otimes z\}. \tag{C.2.6}$$

Choose the A-linear map $r : B \to A$ induced by a K-linear map $L \to K$ taking 1 to 1. For a canonical effective datum $N = B \otimes_A M_0$, invariance says, on writing $z = \sum_i b_i \otimes m_i$,

$$\sum_i b_i \otimes 1 \otimes m_i = \sum_i 1 \otimes b_i \otimes m_i.$$

Applying r to the first factor shows $z = 1 \otimes \sum_i r(b_i) m_i$. Conversely every $1 \otimes m$ is invariant, and the map $m \mapsto 1 \otimes m$ is injective by the same retraction. Thus (C.2.6) recovers M_0 and $B \otimes_A M \to N$ is an isomorphism.

Since A is Noetherian and N is finite over the finite A-algebra B, the submodule M is finite. The difference defining (C.2.6) is a map of finite A-modules. Its kernel is closed and has its canonical complete norm by the finite-module theorem. The effective isomorphism is bounded with bounded inverse.

A morphism of data preserves the equalizer (C.2.6). For canonical data it is therefore the base change of exactly one map of the descended modules. This proves full faithfulness as well as the specified inverse. For a domain algebra A_V, the module $M \otimes_A A_V$ has the restricted datum as its pullback;

the just proved uniqueness identifies it with the equalizer constructed there. Thus no unsupported commutation of a kernel with arbitrary completion is used. Coherent equivalence and these canonical restriction maps glue the construction on ordinary affinoid neighbourhoods of X. On overlaps the isomorphisms agree by full faithfulness. Tensor products are compatible by associativity and the same uniqueness.

It remains to check line bundles. An invertible coherent module on an affinoid corresponds to an invertible finite module: tensor it with its dual, and use affinoid coherent equivalence to identify evaluation and coevaluation. The resulting finite dual-basis identity makes its module finite projective. Explicitly, if coevaluation is $\sum_i u_i \otimes \lambda_i$, then $u = \sum_i \lambda_i(u) u_i$ splits a surjection from a finite free module.

Thus, for a line bundle upstairs, N is finite projective over B, hence finite projective over A, because B is finite free over A. The identification $N = B \otimes_A M$ and the retraction r make M an A-module direct summand of N. Consequently M is finite projective over A. For every prime $\mathfrak{p}$ of A choose a prime of the nonzero finite algebra $B \otimes_A \kappa(\mathfrak{p})$. After its residue-field extension, $M \otimes_A \kappa(\mathfrak{p})$ has dimension one, because N has rank one. The same dimension is therefore one before that field extension. This proves rank one at every prime.

The associated coherent module has flat ordinary stalks; by NAG-001753 it is free on ordinary neighbourhoods. Its rank is one, as may also be checked after evaluation in $\mathcal{H}(x)$. This proves the assertion for line bundles. □

Lemma C.2.7 (The topological coequalizer)**.** *The map $p : Y \to X$ is a closed surjection and hence a quotient map. Every pair $y_1, y_2 \in Y$ with $p(y_1) = p(y_2)$ lifts to a point of $Y^{[2]}$ with projections y_1, y_2. Consequently pullback identifies $C^0(X, \mathbb{R})$ with*

$$\{u \in C^0(Y, \mathbb{R}) : q_1^* u = q_2^* u \text{ on } |Y^{[2]}|\}.$$

Direct inputs: Lemma C.2.4, NAG-001450, NAG-001496, NAG-001692, NAG-001702, and STACKS-00JB.

Proof. At $x \in X$, put $H = \mathcal{H}(x)$. The actual fibre algebra is $C = H \otimes_K L$ by the finite-tensor and affinoid-fibre theorems. It is a nonzero n-dimensional H-algebra. Each residue field of an Artinian local factor is finite over the

complete field H and therefore has the unique extending absolute value. It defines a point of the fibre. Thus p is surjective.

If F is closed in Y and V is an affinoid neighbourhood in X, then $F \cap p^{-1}(V)$ is closed in the compact affinoid $p^{-1}(V)$. Its image is compact, hence closed in the Hausdorff space V. That image is exactly $p(F) \cap V$. The ordinary interiors of such V cover X, so $p(F)$ is closed. A continuous closed surjection is a quotient map.

For the pair assertion, let $E_i = \mathcal{H}(y_i)$, a finite extension of H. The nonzero finite-dimensional H-algebra $E_1 \otimes_H E_2$ has a field quotient F'. Both E_i embed in F'. Uniqueness of the extending absolute values makes these embeddings isometric. The compatible evaluations to F' are bounded; by the finite analytic tensor universal property they define a point of $Y^{[2]}$ with the required projections. This uses the entire tensor, whether or not it is reduced.

The equalizer condition on u now says exactly that u is constant on every fibre of p. It defines a unique function v on X with $u = v \circ p$. For an open set $O \subset \mathbb{R}$, the preimage of $v^{-1}(O)$ is $u^{-1}(O)$; the quotient property proves continuity of v. The converse follows by composition. □

Definition C.2.8. A continuous metric on a line bundle $\mathcal{M}$ assigns a norm on the one-dimensional $\mathcal{H}(x)$-vector space $\mathcal{M}(x)$ for every x. For each ordinary local frame e, the function $\varphi_e(x) = -\log \|e(x)\|$ must be finite and continuous. Scalar homogeneity uses the specified absolute value on $\mathcal{H}(x)$. An isometry of metrics on $Y^{[2]}$ is checked after pullback to the completed residue field of each of its points.

Theorem C.2.9 (Descent of continuous metrized line bundles)**.** *Let $(\mathcal{M}_Y, \delta)$ be a line bundle with the full analytic descent datum of Theorem C.2.6. Let $\|\cdot\|_Y$ be a continuous metric. It is the pullback of a unique continuous metric on the descended line bundle, relative to its specified descent isomorphism, if and only if*

$$\delta : (q_1^*\mathcal{M}_Y, q_1^*\|\cdot\|_Y) \longrightarrow (q_2^*\mathcal{M}_Y, q_2^*\|\cdot\|_Y)$$

is an isometry. Tensor products, duals and isometric isomorphisms are compatible with this descent.

Direct inputs: Theorems C.2.6 and Lemma C.2.7.

Proof. Descend the analytic line bundle first. On an ordinary open set U with descended frame e, let $\widetilde{e}$ be its frame on $p^{-1}(U)$ under the specified descent isomorphism. The function $u = -\log \|\widetilde{e}\|_Y$ is continuous. The cocycle sends the two pullbacks of $\widetilde{e}$ to each other. Its isometry condition therefore gives $q_1^* u = q_2^* u$ above U. Lemma C.2.7, also valid on every open restriction, gives a unique continuous function v_e on U with $p^* v_e = u$.

If $e' = he$ on an overlap, then upstairs $u_{e'} = u_e - \log |p^* h|$. Surjectivity of p implies $v_{e'} = v_e - \log |h|$. Hence $\|ae(x)\| = |a| \exp(-v_e(x))$ is independent of frame and defines the required continuous metric. The necessity and uniqueness follow by pulling back frame weights. Sums and negatives of weights give tensor and dual compatibility. An analytic isomorphism commuting with descent data descends by Theorem C.2.6; whether it is an isometry is checked by the surjective map p. □

The result is a statement about continuous metrics. It does not prove that a continuous descended weight is an ordinary smooth moment function, a model function, or a semipositive potential. Those are distinct regularity conditions on representatives.

Rank for norm-admissible finite maps

Here $q : Y \to X$ may be any norm-admissible finite morphism between the fixed K-spaces, with $q_* \mathcal{O}_Y$ locally free of constant rank $n \geq 1$ on ordinary opens. In particular this applies to the finite constant-extension map above. We work with algebraic determinants of coherent modules, before introducing any metric on a norm bundle.

Lemma C.2.10 (Rank of the finite direct image)**.** *For an analytic line bundle $\mathcal{L}$ on Y, the module $q_* \mathcal{L}$ is locally free of rank n on ordinary opens of X.*

Direct inputs: NAG-001624, NAG-001752, NAG-001753, STACKS-00JB; the finite dual-basis argument in Theorem C.2.6.

Proof. Choose an affinoid neighbourhood on which $B = \Gamma(q^{-1}V, \mathcal{O}_Y)$ is free of rank n over $A = \Gamma(V, \mathcal{O}_X)$. The module $P = \Gamma(q^{-1}V, \mathcal{L})$ is invertible over B. The dual-basis argument makes P a direct summand of a finite free B-module, so it is finite projective over A. For any residue field k of A, the algebra B_k is Artinian of k-dimension n. An invertible module on each local

Artinian factor is free of rank one: lift a nonzero residue generator and apply Nakayama; projectivity splits the resulting surjection, and its kernel has zero residue and hence is zero. It follows that $\dim_k P_k = \dim_k B_k = n$. Thus P is projective of constant rank n. Its coherent sheaf has flat ordinary stalks, and NAG-001753 gives ordinary local freeness of that rank. □

Pointed weighted germs and maximal-rank excision

The finite-module chain and its weights. Let $X = \mathcal{M}(A)$ be pure of analytic dimension d over a complete non-Archimedean field with its specified absolute value, and let a unit tuple f define $t_f : X \to \mathbb{R}^n$. For every finite A-module M there is a canonical finite nonnegative integral d-dimensional polyhedral chain

$$\mathcal{T}_f(M).$$

Its support is contained in $t_f(X)$. On any common finite subdivision of the actual image and $t_f(\partial_K X)$, the weight of a d-cell is the module weight $m_{M,f}(v)$ at any point of its relative interior. Cells of dimension less than d give no d-chain term. The chain is additive in short exact sequences, independent of subdivision. For $M = A$ every occurring d-cell has positive weight.

Proof. Theorem 5.39.3 gives a finite polyhedral image of dimension at most d and a finite boundary image of dimension at most $d - 1$. Choose one finite common subdivision with the boundary image as a subcomplex. At a point in the relative interior of a d-cell, the whole moment fibre is therefore interior, and the local image is contained in that cell's affine d-plane. Theorem 5.40.2 defines the nonnegative integer weight there. It is locally constant, by Theorem 5.42.1 on small convex neighbourhoods with the actual local fan presentations of Theorem 5.38.6. The relative interior of the cell is convex, so the weight is constant there. For the structure module it is positive by Theorem 5.37.1.

On a common subdivision of two choices, the generic weights compute the same whole-fibre module invariant. Thus their chains agree. Additivity follows from the exact-sequence formula of Theorem 5.40.2. □

The finite-cell functional. Let $X = \mathcal{M}(A)$ be a pure generalized affinoid of dimension d over the specified complete field, f a finite tuple of analytic units, and M a finite A-module. Use the canonical chain from the finite-module chain and weights and its weights m_σ. For a smooth (d, d)-superform α on an open neighbourhood of the actual compact image, define

$$\mathcal{I}_{M,f}(\alpha) = \sum_\sigma m_\sigma \int_\sigma \alpha.$$

This is independent of subdivision and is nonnegative when the tangential top coefficients of α are nonnegative.

Proof. All cells with nonzero weights are compact polytopes: the actual moment image is compact, and the complex is finite. Consequently the integral is a finite sum of the integrals constructed in Lemma 5.46.2. That lemma gives subdivision independence and positivity. □

Adjoining unit coordinates on the same affinoid. With the same pure generalized affinoid $X = \mathcal{M}(A)$, finite A-module M, and finite unit tuple f, let g be another finite unit tuple on X. Let a be the projection from the combined coordinates to the f-coordinates. For the canonical finite chains and finite-cell functionals, and every smooth top superform α near the actual f-moment image,

$$a_*\mathcal{T}_{(f,g)}(M) = \mathcal{T}_f(M), \qquad \mathcal{I}_{M,(f,g)}(a^*\alpha) = \mathcal{I}_{M,f}(\alpha).$$

Proof. Take the finite map $p = \mathrm{id}_X$, with $f_B = (f, g)$ and $f_A = f$. Each target unit is the corresponding coordinate of the joint tuple. In the following calculation the two chains and integrals are given by the finite-module chain and weights and the finite-cell functional. For this finite morphism, take finite global subdivisions of the two actual images and their boundary images by finite polyhedrality. Refine along the images of all source cells, using the finite linear elimination and hyperplane construction in the finite refinement calculation. Outside a finite union of polyhedra of dimension at most $d-1$ in each target d-cell, the target whole fibre is interior, and every source weight above it lies in a full-rank d-cell. The entire inverse weight set is finite, with at most one point per such source cell. For this finite identity, relative interior and composition give absolute interior at every point of those source fibres.

The local star of a whole interior fibre supplies pure local images near the target weight and at each source weight above it. Finite patching retains the complete source inverse support in a finite pure presentation on a small convex target neighbourhood in the target local image presentation. Theorem 5.42.2 then identifies the finite lattice-index sum with the target weight of M as an A-module. Its empty-inverse- image case gives zero on both sides. Thus the generic weight of every target d-cell is exactly its pushforward weight. The resulting equality of finite chains is $a_*\mathcal{T}_{f_B}(M) = \mathcal{T}_{f_A}(M)$. This proves the chain formula for the coordinate projection on the same affinoid.

The full actual source support is compact, so this pushforward is proper. On each full-rank source cell, Lemma 5.46.2 gives the factor $[N_\tau : a(N_\sigma)]$

in the integral. On a rank-dropping cell the top-degree pullback is zero. Grouping these finite cell integrals by their target cells proves the integral identity. No ambient support cutoff is needed here, because all the integration polytopes are compact. This proves the integral formula on the same affinoid. □

Fix a complete field K with its specified real-valued non-Archimedean absolute value; the valuation may be trivial. Affinoid algebras are generalized, with arbitrary positive real presentation radii. Finite maps and finite modules carry their canonical Banach structures. Let $X = \mathcal{M}(A)$ be nonempty and pure of analytic dimension $d \geq 1$, let $f = (f_1, \ldots, f_n) \in (A^\times)^n$, and let M be a finite A-module. Write $\mathcal{F}$ for its coherent sheaf and put

$$t = t_f = -\log|f|, \qquad F_w = t^{-1}(w), \qquad r_f(x) = \operatorname{trdeg}_{\widetilde{K}^{\mathrm{gr}}} \widetilde{K}^{\mathrm{gr}}(\widetilde{f_1(x)}, \ldots, \widetilde{f_n(x)}).$$

The graded field is taken inside $\widetilde{\mathcal{H}(x)}^{\mathrm{gr}}$. Thus $0 \leq r_f(x) \leq d$. Set

$$S_f(X) = \{x : r_f(x) = d\}, \qquad S_w = S_f(X) \cap F_w.$$

For an affinoid domain $U = \mathcal{M}(A_U) \subset X$, write $M_U = M \otimes_A A_U$ and use the already constructed finite integral d-chain $\mathcal{T}_{f|U}(M_U)$ of the finite-module chain. Domain purity is 5.35.3. Two such chains have the same *germ at* w when their restrictions to some real neighbourhood of w agree after a common finite subdivision. Equality is determined by the weights on the relative interiors of the d-cells. Only the chain and generic-weight clauses of that frozen theorem are used here, not its integral or pushforward clauses.

Let $T^d = (\mathbf{G}^d_{m,K})^{\mathrm{an}}$, let η_s be its Gauss point of weight $s \in \mathbf{R}^d$, and put $H_s = \mathcal{H}(\eta_s)$ and $\mathbb{T}_s = t_T^{-1}(s)$. The last space is the entire exact-radius polytorus. An ordinary affinoid neighbourhood contains an ordinary open neighbourhood; it need not contain the entire polytorus at the weight of the chosen point. All interiors without a topological subscript are analytic interiors. Compactness and Hausdorffness of affinoids are 2.24.1; the ordinary rational-neighbourhood basis is 2.41.1. Actual domain intersections and finite-module restrictions use 2.36.9 and 2.38.4.

Lemma C.2.11 (Gauss branches and the finite maximal-rank set)**.** *For any analytic map $\psi : X \to T^d$, the underlying set of $\psi^{-1}(\eta_s)$ is finite. If x belongs to this fibre and $x \in \mathrm{Int}(X/K)$, there are arbitrarily small ordinary affinoid neighbourhoods $Y = \mathcal{M}(B)$ of x and $N = \mathcal{M}(C)$ of η_s such that $\psi : Y \to N$ is norm-admissible finite and $\psi^{-1}(\eta_s) \cap Y = \{x\}$. One can take C integral. The ordinary stalk $\kappa_s := \mathcal{O}_{T^d,\eta_s}$ is a field, and, with*

$$E = B\widehat{\otimes}_C H_s = B \otimes_C H_s, \qquad P = M \otimes_A E,$$

E is the actual local Artinian fibre algebra at x, with residue field $\mathcal{H}(x)$. There are natural identifications

$$E = \mathcal{O}_{X,x} \otimes_{\kappa_s} H_s, \qquad P = \mathcal{F}_x \otimes_{\kappa_s} H_s,$$

and the finite integer

$$\delta_\psi(M, x) := \dim_{H_s} P = \dim_{\kappa_s} \mathcal{F}_x = \mathrm{length}_E(P)[\mathcal{H}(x) : H_s] \tag{C.2.7}$$

is independent of the isolating neighbourhoods. After shrinking N ordinarily and taking the inverse image in Y, the direct images of $\mathcal{O}_Y$ and $\mathcal{F}|Y$ are free, of ranks $\delta_\psi(A, x) > 0$ and $\delta_\psi(M, x)$ respectively. Moreover, writing $\beta_{\mathfrak{p}}(M) = \mathrm{length}_{A_{\mathfrak{p}}} M_{\mathfrak{p}}$, one has

$$\delta_\psi(M, x) = \sum_{\mathfrak{p} \in \mathrm{Min}(A)} \beta_{\mathfrak{p}}(M) \dim_{H_s}(E/\mathfrak{p}E). \tag{C.2.8}$$

For every unit tuple f and every w, the set S_w is finite, without an interior assumption on its points.

Proof. Choose a compact polyannulus containing $\psi(X)$. The actual fibre over η_s is affinoid over H_s; 2.33.11 identifies its points and completed residue fields with the points over η_s and their original completed residue fields. The Gauss dimension, tower formula, and Abhyankar bound give

$$0 \le d_{H_s}(y) = d_K(y) - d_K(\eta_s) \le d - d = 0$$

for every such point. Here the dependencies are 3.22.4, 3.22.2, and 3.22.7. The maximum formula therefore makes the fibre zero-dimensional. A zero-dimensional generalized affinoid has finitely many points: strictify it, use dimension invariance and strict finite normalization to make the strictified algebra finite over its field, and project its finite spectrum surjectively back.

These are exactly 1.17.6, 3.21.8, 1.12.2, 3.21.1, 1.14.4, 2.35.1, and 2.33.13. No finiteness assertion over the whole $\mathbb{T}_s$ follows.

We give the field-stalk argument over the original K. If a generalized affinoid D has analytic dimension at most d and $z \in \mathcal{M}(D)$ has $d_K(z) = d$, then $\mathfrak{p} = \ker(D \to \mathcal{H}(z))$ is minimal. Otherwise choose a minimal prime $\mathfrak{q} \subsetneq \mathfrak{p}$. Simultaneously strictify $D/\mathfrak{q}$ and $D/\mathfrak{p}$ by a finite K-free extension, making the new field nontrivially valued as well. The domain-preservation and quotient statements of 5.35.1, together with faithful flatness 1.18.8, preserve the strict inclusion of these primes. The strictified domain has Krull dimension at most d; quotienting by a nonzero prime lowers it to at most $d - 1$, since every prime chain in the quotient can be preceded by the zero prime of the domain. Analytic dimension invariance gives $\dim(D/\mathfrak{p}) \leq d - 1$, contradicting the Abhyankar bound applied to z on that quotient. Here equality of strict analytic and Krull dimensions is the strict dimension theory in 3.21.8 and 1.12.2.

An affinoid neighbourhood of η_s in T^d is an affinoid domain of affine d-space. It is regular by 2.35.23, and is a finite product of integral affinoid algebras by 2.52.2. Pass to the open-and-closed component containing η_s. It is still an ordinary neighbourhood. Its evaluation kernel is minimal by the preceding paragraph, hence zero. If a germ at η_s evaluates to zero, represent it on such an integral neighbourhood inside its domain of definition. It is zero there. Evaluation on the ordinary stalk is therefore injective. The description of its maximal ideal in 2.33.16 makes that ideal zero, so this local ring is the asserted field κ_s. This argument does not identify κ_s with its completion.

The torus is boundaryless over K by 2.33.27, and absolute interior at x implies relative interior for ψ there: test on ordinary affinoid neighbourhoods and use 2.44.6 and the source-factor implication. The finite set already proved makes x isolated in its analytic fibre. The local finite criterion 2.49.1, applied inside an ordinary neighbourhood disjoint from the other fibre points, gives ordinary open finite neighbourhoods. Restrict the target to an ordinary affinoid neighbourhood, and then to its integral component at η_s. Finite base change gives the asserted $Y \to N$; Y remains an ordinary neighbourhood of x.

The finite direct-image and stalk identities 2.35.15 and 2.35.17 give

$$B \otimes_C \kappa_s = \mathcal{O}_{X,x}, \qquad (M \otimes_A B) \otimes_C \kappa_s = \mathcal{F}_x.$$

There is only one summand because the isolated analytic fibre has only x. The finite tensor comparison 2.33.19 then gives the displayed identifications with E and P, retaining their actual canonical complete norms. A finite algebra over the complete field H_s has one analytic point for each local Artinian factor. Thus E is local, and its residue field is precisely $\mathcal{H}(x)$ by 2.33.11. A composition series of P has copies of this residue field as its simple factors, proving (C.2.7). Since κ_s is a field, both finite direct-image stalks are free. Apply 2.35.16 to each, and intersect the resulting ordinary neighbourhoods. This derives freeness from the Gauss stalk; no generic-flatness assumption has been made.

For (C.2.8), the fraction-field argument applies: $C \hookrightarrow H_s$ factors through $\mathrm{Frac}(C)$, so H_s is flat over C. The domain map $A \to B$ is flat by ordinary single-domain flatness; hence $A \to E$ is flat. The algebraic composition-series argument of the local Artinian calculation now applies verbatim to this actual Artinian algebra: flat going down makes its prime contract to a minimal prime of A, and tensoring a composition series at that prime gives the displayed sum. Every other minimal-prime quotient of E is zero. In particular neither nilpotent length nor the full residue-field degree is discarded.

Finally, if $r_f(x) = d$, some d of the n homogeneous elements $\widetilde{f_i(x)}$ are algebraically independent. For that coordinate subset I, the map $\psi_I = (f_i)_{i\in I}$ sends x to η_{w_I}: for every Laurent polynomial the nonzero initial terms of maximal norm cannot cancel, which is exactly the weighted Gauss norm. There are finitely many choices of I, and each $\psi_I^{-1}(\eta_{w_I})$ is finite by the first paragraph. Their union contains S_w. If $n < d$, S_w is empty. □

Theorem C.2.12 (Cofinal pointed weighted germs)**.** *Let $x \in \mathrm{Int}(X/K)$ and $w = t(x)$. There is an ordinary affinoid neighbourhood Y_0 of x such that the germs at w of*

$$\mathcal{T}_{f|U}(M_U) \qquad (x \in \mathrm{Int}_{\mathrm{top}}(U, X),\ U \subset Y_0)$$

are identical for all ordinary affinoid neighbourhoods U. They define a germ $\mathcal{C}_{x,f}(M)$, independent of all auxiliary admissible generic projections and their finite Gauss neighbourhoods. It is additive in M. If $r_f(x) < d$, this germ is zero. If $r_f(x) = d$, it is a nonnegative integral weighted rational d-fan germ on the pure pointed fan $w + C_x$ of 5.55.8; for $M = A$ its support is the whole of that fan germ.

In the case $r_f(x) = d$, a projection $Q : \mathbb{Z}^n \to \mathbb{Z}^d$ is admissible for this proof if it is injective on the span of every d-cone of C_x. For each such Q a finite ordinary Gauss chart as in Lemma C.2.11 exists at x for $\psi = f^Q$. In each such chart Y_Q, for every ordinary affinoid neighbourhood $U \subset Y_Q$ of x, there are a real neighbourhood B of w and finitely many proper affine hyperplanes $H \subset \mathbf{R}^d$ such that

$$t^{-1}(v) \cap Y_Q = t^{-1}(v) \cap U \quad (v \in B,\ Qv \notin H).$$

Both full fibres are then interior in their respective source domains. The inverse images of H have dimension at most $d-1$ on each d-cone.

If C_x is the d-plane $N_{\mathbb{R}}$ for a saturated rank-d lattice $N \subset \mathbb{Z}^n$, the germ has constant weight

$$\mu_{x,f}(M) = \frac{\delta_{fQ}(M, x)}{[\mathbb{Z}^d : Q(N)]} \in \mathbb{Z}_{\geq 0} \tag{C.2.9}$$

for every integral Q injective on N. No analogous single quotient of the total projected degree is asserted at a nonflat fan.

Proof. Write $r = r_f(x)$. The full pointed-fan theorem supplies W_0 such that every ordinary neighbourhood of x inside W_0 has moment-image germ $w+C_x$, of pure dimension r. If $r < d$, no such image has a d-dimensional cell near w, and the support clause of finite-module chain support proves that the chain germ is zero. This includes the case $n < d$.

Suppose $r = d$. Choose an integral Q injective on the span of every maximal cone: the failure for each of the finitely many rational d-planes is a proper determinant-zero condition on a $d \times n$ matrix; a rational matrix outside their finite union exists, and clearing denominators gives the required integer matrix. For every sufficiently small ordinary neighbourhood of x, its f-image contains the pointed d-cones, and their Q-images have dimension d. Apply the full pointed-fan theorem again, now to the d units f^Q. It follows that $r_{fQ}(x) = d$. As in the last paragraph of Lemma C.2.11, this means $f^Q(x) = \eta_{Qw}$.

That lemma gives a finite ordinary affinoid chart $\psi : Y_0 \to N_0$, with central Gauss fibre $\{x\}$. Choose it inside W_0 and inside the inverse image of a sufficiently small real ball where the pointed upper bound holds. Consequently

$$t(Y_0) \subset w + C_x. \tag{C.2.10}$$

These source restrictions are allowed by the arbitrarily small neighbourhood clause of the local finite criterion. They do not replace N_0 by the entire central polytorus.

Fix an ordinary affinoid neighbourhood $U \subset Y_0$ of x. The compact set

$$D = Y_0 \setminus \mathrm{Int}_{\mathrm{top}}(U, Y_0)$$

does not meet the Gauss fibre. Its image is compact and closed in the Hausdorff torus, so

$$O = \mathrm{Int}_{\mathrm{top}}(N_0, T^d) \setminus \psi(D)$$

is an ordinary open neighbourhood of η_{Qw}. Choose a compact full polyannulus with Qw in the interior of its weight box. Apply the frozen whole-torus overlap lemma C.1.43 to O intersected with this polyannulus. There are a real neighbourhood B' of Qw and finitely many proper affine hyperplanes H such that

$$\mathbb{T}_s \subset O, \qquad \psi^{-1}(\mathbb{T}_s) \cap Y_0 \subset \mathrm{Int}_{\mathrm{top}}(U, Y_0) \quad (s \in B' \setminus H). \tag{C.2.11}$$

This assertion retains every analytic point over every such $\mathbb{T}_s$, including all of its Gauss lifts in Y_0.

For v near w with $Qv \in B' \setminus H$, equation (C.2.11) identifies the entire f-fibre in Y_0 with the entire f-fibre in U. These are identical analytic domains, and the restricted modules are identical. The target polytorus is contained in the ordinary interior of N_0 in the boundaryless torus. Its inverse image is therefore absolutely interior in Y_0, by finite relative interior and composition. Its points lie in the ordinary interior of U in Y_0, so they are absolutely interior in U as well. The precise locality inputs are 2.33.18, 2.44.3, and forward composition with ordinary target testing.

The inverse image of every hyperplane in H cuts each d-cone of C_x in dimension at most $d-1$, since Q is injective on its span. Make a common finite subdivision of the two image germs, these cuts, and their faces. At generic points of every d-cell, the local image lies in its affine d-plane and the whole fibre is interior on both sides. The exact-domain identification above and 5.40.2 therefore give identical weights, using the saturated tangent lattice of that cell. This proves equality of the two d-chain germs. Finite polyhedrality makes each germ a weighted rational fan after shrinking at w; for the structure module, positivity in finite-module chain positivity and full stabilization give exactly the asserted support. Restriction $M \mapsto M_U$

is exact by ordinary single-domain flatness. Additivity then follows from the finite-module chain.

For clarity, the comparison just proved first compares each $U \subset Y_0$ with Y_0. Two such U's can be compared through a common ordinary affinoid neighbourhood of x inside their ordinary interiors. Charts constructed using a different admissible projection can likewise be compared through a common smaller ordinary affinoid neighbourhood, applying the same argument in each chart. Thus both the cofinal germ and the full-fibre comparison off the indicated cuts are independent of the chosen projection. Different nearby Gauss lifts have not been identified or removed; they occur in the same whole fibre being compared.

Finally suppose $C_x = N_{\mathbb{R}}$. Use the free direct-image shrinking in Lemma C.2.11, retaining (C.2.10). For $s = Qv$ near Qw outside the hyperplanes, the finite inverse image of $\mathbb{T}_s$ in this chart equals the single original moment fibre at v: Q is injective on the entire plane containing the moment image. Its actual Gauss module has dimension $\delta_{fQ}(M, x)$, because the direct image is free of that rank. The interior flat-germ formula 5.40.2 divides this number by exactly $[\mathbb{Z}^d : Q(N)]$. It determines the weight on a dense subset of every d-cell, and hence the constant weight germ. Equation (C.2.7) keeps the actual local length and full field degree, while (C.2.8) keeps the generic component lengths. □

Theorem C.2.13 (Excision of lower-rank central loci in top degree)**.** *Let $w \in t(X)$ and suppose only that*

$$S_w \subset \operatorname{Int}(X/K). \tag{C.2.12}$$

Choose pairwise disjoint ordinary affinoid neighbourhoods U_x of all $x \in S_w$, sufficiently small for Theorem C.2.12, and contained in $\operatorname{Int}(X/K)$. Then

$$[\mathcal{T}_f(M)]_w = \sum_{x \in S_w} \mathcal{C}_{x,f}(M). \tag{C.2.13}$$

More precisely, there are a real neighbourhood B of w and a finite union E of rational polyhedral fan germs translated to w, each of dimension at most $d-1$, such that for $v \in B \setminus E$ the entire original source fibre satisfies

$$F_v = \coprod_{x \in S_w} (F_v \cap U_x) \subset \bigcup_{x \in S_w} \operatorname{Int}_{\mathrm{top}}(U_x, X). \tag{C.2.14}$$

The assertion permits positive-dimensional analytic projection fibres and boundary points elsewhere in the central fibre F_w. If S_w is empty, the entire image germ has dimension at most $d-1$ and the d-chain germ is zero.

Proof. Lemma C.2.11 makes S_w finite. Hausdorffness, the ordinary affinoid-neighbourhood basis, and the openness of analytic interior allow the indicated disjoint U_x. Their ordinary interiors in X cover every point of S_w. The residual compact set

$$C = F_w \setminus \bigcup_{x \in S_w} \mathrm{Int}_{\mathrm{top}}(U_x, X)$$

consists entirely of points y with $r_f(y) < d$. For each such y, the pointed upper bound 5.55.7 supplies an ordinary affinoid neighbourhood V_y, a real neighbourhood of $w = t(y)$, and a finite rational fan C_y of dimension $r_f(y)$ such that $t(V_y)$ in that neighbourhood is contained in $w + C_y$. This bound requires neither interior nor purity at y. Choose finitely many V_y whose ordinary interiors cover C, and let E be the union of their translated fans near w. It has dimension at most $d-1$.

Let G be the union of these ordinary interiors and the ordinary interiors of all U_x. It is an ordinary open set containing F_w. The complement $X \setminus G$ is compact; its image under t is compact and does not contain w. Shrink a real neighbourhood B to miss that image and to satisfy all the finitely many pointed upper bounds. Every point of F_v, for $v \in B \setminus E$, must then lie in an ordinary interior of some U_x. Pairwise disjointness gives (C.2.14). Notice that this is a statement about the whole fibre in the fixed original X, not merely an inverse image within one selected local branch.

At such a weight the partition into $F_v \cap U_x$ is a finite disjoint partition by relatively open and closed analytic domains. The degree-zero equalizer on this disjoint cover and the actual domain restrictions give

$$\mathcal{O}(F_v) = \prod_{x \in S_w} \mathcal{O}(F_v \cap U_x), \qquad M|_{F_v} = \bigoplus_{x \in S_w} M|_{F_v \cap U_x},$$

with zero factors omitted. These are the actual fibre algebras and modules, including every local Artinian factor. Each point of the fibre is absolutely interior in X, since $U_x \subset \mathrm{Int}(X/K)$, and in U_x, since it is ordinarily interior there. The last assertion uses the ordinary domain test and forward composition.

Take a common finite polyhedral subdivision for $t(X)$, the images of the U_x, the exceptional set E, and their faces, and then work at generic points of its

d-cells. All applicable local image germs lie in the same affine d-plane, with the same saturated tangent lattice N; absent local images contribute zero. Choose an integral projection injective on N. The interior module-weight theorem 5.40.2 applies to X and every nonempty U_x fibre. Tensoring the displayed finite product decomposition with the projected Gauss field retains all factors, so the dimensions of the actual Gauss modules add. Dividing every term by the common index $[\mathbb{Z}^d : Q(N)]$ proves equality of the generic weights. By the finite-module chain, this proves the chain-germ equality (C.2.13) by Theorem C.2.12. If S_w is empty, the same compact-cover argument puts the whole image near w inside E, giving the final assertion. □

Principal zero spaces on generalized affinoids

Theorem C.2.14 (Generalized affinoid principal zero purity; F8ZP-G)**.** *Let A be a nonzero generalized K-affinoid algebra pure of analytic dimension $n \geq 1$. If f avoids every minimal prime of A, then $\mathcal{M}(A/fA)$ is empty or pure of analytic dimension $n-1$. In particular this holds for every non-zero-divisor $f \in A$. For $n = 0$, every element avoiding the minimal primes is a unit. Moreover, in the original algebra A, for every $\mathfrak{q} \in \mathrm{Min}_A(fA)$ and $\mathfrak{p} \in \mathrm{Min}(A)$ contained in $\mathfrak{q}$, the ordinary height of $\mathfrak{q}/\mathfrak{p}$ in $A/\mathfrak{p}$ is one.*

Proof. Put $B = A/fA$. This is an actual affinoid quotient by NAG-001561–001562. If $B = 0$, there is nothing to prove. Choose one finite K-free polyradius r, and put $L = K_r$, such that A_L and B_L are strict; NAG-001557 permits this simultaneous choice. If K is trivially valued, include any additional radius other than 1 in the strictification request, so that L is nontrivially valued. The quotient comparison and faithful flatness in NAG-001566 give

$$B_L = (A/fA)_L \simeq A_L/fA_L \neq 0. \tag{C.2.15}$$

By NAG-002291, the minimal primes of A_L are exactly $\mathfrak{p}A_L$ for $\mathfrak{p} \in \mathrm{Min}(A)$, with contraction $\mathfrak{p}$ and with the same componentwise analytic dimension. Thus A_L is pure of dimension n, and f avoids each of its minimal primes. Analytic and Krull dimensions agree for these strict algebras by NAG-001664. Proposition C.1.21 makes B_L pure of dimension $n-1$ (and rules out $B \neq 0$ when $n = 0$).

Apply NAG-002291 again, now to the full quotient B. For every $\mathfrak{b} \in \mathrm{Min}(B)$, the prime $\mathfrak{b}B_L$ is minimal and

$$\dim_K \mathcal{M}(B/\mathfrak{b}) = \dim_L \mathcal{M}\big(B_L/\mathfrak{b}B_L\big) = n-1.$$

This is the required descent of componentwise analytic purity. Nonzero affinoids have nonempty spectra by NAG-001572, so the empty-space and zero-algebra alternatives agree. The regular case follows from Lemma C.1.13; its regularity also persists upstairs by the flatness in NAG-001566. The ordinary height assertion in the original A follows by the minimal-prime and Tag 00KV argument of Proposition C.1.21: it uses only that $A/\mathfrak{p}$ is a Noetherian domain and that f is nonzero there. It is the strictification argument, not this ordinary height statement alone, that supplies the asserted analytic dimension.

Only this finite free-radius extension, with its exact minimal-prime bijection, was used. No assertion of purity ascent by arbitrary flat extension, of freeness over completed residue fields, or of equality between generalized analytic dimension and ordinary Krull dimension has entered the argument. □

Theorem C.2.15 (Actual refinements and zero-space purity; F8ZP-R)**.** *Let X be a good Hausdorff K-analytic space pure of analytic dimension $n \geq 1$, let $U \subseteq X$ be open, and let $f \in \mathcal{O}_{U_G}(U)$ act injectively on $\mathcal{O}_{U_G}$. Let $D = V(f) \hookrightarrow U$ be the actual principal closed analytic subspace. Then:*

(i) D is empty or pure of analytic dimension $n-1$.

(ii) For every actual affinoid domain $V = \mathcal{M}(B) \subseteq U$, including a domain that is not an ordinary neighbourhood in U, its restricted zero space is the full quotient $D \cap V = \mathcal{M}(B/fB)$, empty or pure of analytic dimension $n-1$.

(iii) These conclusions hold on every nonempty finite intersection $V_I = \bigcap_{i \in I} V_i$ of actual affinoid domains in U, and on further actual affinoid-domain refinements of V_I.

The same conclusion holds for an already given effective Cartier closed subspace locally defined by such regular sections.

Proof. If V is nonempty, NAG-002413 makes B pure of analytic dimension n. The kernel sheaf is formed on sections: kernels of compatible sections glue uniquely. Thus a section on the G-domain V killed by f belongs to this zero kernel sheaf. This gives an injection $B \xrightarrow{f} B$. Theorem C.2.14 applies to this ring and section. The defining quotient is actual by NAG-001562. Its restriction from an affinoid chart is the principal quotient just written, by NAG-001846 and the finite tensor comparison NAG-001565. This proves (ii), with the zero-algebra convention covering empty domains.

For clarity, on a further actual affinoid domain $W = \mathcal{M}(C) \subseteq V$ these same interfaces give bounded canonical identifications

$$C \widehat{\otimes}_B (B/fB) \simeq C \otimes_B (B/fB) \simeq C/fC. \tag{C.2.16}$$

The first tensor has a finite canonical second factor. It is not an assertion about arbitrary Banach modules. Moreover the restriction $B \to C$ is flat by ordinary single-domain flatness, so f remains a non-zero-divisor in C even if regularity was originally specified on B alone. The quotient in (C.2.16) is the actual inverse-image domain in $D \cap V$, with its nilpotents. Both purity of C and purity of its zero quotient follow from the statements already applied.

The intersections V_I are actual affinoid domains by NAG-002411; hence (ii) and (C.2.16) apply to them and to their refinements. This proves (iii). Each point of D has an ordinary affinoid neighbourhood obtained by intersecting D with an affinoid neighbourhood in U. Assertion (ii) proves purity on these neighbourhoods, which is exactly the good-space definition. Thus (i) follows. In the effective Cartier variant apply the same argument on its defining open charts. On overlaps two local equations differ by a unit, hence define the same ideal and actual quotient. Purity is local in these neighbourhoods, so the conclusions agree on overlaps. No global irreducible-component matching is required. □

A specified complete-intersection slice

Corollary C.2.16 (Determinants after a DVR slice)**.** *Let $(R, \mathfrak{m}, k)$ be Noetherian local, let S be a finite free commutative R-algebra of rank $n \geq 1$, and let $f_1, \ldots, f_c \in \mathfrak{m}$ be an R-regular sequence (the empty sequence is allowed). Put $I = (f_1, \ldots, f_c)$, and assume $A = R/I$ is a DVR. For $b \in S$, assume its image $\bar{b}$ is a non-zero-divisor in $B = S/IS$, and assume $B/\bar{b}B \neq 0$. Put $D = \det_R(m_b : S \to S)$. Then*

$$\begin{aligned} \operatorname{length}_R R/(I, D) &= \operatorname{ord}_A(\bar{D}) \\ &= \sum_{\mathfrak{q} \in \operatorname{Max} S} [\kappa(\mathfrak{q}) : k] \operatorname{length}_{S_{\mathfrak{q}}} S_{\mathfrak{q}}/(I, b)S_{\mathfrak{q}}. \end{aligned} \tag{C.2.17}$$

All lengths are finite. The sequence $(f_1, \ldots, f_c, D)$ is regular in R. On every local factor where the final quotient is nonzero, $(f_1, \ldots, f_c, b)$ is regular in $S_{\mathfrak{q}}$. Thus these are ordinary local complete-intersection lengths whenever this ring data describe the chosen geometric intersection.

Direct inputs: Lemma C.1.95; free tensors, determinant polynomials and the regular-sequence argument below.

Proof. Because $S \simeq R^n$ as an R-module, $B \simeq A^n$. Reducing the multiplication matrix modulo I gives $\bar{D} = \det_A(m_{\bar{b}}) \neq 0$ by Lemma C.1.95. This also proves that $\bar{D}$ is a non-zero-divisor in A, giving the regular sequence in R. The quotients $R/(I, D)$ and $S/(I, b)$ are annihilated by I, so their submodule lattices, and hence their lengths, can be computed over the corresponding quotient rings. Apply the lemma to $A \to B$ and identify $B_{\bar{\mathfrak{q}}}/(\bar{b})$ with $S_{\mathfrak{q}}/(I, b)$. Every maximal ideal of S contracts to $\mathfrak{m}$, by the finite-integral argument in the lemma, so contains I. Their residue fields are unchanged by this quotient. This proves (C.2.17).

At each step of the R-regular sequence, the injection given by multiplication by f_i remains injective on the free quotient module $S/(f_1, \ldots, f_{i-1})S \simeq (R/(f_1, \ldots, f_{i-1}))^n$. Localization preserves injectivity. The final multiplication by $\bar{b}$ is injective by assumption. On a factor with nonzero final quotient, all elements of the sequence belong to its maximal ideal and all intermediate quotients are nonzero. This is the stated regular-sequence assertion. □

Appendix D

Polarized towers with compatible cyclic actions

A *polarized isomorphism* $(X, \mathcal{L}) \to (Y, \mathcal{M})$ is a pair (f, λ) consisting of an isomorphism of schemes and a specified isomorphism $\lambda : f^*\mathcal{M} \simeq \mathcal{L}$. Thus its line-bundle map is part of the datum.

Proposition D.0.1 (Orbit tensor and its canonical linearization)**.** *Let a cyclic group $G = \langle \tau \rangle$ of order e act on a scheme X, and let $\mathcal{A}$ be an invertible sheaf on X, with no chosen linearization. The orbit tensor*

$$\mathcal{N} = \bigotimes_{j=0}^{e-1} (\tau^j)^* \mathcal{A} \tag{6}$$

has a canonical G-linearization. If $i : Z \hookrightarrow X$ is an invariant closed subscheme and G acts identically on Z as a scheme, then this linearization acts identically on $i^*\mathcal{N}$. If X is separated over an affine scheme S and $\mathcal{A}$ is relatively ample over S, then so is $\mathcal{N}$; the group action need not be S-linear.

Proof. The factors of $\tau^*\mathcal{N}$ have indices $1, 2, \dots, e$. Using $\tau^e = \mathrm{id}$, reorder them cyclically into indices $0, 1, \dots, e-1$. This gives $\lambda : \tau^*\mathcal{N} \simeq \mathcal{N}$. Iterating this construction e times returns every factor to its original position. The ordinary tensor symmetry is the permutation of pure tensors, so the composite is the identity. The iterates of λ therefore satisfy the cyclic group law and define the claimed linearization.

On Z, the equality $\tau^j \circ i = i$ gives canonical identifications

$$i^*(\tau^j)^*\mathcal{A} = i^*\mathcal{A}, \qquad i^*\mathcal{N} \simeq (i^*\mathcal{A})^{\otimes e}. \tag{7}$$

The restricted λ is the cyclic permutation of these identical line-bundle factors. On an open of Z where $i^*\mathcal{A}$ has a generator a, it fixes $a^{\otimes e}$. It fixes every coefficient as well, because $\tau|_Z$ is the identity morphism. Hence it fixes every local section. This proves identity of the full module, including its behaviour over any nilpotent functions on Z. It also proves identity on the associated total line-bundle scheme.

For ampleness, Stacks Tag 01VK turns relative ampleness over the affine S into ampleness on X. Each automorphism τ^j preserves ampleness, by Stacks Tag 0B3E. For two ample invertible sheaves $\mathcal{H}_1, \mathcal{H}_2$ on X, Stacks Tag 0DNK makes $\mathrm{pr}_1^*\,\mathcal{H}_1 \otimes \mathrm{pr}_2^*\,\mathcal{H}_2$ ample on $X \times_S X$. Here S is quasi-separated because it is affine. Pulling back along the closed diagonal by Stacks Tag 0B3E shows that $\mathcal{H}_1 \otimes \mathcal{H}_2$ is ample on X. Induction gives ampleness of (6), and Stacks Tag 01VK converts it back to relative ampleness over S. □

Lemma D.0.2 (Full faithfulness for polarized isomorphisms)**.** *Let R be a ring, let $\pi \in R$, and suppose that the canonical map $R \to \varprojlim_{n\geq 1} R/\pi^n R$ is an isomorphism. Write $R_n = R/\pi^n R$. Let X, Y be proper, flat, finitely presented R-schemes, and let $\mathcal{L}, \mathcal{M}$ be relatively ample invertible sheaves on them. Reduction gives a bijection*

$$\mathrm{Isom}_R^{\mathrm{pol}}((X,\mathcal{L}),(Y,\mathcal{M})) \xrightarrow{\sim} \varprojlim_n \mathrm{Isom}_{R_n}^{\mathrm{pol}}((X_n,\mathcal{L}_n),(Y_n,\mathcal{M}_n)). \tag{1}$$

Here the inverse limit means compatible polarized isomorphisms with respect to the specified reduction maps. The analogous statement holds for polarized isomorphisms covering a fixed automorphism b of $\operatorname{Spec} R$ that preserves the closed subscheme $\operatorname{Spec} R_n$ for every n. No Noetherian hypothesis on R is imposed.

Proof. Apply Stacks Tag 0D4F to each polarized scheme, allowing the identity thickening of its affine base, and enlarge the two bounds to a common $d_0 \geq 1$. For every $d \geq d_0$, the modules

$$P_d = H^0(X, \mathcal{L}^{\otimes d}), \qquad Q_d = H^0(Y, \mathcal{M}^{\otimes d})$$

are finite projective over R. The arbitrary-base-change assertion in the proof of that lemma identifies their reductions with $H^0(X_n, \mathcal{L}_n^{\otimes d})$ and $H^0(Y_n, \mathcal{M}_n^{\otimes d})$. Moreover the graded algebras

$$A_X = R \oplus \bigoplus_{d\geq d_0} P_d, \qquad A_Y = R \oplus \bigoplus_{d\geq d_0} Q_d \tag{2}$$

functorially reconstruct the pairs as $(\operatorname{Proj} A_X, \mathcal{O}(1))$ and $(\operatorname{Proj} A_Y, \mathcal{O}(1))$.

For any finite projective R-module P, the canonical map $P \to \varprojlim_n P/\pi^n P$ is an isomorphism. Indeed, write P as the image of an idempotent matrix E on R^m. The assertion becomes $ER^m = \varprojlim_n \overline{E} R_n^m$, which follows from the assumed identity for R. This is the finite-projective completeness argument in the proof of Stacks Tag 0D4B.

Let (f_n, λ_n) be a compatible system on the right of (1). For every $d \geq d_0$, its maps on sections are

$$u_{n,d} : Q_d/\pi^n Q_d \longrightarrow P_d/\pi^n P_d, \qquad s \longmapsto \lambda_n^{\otimes d}(f_n^* s). \tag{3}$$

Taking the inverse limit in each degree gives $u_d : Q_d \to P_d$. The same construction applied to the inverse polarized isomorphisms gives inverse maps. The u_d preserve products: after reduction modulo every π^n the required equality holds by (3), and its values lie in the separated module $P_{d+d'}$. Together with the identity on degree zero, they therefore give a graded isomorphism $A_Y \simeq A_X$.

Functoriality of Proj, including the maps on all twists in Stacks Tag 01MY, gives an isomorphism of schemes and an isomorphism of their $\mathcal{O}(1)$ sheaves. The canonical identifications from Stacks Tag 0D4F turn this into (f, λ) on the original pairs. Its reductions are exactly (f_n, λ_n), by the functoriality of those identifications. Conversely, any polarized isomorphism inducing the prescribed reductions has the same maps (3), hence the same u_d by completeness and separation. The same functorial reconstruction makes it equal to (f, λ). This proves both directions of (1).

The limit was taken degree by degree; it was not interchanged with an infinite direct sum. All degrees $d \geq d_0$ were retained, so the reconstruction recovers the actual invertible sheaf and its map, not merely a selected tensor power. Finally, an isomorphism covering b is an R-isomorphism to the pullback pair $b^*(Y, \mathcal{M})$. This twist commutes with reduction by the stated hypothesis on b. Applying (1) to the twisted target proves the last assertion. □

Theorem D.0.3 (Equivariant algebraization of a supplied nodal tower)**.** *Let F be a complete nontrivially real-valued field, $R = F^\circ$, $\mathfrak{m}_R = F^{\circ\circ}$, and $k_R = R/\mathfrak{m}_R$. Let a cyclic group G of order $e \geq 1$ act isometrically on F, and put $b_g = \operatorname{Spec}(g^{-1}|_R)$. Fix $0 \neq \pi \in \mathfrak{m}_R$, set $R_n = R/\pi^n R$, and suppose given proper, flat, finitely presented R_n-schemes X_n with cartesian*

transition closed immersions $i_n : X_n \hookrightarrow X_{n+1}$. Suppose compatible semilinear G-actions on these schemes are specified, covering the induced $b_{g,n}$. Assume that $C = X_1 \times_{R_1} k_R$ is at-worst-nodal of pure dimension one and that the action on the entire scheme *C is the identity.*

For any ample invertible sheaf $\mathcal{A}_C$ on C, one can choose compatible ample lifts $\mathcal{A}_n$ and form the orbit tensors

$$\mathcal{N}_n = \bigotimes_{j=0}^{e-1} (\tau_n^j)^* \mathcal{A}_n, \tag{4}$$

where τ_n is the action of a generator of G. These form a compatible G-linearized ample tower, with identity action on $\mathcal{N}_n|_C \simeq \mathcal{A}_C^{\otimes e}$. There exist a projective, flat, finitely presented nodal R-scheme Y' of relative dimension one, an ample invertible sheaf $\mathcal{N}'$ on Y', a semilinear G-action on Y', and a compatible linearization of $\mathcal{N}'$, together with compatible equivariant polarized identifications

$$(Y', \mathcal{N}') \times_R R_n \simeq (X_n, \mathcal{N}_n). \tag{5}$$

The actions on both Y'_{k_R} and $\mathcal{N}'|_{Y'_{k_R}}$ are the identity. For a fixed polarized tower (4), this algebraization is unique up to the unique compatible equivariant polarized isomorphism. Invertibility of e is not required here.

Proof. The isometries preserve R and every ideal $\pi^n R$: membership in this ideal is the inequality $v(a) \geq nv(\pi)$. Hence all indicated actions on quotient bases exist. The rank-one completeness argument in B.1.3 gives $R = \varprojlim R_n$.

The exact result B.1.2 gives the compatible ample $\mathcal{A}_n$, with transition isomorphisms $\varphi_n : i_n^* \mathcal{A}_{n+1} \simeq \mathcal{A}_n$ and a specified restriction to $\mathcal{A}_C$. It also supplies at least one ample $\mathcal{A}_C$, if none was prescribed. Apply D.0.1 at each level. Its hypotheses hold because X_n is separated over the affine base $\operatorname{Spec} R_n$. It gives ampleness of (4), its canonical permutation linearization, and identity on the full restricted line bundle on C.

We check the extra tower compatibility explicitly. Equivariance of i_n gives canonical identifications

$$i_n^* (\tau_{n+1}^j)^* \mathcal{A}_{n+1} \simeq (\tau_n^j)^* i_n^* \mathcal{A}_{n+1}.$$

Tensor the maps $(\tau_n^j)^* \varphi_n$ over all j to obtain $\nu_n : i_n^* \mathcal{N}_{n+1} \simeq \mathcal{N}_n$. Applying the cyclic permutation linearization before or after this tensor map permutes the same indexed factors and applies the same maps on them. Thus ν_n is

equivariant. Composing these maps gives compatibility at all levels. Their restrictions to C identify (4) with $\mathcal{A}_C^{\otimes e}$, with the identity action already given by the orbit-tensor result.

Now apply B.1.3 to the ordinary polarized tower $(X_n, \mathcal{N}_n, \nu_n)$. It gives the projective flat finitely presented pair $(Y', \mathcal{N}')$ and the underlying polarized identifications (5). The nodal hypothesis on C gives nodality of relative dimension one. At this stage no action on Y' has been asserted.

Let b be the base automorphism corresponding to the chosen generator. Via (5), its tower action and linearization are compatible polarized R_n-isomorphisms from $(Y', \mathcal{N}')_{R_n}$ to its b_n-twist. Both algebraic pairs $(Y', \mathcal{N}')$ and $b^*(Y', \mathcal{N}')$ satisfy Lemma D.0.2. That lemma gives a unique polarized R-isomorphism between them. Composing its scheme map with the first projection from the twist gives a semilinear automorphism $\tau : Y' \to Y'$ covering b, and its line-bundle map is $\lambda : \tau^* \mathcal{N}' \simeq \mathcal{N}'$.

The e-fold composite of this polarized semilinear automorphism covers $b^e = \mathrm{id}$. At every level it is the identity polarized automorphism, by the given action and its linearization. Injectivity in Lemma D.0.2 therefore makes it the identity on the algebraic pair. The iterates of (τ, λ) give the required G-action and linearization, and (5) is equivariant. Restricting (5) for $n = 1$ further to C proves the full residual identities. Finally, the same lemma gives a unique polarized comparison of any two algebraizations with (5). Its reductions commute with the specified actions, so injectivity makes the comparison equivariant. □

Appendix E

Projective descent in the tame Kummer class

Retain the coefficient class of C.1.53. Let K be complete and nontrivially real-valued, with valuation ring O, value group Γ, and residue field k. Let $e \geq 2$ be invertible in O, and let $\zeta \in O$ have order e, with residue also of order e. Assume

$$L = K(s), \qquad s^e = c \in K^\times, \qquad \gamma = v(s) > 0, \qquad i\gamma \notin \Gamma \quad (0 < i < e). \tag{K}$$

Write $O' = L^\circ$, $\mathfrak{m}'$ for its maximal ideal, and $G = \langle \sigma \rangle$, where $\sigma(s) = \zeta s$. The cited criterion gives a faithfully flat map $O \to O'$, identifies both residue fields with k, and gives identity coefficient action on k. In particular, its character-zero summand is $(O')^G = O$. The value group need not be discrete, and O' is the actual valuation ring; it need not be finite as an O-module.

Theorem E.0.1 (Projective descent in the exact tame Kummer class)**.** *Assume (K). Let Y'/O' be a supplied projective, flat, finitely presented nodal scheme of relative dimension one, equipped with a semilinear G-action. Then the following are equivalent:*

1. *G acts identically on the entire special-fibre scheme Y'_k.*
2. *There is a projective, flat, finitely presented nodal O-scheme Y of relative dimension one and a G-equivariant isomorphism $Y \times_O O' \simeq Y'$.*

The descent is unique with the specified equivariant identification. For every relatively ample invertible sheaf $\mathcal{A}'$ on Y', its canonically linearized orbit tensor

$$\mathcal{N}' = \bigotimes_{j=0}^{e-1} (\sigma^j)^* \mathcal{A}' \tag{8}$$

is the equivariant pullback of a relatively ample invertible sheaf $\mathcal{N}$ on Y.

Proof. Assume condition 1. The affine base $\operatorname{Spec} O'$ has an ample structure sheaf. By Stacks Tag 0B45, (1) $\Rightarrow$ (6), the supplied projective scheme Y'/O' is proper and has a relatively ample invertible sheaf. Fix any such $\mathcal{A}'$. Theorem C.1.81 supplies a separated, flat, finitely presented nodal O-scheme Y with the required equivariant identification and descends properness to Y/O.

Apply Proposition D.0.1 with $X = Y'$, $S = \operatorname{Spec} O'$, and $Z = Y'_k$. It makes (8) relatively ample and gives a canonical linearization whose restriction to the full special fibre is the identity. Under the supplied identification $Y' = Y \times_O O'$, Proposition C.1.83 therefore produces the invertible sheaf

$$\mathcal{N} = (p_* \mathcal{N}')^G$$

and its equivariant pullback identification; it also proves that $\mathcal{N}$ is relatively ample over O. The base $\operatorname{Spec} O$ has the ample invertible sheaf $\mathcal{O}$. Applying Stacks Tag 0B45, (6) $\Rightarrow$ (1) to the proper scheme Y/O with the descended relatively ample invertible sheaf $\mathcal{N}$ makes Y/O projective. The flatness, finite presentation, nodality, relative dimension and uniqueness are those of Theorem C.1.81.

Conversely, an equivariant presentation in condition 2 has special fibre $Y \times_O k$, with coefficient action. That action is the identity because G acts identically on k. This proves condition 1. □

Appendix F

Descent of an algebraized polarized tower

Corollary F.0.1 (A descended polarization in the exact tame Kummer class)**.** *Let K be complete and nontrivially real-valued, with valuation ring O, residue field k, and value group Γ. Assume the exact coefficient class of C.1.53: $e \geq 2$ is invertible in O, $\zeta \in O$ and its residue have order e, and*

$$L = K(s), \quad s^e = c \in K^\times, \quad \gamma = v(s) > 0, \qquad i\gamma \notin \Gamma \quad (0 < i < e). \tag{K}$$

Put $O' = L^\circ$ and $G = \langle \sigma \rangle$, where $\sigma(s) = \zeta s$. Choose $0 \neq \pi \in \mathfrak{m}_O$. Suppose a cartesian proper flat finitely presented tower over $O'/\pi^n O'$ with compatible semilinear G-actions satisfies the nodal and full special-fibre identity hypotheses of Theorem D.0.3. Then there exist a projective, flat, finitely presented nodal O-scheme Y of relative dimension one and a relatively ample invertible sheaf $\mathcal{P}$ on Y, with compatible equivariant polarized isomorphisms

$$(Y, \mathcal{P}) \times_O (O'/\pi^n O') \simeq (X_n, \mathcal{N}_n). \tag{6}$$

Here $\mathcal{N}_n$ is the chosen orbit-tensor tower (4). The algebraized bundle $\mathcal{N}'$ itself descends to $\mathcal{P}$; no further tensor power of $\mathcal{N}'$ is needed. In particular $\mathcal{P}|_{Y_k}$ identifies with $\mathcal{A}_C^{\otimes e}$ under the induced residue identification. The reductions $(Y, \mathcal{P}) \times_O O/\pi^n O$ form the corresponding descended polarized tower.

Proof. The coefficient criterion identifies the residue fields of O and O' with k, gives identity coefficient action on k, and uses the actual complete valued field L and its valuation ring. Thus Theorem D.0.3, applied over O', first supplies

an algebraic projective nodal pair $(Y', \mathcal{N}')$ with the specified semilinear action and full residual identities. This step uses no ramified descent. For clarity, with $b_g = \mathrm{Spec}(g^{-1})$ the induced left action on functions is $g \cdot a = \rho_{g^{-1}}^* a$, and on linearized sections it is $g \cdot t = \lambda_{g^{-1}}(\rho_{g^{-1}}^* t)$. Thus its coefficient action on O' is exactly g, as in the cited tame descent results.

Theorem E.0.1 applies to Y'/O'. It supplies a projective flat finitely presented nodal Y/O and an equivariant isomorphism $Y \times_O O' \simeq Y'$, with the prescribed coefficient action on the base change. Properness is retained: Y' is projective and proper, and the cited result descends properness before concluding projectivity.

Under this identification, $\mathcal{N}'$ is an already existing G-linearized invertible sheaf on $Y \times_O O'$ whose action on the entire special-fibre module is the identity. Apply C.1.83 to this bundle itself. For $p : Y \times_O O' \to Y$, it gives

$$\mathcal{P} = (p_* \mathcal{N}')^G, \qquad p^* \mathcal{P} \simeq \mathcal{N}', \tag{7}$$

and makes $\mathcal{P}$ relatively ample. There is no need to replace $\mathcal{N}'$ by a second orbit tensor. The scheme and bundle descents are unique with their specified identifications, by the two cited results.

Reduce the algebraic isomorphisms just constructed modulo π^n and use the level comparisons (5) of Theorem D.0.3. This gives (6), with all transition maps and linearizations, and then the asserted residue polarization. The $O/\pi^n O$ reductions of the actual pair $(Y, \mathcal{P})$ are automatically cartesian, proper, flat and finitely presented. Their base changes to $O'/\pi^n O'$ are exactly the supplied polarized levels. In particular no valuation-ring descent theorem has been applied directly to the non-valuation quotient rings $O'/\pi^n O'$. □

F.1 Prescribed subdivisions of an existing model

Let K be a complete non-Archimedean field with a specified nontrivial real-valued absolute value. Write

$$O = K^\circ, \qquad k = \widetilde{K}, \qquad v(c) = -\log|c|, \qquad \Gamma = v(K^\times) \subset \mathbb{R}.$$

Let C/K be a smooth projective geometrically connected curve. A model means a projective flat finitely presented nodal O-curve with generic fibre identified with C and geometrically connected, geometrically reduced special fibre, as in 4.45.3. A marking D, when present, is a fixed finite etale O-scheme embedded in the relative smooth locus. All model morphisms below induce the identity on C.

Fix an actual model $\mathcal{X}$. Choose a finite unramified Galois residue lift L/K splitting its nodes. Put $l = \widetilde{L}$ and $G = \mathrm{Gal}(L/K)$. Here *unramified* means the actual finite free etale coefficient extension of 4.43.1; in particular $v(L^\times) = \Gamma$. The splitting field and rational pointed etale nodal charts exist by 4.18.2.

For each node e of $\mathcal{X}_l$, choose an ordering of its two branches and a pointed chart $x_e y_e = a_e$, with $0 < |a_e| < 1$. Put $\ell_e = v(a_e)$. By 4.39.1 and 4.39.3, its entire tube is the standard open annulus

$$|a_e| < |x_e| < 1, \qquad s = v(x_e) \in (0, \ell_e).$$

The coordinate s increases from the chosen first end to the second. These are two distinct *branch ends* even if their component vertices coincide.

Use an algebraically closed complete isometric comparison field $\Omega \supset L$ with residue field $\overline{k}$, as in 4.45.1, and write $p : C_\Omega^{\mathrm{an}} \to C^{\mathrm{an}}$. The geometric component vertices of a model are exactly $p^{-1}(V(\mathcal{X}))$, by 4.45.2. Write $\zeta_e(r)$ for the Gauss point of radius r in the selected annular tube over Ω.

Definition F.1.1 (Compatible cut data)**.** A cut datum consists of a finite set $S_e \subset (0, \ell_e) \cap \Gamma$ for each split node e. The canonical semilinear action of $g \in G$ takes the skeleton coordinate s either to s or to $\ell_e - s$ on the ge-tube, according as it preserves or exchanges the chosen branch orderings. Require respectively

$$S_{ge} = S_e \quad \text{or} \quad S_{ge} = \ell_e - S_e.$$

Empty sets are permitted.

These conditions concern labelled tubes of the *given* model. The coordinate-change result 4.19.1 makes them independent of normalized annular coordinates. A stabilizer exchanging the two branches forces reflection invariance of S_e; a stabilizer preserving both branches permits asymmetric cuts. A self-loop alone imposes no reflection condition: the issue is the branch action, not equality of endpoint vertices.

Theorem F.1.2 (Exact arithmetic subdivisions)**.** *Every compatible cut datum $S = (S_e)$ has a model $\mathcal{X}[S]$, preserving D, with geometric vertices exactly*

$$p^{-1}(V(\mathcal{X})) \ \cup \ \bigcup_e \{\zeta_e(\exp(-s)) : s \in S_e\}. \tag{*}$$

It dominates $\mathcal{X}$ and is unique up to the unique marked generic-identity isomorphism. It is independent of the splitting field and coordinates when the prescribed analytic points are fixed.

If $S_e \subset T_e$ for all e, there is a unique compatible morphism $\mathcal{X}[T] \to \mathcal{X}[S]$. The model $\mathcal{X}[S \cup T]$ is the least common dominating model of $\mathcal{X}[S]$ and $\mathcal{X}[T]$, even among models with vertices outside the original skeleton.

Proof. First form the reflection closure $S_e^{\#} = S_e \cup (\ell_e - S_e)$. For nodes above one original closed node, these are the same finite numerical set independently of branch ordering: G acts transitively above that node, and reflection no longer changes the set.

We construct an original-ring model $\mathcal{X}^{\#}$ with exactly these extra cuts. For a nonempty reflection-invariant set in $(0, \ell)$, let d be its smallest member. Then $d \in \Gamma$ and $d \le \ell/2$. Apply Lemma C.1.84. If $d < \ell/2$, all remaining cuts lie in the central annulus, of length $\ell - 2d$; their new coordinates $s - d$ again form a reflection-invariant set. If $d = \ell/2$, there was just one cut.

Over l, the new central nodes are rational and split by the displayed charts. They form a G-invariant collection, hence are the full inverse image of a collection of closed nodes of the actual current k-model. Perform the same original-ring operation at these nodes. At each nonempty step at least one member of the finite list is removed. All new distances are differences in Γ, so the required scalars belong to K. This finite process, applied at the finitely many original nodes, constructs $\mathcal{X}^{\#}$ and its actual map to $\mathcal{X}$. It uses no least positive value and no discreteness assumption.

Retain all old geometric components and exactly the new components labelled by S_e, discarding those in $S_e^{\#} \setminus S_e$. This selection is G-invariant.

The new components and their attachment points are split over l: they are the exceptional projective lines in the accepted chart calculation, and the pointed etale maps induce isomorphisms on the exceptional fibres. Thus the action of $\mathrm{Aut}(\overline{k}/k)$ on the new components factors through $\mathrm{Gal}(l/k)$. All old geometric components are retained. The selection is therefore invariant under the full residual action. By 4.49.1, it is the entire inverse image of a subset $V \subset V(\mathcal{X}^{\#})$ of actual original-field component vertices.

Each connected collection of discarded geometric components is a chain of smooth projective lines with no marking and two attaching branches on retained components. It cannot be a cycle: every original edge has retained endpoints, including the retained old vertex at both ends of a self-loop. If the two attaching branches meet the same retained component, they are counted twice. This is exactly the marked forest condition 4.45.4, with $b = 2, m = 0$. The actual original-ring theorem 4.45.5 now gives a projective model $\mathcal{X}[S]$ with precisely (*).

All old vertices remain, so 4.46.2 gives $\mathcal{X}[S] \to \mathcal{X}$. That accepted theorem and 4.46.3 also give uniqueness, marking compatibility and the morphisms for $S \subset T$. They prove independence of auxiliary choices, using 4.45.2 to identify original vertex sets from their entire geometric inverse images.

The union datum is compatible. Every model dominating both $\mathcal{X}[S]$ and $\mathcal{X}[T]$ contains both vertex sets, hence their union, which is $V(\mathcal{X}[S \cup T])$. Applying 4.46.2 gives its unique morphism to $\mathcal{X}[S \cup T]$, as required. □

Proposition F.1.3 (The full tubes of a subdivision)**.** *In a geometric node tube A_e, list the cuts $0 < s_1 < \cdots < s_m < \ell_e$, and set*

$$r_0 = 1, \qquad r_j = \exp(-s_j), \qquad r_{m+1} = |a_e|.$$

The closed-point tubes of $\mathcal{X}[S]_{\Omega^\circ}$ inside A_e are precisely the open annuli

$$\{r_{j+1} < |x_e| < r_j\}, \quad 0 \le j \le m, \tag{1}$$

and the open discs, for $1 \le j \le m$,

$$\{|x_e/b_j - \widehat{\alpha}| < 1\}, \quad \alpha \in \overline{k}^{\times}, \quad b_j \in K^{\times}, \quad v(b_j) = s_j. \tag{2}$$

Here $\widehat{\alpha} \in \Omega^\circ$ is any lift of α. The omitted point on $|x_e| = r_j$ is its Gauss vertex. The old smooth tubes are unchanged as analytic subsets.

The two ends of (1) carry consecutive component labels, allowing coincident endpoint labels at an original self-loop. Each disc (2) has the inserted

vertex as its sole boundary point. On an inserted geometric component the two annular directions are the normalization points $0, \infty$; the other residual points give (2).

Proof. On $|x_e| = r_j$, the coordinate $z = x_e/b_j$ gives $\mathcal{M}(\Omega\langle z, z^{-1}\rangle)$. Its canonical reduction is $\overline{k}[z, z^{-1}]$, with one component point, by 3.20.3. The inverse images of its closed points are exactly (2), by 3.20.1; these are open unit discs with coordinate $z - \widehat{\alpha}$. The intervals between cut circles give the standard open annuli (1). These open connected sets partition the complement of the inserted vertices in A_e, so they are its connected components.

No new vertex lies in an old smooth tube. The specialization partition 4.39.5, applied over Ω, identifies precisely these components with the closed-point tubes of $\mathcal{X}[S]$. The boundary assertions follow from 4.39.3. The two ends are retained before any identification of component labels, so this includes self-loops. The accepted contraction theorem only removes chains between these retained endpoints. □

Over the original field, specialization commutes with coefficient extension by 4.28.1. The inverse image of an original closed-point tube is therefore the union of the geometric tubes above that *residual closed point*. A finite unramified field splitting the nodes need not split every smooth residual closed point. An abstract edge and a list of radii do not record this information. The actual blowups and contractions supply the residual schemes and their morphisms. In a nonsplit situation a stabilizer can exchange $0, \infty$; its action on these points and on the other residual points must be retained. No assertion that the descended component or all its tubes are split is used.

Corollary F.1.4 (A literal-union common refinement)**.** *Let $\mathcal{X}, \mathcal{Y}$ be two given models of C, with the same D when marked. Let $\Sigma_{\mathcal{X},\Omega}$ be the embedded compact geometric skeleton of $\mathcal{X}$, including its component vertices. Assume*

$$V(\mathcal{Y}_{\Omega^\circ}) \subset \Sigma_{\mathcal{X},\Omega}. \tag{3}$$

There is then a least common dominating model $\mathcal{Z}$ with

$$V(\mathcal{Z}) = V(\mathcal{X}) \cup V(\mathcal{Y}).$$

It is the exact subdivision of $\mathcal{X}$ in Theorem F.1.2, with the full tube description of Proposition F.1.3. Condition (3) holds, in particular, if the two embedded geometric skeleta agree.

Proof. Choose a common finite unramified Galois splitting field for the nodes of both models. Every geometric vertex of $\mathcal{Y}$ not already a geometric vertex of $\mathcal{X}$ lies on the radial skeleton of one of the split $\mathcal{X}$-annuli. Its image $w \in C_L^{\mathrm{an}}$ is a component vertex of $\mathcal{Y}_{L^\circ}$, by 4.45.2. The annular coordinate is analytic on its entire L-tube, so its evaluation lies in $\mathcal{H}(w)$. Consequently

$$v(x_e(w)) \in v(\mathcal{H}(w)^\times) = v(L^\times) = \Gamma.$$

The finite cut sets obey the branch compatibility because both models are defined over K. The theorem constructs $\mathcal{X}[S]$ whose geometric vertices are their union. The entire-inverse-image assertion 4.45.2 identifies its original vertex set with the asserted original union. The two domination maps and least-common property follow from 4.46.2. Marking compatibility follows from 4.46.3. □

Residual action at the ramified midpoint

Use the field and model of Proposition C.1.85. Its quadratic extension is $L = K(b)$ with $b^2 = t$, and $O' = L^\circ$. The coefficient ring is the actual ring of Proposition C.1.86.

Proposition F.1.5 (The midpoint's residual action is nontrivial)**.** *Let $\mathcal{Y}/O'$ be the three-vertex projective model constructed in the audited midpoint proof by symmetric insertion in $TU = t = b^2$. The canonical action fixing T, U and sending b to $-b$ extends to $\mathcal{Y}$. On the new residual component it acts as*

$$\overline{u} \longmapsto -\overline{u}, \qquad u = T/b. \tag{14}$$

Its two branch ends $0, \infty$ are fixed. For $\alpha \in k^\times$, the geometric residual-direction disc labelled α is carried to that labelled $-\alpha$. Thus the invariant midpoint and its fixed branch ends do not carry trivial residual-scheme or tube action. This gives a residual-action obstruction to effective descent of this given *model with its fixed generic identification.*

Proof. The audited symmetric insertion uses the ideal (T, U, b) on the node chart. This ideal is invariant under the stated action, so its Rees algebra and blowup inherit the action; on the rest of the projective model the original coefficient action already exists. These actions agree on overlaps. The accepted symmetric blowup charts, used in the passing proof, give its middle chart as

$$O'[u, v]/(uv - 1), \qquad T = bu, \quad U = bv. \tag{15}$$

Here $\sigma(u) = -u$, $\sigma(v) = -v$. The two adjacent node charts add the missing ends $0, \infty$ of this residual $\mathbb{P}^1_k$, proving (14) on the whole component. Since $\mathrm{char}(k) = 0$, it is a nontrivial scheme automorphism.

The full tube description in F.1.3 identifies the smooth residual direction $\alpha \neq 0, \infty$ with

$$|T/b - \widehat{\alpha}| < 1.$$

Here one may use the constant lift $\widehat{\alpha} = \alpha \in k$. The action fixes this lift and changes T/b to $-T/b$. It therefore carries this disc to the disc for $-\alpha$, which is distinct because $\alpha \neq 0$ and the residue characteristic is zero.

Every actual base change from O has identity inertia on its special fibre, because $O'/\mathfrak{m}' = O/\mathfrak{m} = k$ and the coefficient action on k is the identity. An isomorphism giving descent with the prescribed generic identification would transport that action to the displayed action on $\mathcal{Y}$. Indeed extensions of a fixed generic action to a flat separated model are unique: their equalizer is closed by separatedness, and its defining ideal vanishes after inverting the nonzero elements of O', so vanishes by flatness. This contradicts (14). This argument diagnoses the residual mechanism of the already audited obstruction; it does not replace that earlier proof or assert a new model-existence theorem. □

Ordinary moment support and finite freeness

Moment norms near a supplied retraction

Let K be a complete non-Archimedean field with its given real-valued absolute value. We use $t_f = (-\log|f_j|)_j$ and write $\mathrm{Int}_{\mathrm{top}}(V,U)$ for the ordinary interior of V in U.

Lemma F.1.6 (Local equality of moment norms)**.** *Let U and Y be good Hausdorff K-analytic spaces, let $i : Y \hookrightarrow U$ be a closed immersion, and let $r : U \to Y$ be an analytic morphism with $r \circ i = \mathrm{id}_Y$. Assume that every affinoid domain of Y under consideration has analytic dimension at most d. Let $z = i(y)$, let $V \subset U$ be an ordinary affinoid neighbourhood of z, and let $f = (f_1, \dots, f_N)$ be analytic units on V. There is an ordinary affinoid neighbourhood $W \subset V$ of z such that*

$$\dim t_f(W) \le d.$$

The choice of W depends on the tuple, but not on any ambient superform subsequently pulled back by that tuple. Thus all such forms of bidegree (p,q) with $\max(p,q) > d$ induce zero ordinary sections on $\mathrm{Int}_{\mathrm{top}}(W,U)$.

Proof. Choose an ordinary affinoid neighbourhood B of y in Y contained in $i^{-1}(\mathrm{Int}_{\mathrm{top}}(V,U))$. Write $g_j = i^* f_j|_B$, which is a unit on B. On the ordinary open neighbourhood

$$O_0 = \mathrm{Int}_{\mathrm{top}}(V,U) \cap r^{-1}(\mathrm{Int}_{\mathrm{top}}(B,Y))$$

of z, the functions $a_j = r^* g_j$ are units. The analytic-domain restriction and neighbourhood basis used here are those in `v037:forms:germsheaf`. Since $ri = \mathrm{id}$, each $f_j - a_j$ has value zero at z, whereas $|a_j(z)| > 0$. By continuity, the open set

$$O_1 = \{x \in O_0 : |f_j(x) - a_j(x)| < |a_j(x)| \text{ for every } j\}$$

contains z. Choose an ordinary affinoid neighbourhood W of z contained in O_1. At every $x \in W$, the strict ultrametric inequality gives $|f_j(x)| = |a_j(x)|$: one inequality follows from $f_j = a_j + (f_j - a_j)$, and a strict reverse inequality would contradict the same triangle inequality applied to $a_j = f_j - (f_j - a_j)$. Consequently

$$t_f(W) = t_g(r(W)) \subseteq t_g(B).$$

By v037:globaltrop:finiteimage, the right-hand side is a finite polyhedral set of dimension at most d, and the left-hand side is also finite polyhedral. Hence its dimension is at most d. On every face its tangent space has dimension at most d, so one of the exterior factors of a form with $\max(p,q) > d$ restricts to zero. The ordinary moment definition then gives the asserted zero sections. □

Avoiding the regular zero space

Let X be good, Hausdorff, and pure of analytic dimension $n \geq 1$ over a complete real-valued non-Archimedean field K, possibly trivially valued. Let η be an ordinary smooth compactly supported $(n-1,n-1)$-form whose actual support is contained in the absolute analytic interior $\mathrm{Int}(X/K)$. Let f be a regular analytic function on X, with $D = V(f)$. On the affinoid neighbourhoods at issue its representative is a non-zero-divisor in the actual affinoid algebra.

Lemma F.1.7 (Support avoidance from the exact F7 support lemma; F8F7-S)**.** *For the test η above,*

$$\mathrm{supp}(d''\eta) \cap D = \varnothing. \tag{2.1}$$

In particular the extension by zero

$$\mathrm{ext}_0\big(\log|f|\, d'd''\eta|_{X\setminus D}\big) \tag{2.2}$$

is an ordinary smooth compactly supported top form on X.

Proof. At a point x of $\mathrm{supp}(d''\eta)$, choose an ordinary affinoid neighbourhood $V = \mathcal{M}(A)$ carrying one unit-moment representative of $d''\eta$, and on which $f \in A$ is a non-zero-divisor. It can be chosen inside the analytic interior around x. The exact F7 lemma NAG-002578, lines 165–225, applies to this $(n-1,n)$-form: its germ is nonzero, and the evaluation kernel $\ker(x)$ is a minimal prime of A.

A non-zero-divisor in a Noetherian ring avoids every minimal prime. Indeed, localization at a minimal prime is a nonzero zero-dimensional Noetherian local ring, hence Artinian by Stacks 00KH, forward direction; an element of its maximal ideal is nilpotent and cannot act injectively. Localization preserves injectivity. Thus $f \notin \ker(x)$, so $|f(x)| > 0$, proving (2.1). Here Noetherianity is the same NAG-001560 used in the F7 source.

Locality of d' gives $\operatorname{supp}(d'd''\eta) \subseteq \operatorname{supp}(d''\eta)$. This compact support is disjoint from D. On $X \setminus D$, the logarithm is a smooth function of the unit f; near D the tested top form is identically zero. Gluing gives the smooth extension (2.2). □

Freeness at defect at most one

Use the given complete field and the same convention for analytic dimension. Write $d_K(s)$ for the Abhyankar dimension of $\mathcal{H}(s)$ over K.

Lemma F.1.8 (Finite maps become free along the section; F8RC-F)**.** *Let $F : Y \to Z$ be finite between good Hausdorff spaces pure of analytic dimension n. Suppose the ordinary local rings of Z are regular, and every affinoid domain of Y has S_1 algebra. At every $s \in Z$ with $d_K(s) \geq n-1$, the finite coherent module $F_*\mathcal{O}_Y$ is free on an ordinary neighbourhood of s. Rank zero is allowed when the fibre is empty.*

Proof. Put $R = \mathcal{O}_{Z,s}$ and $M = (F_*\mathcal{O}_Y)_s$. By Lemma C.1.58, R is regular local of dimension zero or one. In dimension zero it is a field, and the finite module M is free. Suppose $\dim R = 1$, and choose a generator π of its maximal ideal. A regular local ring is a domain by Stacks 00NP, so $\pi \neq 0$.

Represent π by a on a sufficiently small ordinary affinoid neighbourhood $\mathcal{M}(C)$ of s. Write $U = \mathcal{M}(C)$ for this chosen domain. At every $x \in U$, including its domain boundary, the regular ordinary-stalk comparison makes $\mathcal{O}_{Z,x} \to \mathcal{O}_{U,x}$ a flat local map of Noetherian local rings with regular closed fibre. The assumed regularity of $\mathcal{O}_{Z,x}$ then gives regularity of $\mathcal{O}_{U,x}$ by Stacks 031E. Thus all ordinary stalks of this affinoid are regular. By `NAG-001861`, we may retain the integral, open-and-closed component containing s. Its inverse image is affinoid, say $\mathcal{M}(B)$, finite over C, and is either empty or pure of dimension n. The hypothesis makes B an S_1 ring. We claim that every minimal prime q of B contracts to zero in C.

Indeed, if $p = q \cap C$, then $C/p \to B/q$ is injective and finite. Such a map is surjective on analytic spectra: its finite module has support all of $\operatorname{Spec}(C/p)$, so every residue-field fibre is nonzero by Stacks 00DV(2) by contraposition at the corresponding local ring; extending to the complete residue field gives a nonzero finite-dimensional affinoid algebra and hence an

analytic point. Completed residue extensions at points of a finite map are finite, by NAG-001590. The maximum formula NAG-001591 therefore gives

$$\dim_K \mathcal{M}(C/p) = \dim_K \mathcal{M}(B/q) = n.$$

If $p \neq 0$, dimension drop (NAG-002374) in the integral pure n-dimensional algebra C contradicts this equality. Thus $p = 0$.

The element a is nonzero in C, since its germ is $\pi \neq 0$. It avoids every minimal prime of B, hence every associated prime, because B is S_1 by Stacks 031Q, (2) implies (1). Multiplication by a on B is injective. The ordinary comparison $C \to R$ is flat (NAG-001698, or NAG-001782 after localization), and $M = B \otimes_C R$ by finite coherent restriction. Thus π acts injectively on M.

Lift a basis of $M/\pi M$ to obtain $R^r \to M$, surjective by Nakayama (Stacks 00DV(2) on the finite cokernel). Its kernel N is finite. The resolution $0 \to R \xrightarrow{\pi} R \to R/(\pi) \to 0$ and injectivity of π on M give $\operatorname{Tor}_1^R(M, R/(\pi)) = 0$. Tensoring the presentation of M therefore gives $N/\pi N = 0$. Nakayama gives $N = 0$ by Stacks 00DV(2) on N, proving that M is free. Finally NAG-001753 spreads the free stalk to an ordinary neighbourhood. This proves actual local freeness, including its analytic base changes; mere torsion-freeness over an unspecified higher-dimensional ring has not been used. □

Serre comparison and Cartier coefficients

Fix a complete non-Archimedean field with its specified real-valued absolute value, possibly trivial. Use actual generalized affinoids with their canonical quotient and finite-module norms. All dimensions of analytic spaces in this section are analytic dimensions.

Serre S_1 for analytic stalks

Theorem F.1.9 (Analytic Serre comparison; F8ST-A)**.** *Let A be a generalized affinoid algebra, $X = \mathcal{M}(A)$, M a finite A-module, and $\widetilde{M}$ its coherent sheaf. For $x \in X$, put $\mathfrak{p} = \ker_A(x)$. Then*

$$M_{\mathfrak{p}} \text{ is } S_1 \iff \widetilde{M}_x \text{ is } S_1 \text{ as a module over } \mathcal{O}_{X,x}. \tag{F.1.1}$$

Thus M is S_1 if and only if all these analytic stalk modules are S_1. If V is a good analytic domain in a good analytic space X, and $\mathcal{F}$ is coherent, then at every $x \in V$

$$\mathcal{F}_x \text{ is } S_1 \iff (\mathcal{F}|_V)_x \text{ is } S_1. \tag{F.1.2}$$

The same comparison applies to a finite-type scheme over an affinoid base, its analytification, and an affinoid domain therein, with the corresponding algebraic and analytic stalks.

Proof. By NAG-001624/001666, $\widetilde{M}_x = M \otimes_A \mathcal{O}_{X,x}$. The map $A_{\mathfrak{p}} \to \mathcal{O}_{X,x}$ is regular by NAG-001782 and is local, hence faithfully flat. Lemma C.1.15 proves (F.1.1). Every prime of A is the kernel of an analytic point by NAG-001860, proving the assertion for all of M. For (F.1.2), use the tensor identity NAG-001666 and the regular local map NAG-001792. For the last assertion use the regular comparison square NAG-001791 and the same finite-presentation stalk calculation. All localizations required in Lemma C.1.15 are Noetherian. □

The ordinary stalk identifications are the finite-coherent equivalence and coherent restriction. The regular maps used above are affinoid comparison, good-domain restriction, and comparison over an affinoid base. The passage to all primes uses realization by analytic points.

Let X be pure of analytic dimension $n \geq 1$, and let $f \in A$ be regular. Write $f_i = f|_{X_i}$ for its component restrictions. For an affinoid $X = \mathcal{M}(A)$ pure of dimension n, write

$$\operatorname{Min} A = \{\mathfrak{q}_1, \dots, \mathfrak{q}_s\}, \qquad X_i = \mathcal{M}(A/\mathfrak{q}_i), \quad i_i : X_i \hookrightarrow X, \quad m_i = \operatorname{length}_{A_{\mathfrak{q}_i}} A_{\mathfrak{q}_i}. \tag{F.1.3}$$

Proposition F.1.10 (Component scope and support; F8CR-S)**.** *In* (F.1.3)*, every X_i is integral and pure of dimension n, every f_i is regular, and every actual good affinoid domain in X_i has an S_1 coordinate ring. For an ordinary compactly supported form η on X,*

$$\operatorname{Supp}(i_i^*\eta) \subseteq i_i^{-1} \operatorname{Supp} \eta.$$

If $\operatorname{Supp}\eta \subset \operatorname{Int}(X/K)$*, its pullback has compact support in* $\operatorname{Int}(X_i/K)$*. Moreover $i_i^*(d'd''\eta) = d'd''(i_i^*\eta)$. The support and functoriality assertions also hold for an arbitrary closed immersion of good Hausdorff analytic spaces.*

Proof. The quotients by minimal primes have their actual affinoid structures by NAG-001561 and NAG-001562. Purity of X gives their analytic dimension n. Proposition C.1.14's avoidance argument makes $f_i \neq 0$ in the domain $A/\mathfrak{q}_i$. Every domain is S_1: at a nonzero prime its local ring has a nonzero element of the maximal ideal which is regular, and the zero-prime localization is a field. The finite coherent comparison NAG-002765 applies to the structure module of this affinoid and then to its actual good analytic domains. It gives the asserted analytic stalk and affinoid S_1 statements. It is never applied to infer S_1 for the original possibly embedded-component ring.

Closed immersions are finite locally with the canonical quotient norm. By NAG-001701, every point is relatively interior; NAG-001704 and the atlas definition of relative interior give

$$i_i^{-1} \operatorname{Int}(X/K) \subseteq \operatorname{Int}(X_i/K).$$

Their underlying maps identify the source with a closed subspace. The preimage of the compact support is therefore compact. Pullback of a zero germ is zero, proving the support inclusion. Finally NAG-002424 gives pullback commuting with both differentials, with their fixed order unchanged. These statements are about the true analytic interior; compactness alone does not remove an analytic boundary. □

Proposition F.1.11 (Points computing full generic lengths; F8ST-G)**.** *Let $Y = \mathcal{M}(B)$ be nonempty and pure of analytic dimension d, $\mathfrak{p} \in \operatorname{Min} B$, and M a finite B-module. There is $x \in \mathcal{M}(B/\mathfrak{p})$ with $d_K(x) = d$. Every such point has kernel $\mathfrak{p}$ on B, belongs to no other irreducible component, and has the following property. For every affinoid domain $V \subset Y$ containing x, the ordinary local ring $S_V = \mathcal{O}_{V,x}$ is Artinian, and*

$$\operatorname{length}_{S_V}(M \otimes_B S_V) = \operatorname{length}_{B_{\mathfrak{p}}} M_{\mathfrak{p}}. \tag{F.1.4}$$

The same equality holds for the pointed analytic-domain colimit $\mathcal{O}_{Y_G,x}$ and the coherent module colimit. These colimit modules have finite length. Thus the analytic generic multiplicity can be computed by the algebraic generic length, including nilpotents.

Proof. The reduced component $\mathcal{M}(B/\mathfrak{p})$ is pure of dimension d. The maximum formula gives the required point. A nonzero element of $B/\mathfrak{p}$ has zero locus of dimension at most $d-1$, or empty when $d = 0$, by NAG-002374. Such a zero locus cannot contain a point of Abhyankar dimension d. Hence the kernel on B is exactly $\mathfrak{p}$. For another minimal prime $\mathfrak{p}'$, an element of $\mathfrak{p}' \setminus \mathfrak{p}$ proves that x is not on that component.

For any affinoid domain $W = \mathcal{M}(C)$ containing x, $\dim_K W \le d$ by NAG-001592. Its evaluation kernel $\mathfrak{q}$ is minimal in C. The prime choice below it uses Stacks 00E0(4). Indeed, if $\mathfrak{r} \subsetneq \mathfrak{q}$ were a minimal prime, a nonzero element of $\mathfrak{q}/\mathfrak{r}$ would cut the integral affinoid $\mathcal{M}(C/\mathfrak{r})$ down to dimension at most $d-1$, contradicting $d_K(x) = d$. This also covers $d = 0$ using the empty-locus assertion of NAG-002374.

Now let h be in the maximal ideal of S_V. By NAG-001698, it is represented by an analytic section on an affinoid ordinary neighbourhood W of x in V. Its image lies in the minimal prime $\ker_C(x)$. The localization $C_{\ker_C(x)}$ is Artinian. Its maximal ideal is nil by Stacks 00E0(7), so some power of h is annihilated in C by an element nonzero at x. That element is a unit in the ordinary stalk. Thus h is nilpotent in S_V. The stalk is Noetherian by NAG-001747; a Noetherian local ring with nil maximal ideal is Artinian.

The natural local map $B_{\mathfrak{p}} \to S_V$ is regular by NAG-001791; both rings are Artinian. The coherent restriction identity and Lemma C.1.12 prove (F.1.4). In particular $\mathfrak{p}S_V$ is the maximal ideal of S_V.

For completeness, use the definition of the pointed G-local ring as the filtered colimit over analytic domains containing x. Taking ordinary stalks

on those domains gives the same colimit: a representative section restricts to an ordinary neighbourhood in its domain, and that neighbourhood has an affinoid refinement containing x. Finite intersections admit such refinements (NAG-002411). Tensor a composition series of $M_{\mathfrak{p}}$ with every S_V, then pass to this filtered colimit. Each factor is the filtered colimit of the fields $S_V/\mathfrak{p}S_V$. The transition maps of these fields are unital and injective, so this colimit is a field. It is precisely the residue field of the colimit local ring, because every stage has maximal ideal $\mathfrak{p}S_V$. The resulting series has exactly $\operatorname{length}_{B_{\mathfrak{p}}} M_{\mathfrak{p}}$ nonzero simple factors. Taking $M = B$ also shows directly that the colimit ring is Artinian. No general Noetherianity theorem for G-local rings is needed here. □

Purity of the neighborhood used for an effective coefficient. Let $Z = \mathcal{M}(B)$, let $\mathfrak{p}$ be the minimal prime of the chosen reduced component $Y = \mathcal{M}(B/\mathfrak{p})$, and let $x \in Y$ be away from the other components. Take an ordinary affinoid neighborhood $W = \mathcal{M}(C)$ of x in Z disjoint from those components. Actual domain base change and the finite quotient tensor identify the inverse image of W in Y with the affinoid domain $\mathcal{M}(C/\mathfrak{p}C)$ of Y. Every analytic point of W maps into Y, hence its kernel contains $\mathfrak{p}C$. By realization of every prime of C as an analytic kernel, $\mathfrak{p}C$ is contained in every prime of C. Thus $\mathfrak{p}C$ is a nil ideal by Stacks 00E0(7). Consequently C and $C/\mathfrak{p}C$ have the same minimal-prime quotients. Domain purity on Y gives purity of the latter domain of dimension $\dim_K Y$, so the full W is pure of that dimension. Apply the generic Artin-length argument on the full W. Passing to $C/\mathfrak{p}C$ in the purity check changes none of the nilpotent structure used in computing the actual coefficient on W.

Theorem F.1.12 (Cartier coefficient transport with scoped gluing; F8ST-C-R1)**.** *Let A be generalized affinoid and $f \in A$ a regular element. Put $B = A/(f)$, with its actual quotient analytic structure. For a component $Y = \mathcal{M}(A/\mathfrak{p})$ of the Cartier zero space, $\mathfrak{p}$ minimal over (f), its coefficient is*

$$c_Y(f) = \operatorname{length}_{A_{\mathfrak{p}}}(A_{\mathfrak{p}}/fA_{\mathfrak{p}}) = \operatorname{length}_{\mathcal{O}_{X,x}}(\mathcal{O}_{X,x}/f\mathcal{O}_{X,x}), \qquad X = \mathcal{M}(A), \tag{F.1.5}$$

where x can be chosen on Y, away from the other zero-space components, of maximal Abhyankar dimension in Y. Equivalently, the right side is the generic length of the analytic quotient sheaf. The lengths are finite positive integers. The assertion applies in particular to every codimension-one Cartier

component. It makes no claim about an arbitrary closed integral subspace of the zero locus.

The effective coefficients are compatible with actual affinoid-domain restriction and ordinary gluing. For regular a, b, product additivity is asserted when $\mathrm{Min}_A(a) \cup \mathrm{Min}_A(b)$ is an antichain: no two distinct primes in this union contain one another. Here $\mathrm{Min}_A(a)$ means primes of the actual common ring A minimal over (a), with the empty set for a unit. A sufficient condition is that the two actual zero spaces are empty or pure of one common analytic dimension.

For regular meromorphic presentations, the differences $\mathrm{div}(a) - \mathrm{div}(b)$ are independent and glue among atlases for which this antichain condition holds for the cross-products on every actual common affinoid refinement. In particular this holds when all local numerator and denominator zero spaces are empty or pure of one fixed analytic dimension. The effective coefficient formula above needs no such purity assumption. No reduction of A, B, or their finite fibres is permitted. The previously unrestricted product and meromorphic clauses are not claimed closed in this induced revision.

Proof. The prime $\mathfrak{p}/(f)$ is minimal in B, so $B_{\mathfrak{p}/(f)} = A_{\mathfrak{p}}/(f)$ is Artinian. Its length as a module over itself is its length as an $A_{\mathfrak{p}}$-module. Choose x on the integral component Y of maximal Abhyankar dimension. It has kernel $\mathfrak{p}/(f)$ on B and is on no other component, by the dimension-drop argument in Proposition F.1.11. Shrink to an affinoid ordinary neighbourhood in the zero space avoiding the other components. It is pure of dimension $\dim_K Y$ by the mixed-neighbourhood argument above and domain purity NAG-002413. The proof of Proposition F.1.11 makes its ordinary stalk at x, hence $\mathcal{O}_{\mathcal{M}(B),x}$, Artinian. The regular comparison NAG-001782 for B, followed by Lemma C.1.12, gives its length as length $B_{\mathfrak{p}/(f)}$. The finite closed-immersion case of NAG-001735 identifies

$$\mathcal{O}_{\mathcal{M}(B),x} = \mathcal{O}_{X,x} \otimes_A B = \mathcal{O}_{X,x}/f\mathcal{O}_{X,x}.$$

Length over a local ring is unchanged when computed over a quotient annihilating the module, proving (F.1.5). The same argument on the pointed domain colimit proves the generic-length interpretation.

For a domain $\mathcal{M}(C) \subset \mathcal{M}(B)$ and $\mathfrak{q} \in \mathrm{Min}\, C$, its contraction $\mathfrak{r}$ is minimal in B by flat going down (Stacks 00HS). Choose an analytic point of $\mathcal{M}(C)$ with kernel $\mathfrak{q}$, using NAG-001860. The upper arrow of NAG-001791 gives a regular local map $B_{\mathfrak{r}} \to C_{\mathfrak{q}}$. Both rings are Artinian, so their lengths

agree. The same calculation holds for any finite coherent module. Actual domain/quotient base change, NAG-001702/001846, identifies this quotient with the restriction of $A/(f)$. Flatness preserves the injectivity of multiplication by f, so the restricted equation is still regular. This proves compatibility on every actual domain and hence on affinoid refinements of overlaps.

We first supply the missing component inclusion under the stated antichain hypothesis. In any Noetherian ring, $\mathrm{Min}_A(ab)$ is the set of inclusion-minimal members of $\mathrm{Min}_A(a) \cup \mathrm{Min}_A(b)$. Indeed a prime containing ab contains a factor and therefore a prime minimal over that factor by Stacks 00E0(4). A prime minimal over ab must equal that smaller prime. Conversely, if p is inclusion-minimal in the union and $q \subset p$ contains ab, choose by Stacks 00E0(4) a factor-minimal prime $r \subset q$. Then $r \subset q \subset p$ forces $r = q = p$. Thus, for an antichain, every factor component occurs in the product:

$$\mathrm{Min}_A(ab) = \mathrm{Min}_A(a) \cup \mathrm{Min}_A(b).$$

The analytic purity criterion for this hypothesis uses only frozen NAG-002374. If the factor zero spaces are empty or pure of one common dimension d, all primes in the union define integral affinoids of dimension d. A strict inclusion $q \subsetneq p$ would make the nonzero ideal p/q in A/q cut out $\mathcal{M}(A/p)$ of dimension at most $d-1$, or the empty space when $d = 0$. This is impossible. Their union is therefore an antichain, and the product zero space is also empty or pure of dimension d.

For regular a, b, multiplication by b gives the exact sequence

$$0 \longrightarrow A/(a) \xrightarrow{b} A/(ab) \longrightarrow A/(b) \longrightarrow 0.$$

At each prime in the now identified component union, each factor quotient is either zero (a unit after localization) or Artinian. A prime in the union containing a factor is minimal over that factor; otherwise a smaller factor-minimal prime would violate the antichain condition. Add localized finite lengths to get the coefficient identity on every component, including all factor components.

For meromorphic representatives in the stated scope, equality $a/b = c/e$ gives $ae = bc$ on an actual common affinoid restriction: localization at regular elements is injective. The cross-product antichain hypotheses hold there by assumption. In the common pure-zero-space case they hold by the preceding dimension-drop argument: quotient/domain base change identifies the restricted zero spaces with actual domains in the original zero spaces,

and NAG-002413 preserves their purity. Additivity yields $\operatorname{div}(a) - \operatorname{div}(b) = \operatorname{div}(c) - \operatorname{div}(e)$. On a good space, local quotient representatives may be taken on ordinary neighbourhoods. If regularity is initially known only at a germ, the kernel of multiplication is coherent, so it vanishes after shrinking. For a unit of the local total quotient ring, a representative numerator is regular as well: multiplying by an inverse shows that it divides a regular element. These observations justify regular numerator and denominator representatives after the necessary restrictions. Domain compatibility just proved makes their local cycles glue. □

Theorem F.1.13 (Additivity in the verified scope; F8CA-C)**.** *Let A be Noetherian and let a, b be non-zero-divisors. Assume $\operatorname{Min}_A(a) \cup \operatorname{Min}_A(b)$ is an antichain. Define the effective cycle of a regular equation by its actual components and the ambient lengths*

$$\operatorname{div}(a) = \sum_{p \in \operatorname{Min}_A(a)} \operatorname{length}_{A_p}(A_p/aA_p)[\operatorname{Spec}(A/p)].$$

Then $\operatorname{div}(ab) = \operatorname{div}(a) + \operatorname{div}(b)$. For generalized affinoids, the same assertion holds for the actual analytic cycles and their verified effective coefficient transport. In particular it holds under Lemma C.1.57's hypotheses.

Proof. Lemma C.1.29 identifies all components on both sides, including the converse inclusion missing from the original proof. At a prime p in this union, each of $A_p/(a)$ and $A_p/(b)$ is either zero (when the factor is a unit in A_p) or Artinian (when p is minimal over that factor). It is minimal over every factor it contains: otherwise a smaller minimal prime of that factor would contradict the antichain condition. The regularity of b makes the sequence

$$0 \longrightarrow A/(a) \xrightarrow{b} A/(ab) \longrightarrow A/(b) \longrightarrow 0$$

exact. Localize at p and add finite lengths. This gives the coefficient equality on the now identical component sets, the selected algebraic antichain clause. The effective analytic comparison and actual-domain compatibility are the unchanged, independently verified portions of NAG-002772 effective coefficients and actual domain transport; no new length comparison is being inferred from flatness. □

Proposition F.1.14 (Ambient regular representatives; F8NM-R)**.** *Ambient S_1 is unnecessary for local regular numerator and denominator representatives of a unit in the total quotient sheaf. Such representatives remain regular after every actual affinoid restriction, and their pullbacks to the reduced components are nonzero and regular. Equality of two representations $a/b = c/d$ gives $ad = bc$ after an actual common ordinary refinement. Componentwise nonvanishing alone is not a substitute for ambient regularity.*

Proof. For a ring A, localization at its regular elements is injective. If a/b is a unit, write its inverse as c/d, where b, d are regular. Equality in the localization gives $ac = bd$ in A. The product bd is regular. If $az = 0$, then $bdz = acz = 0$, so $z = 0$. Thus a is regular; the same argument applies to c. No associated-prime purity hypothesis is used.

The good-space construction at the end of the proof of frozen NAG-002772 takes these quotients on ordinary neighbourhoods. When injectivity is first known at a germ, the multiplication kernel is coherent and vanishes after shrinking. A finite collection of numerators, denominators, inverse representatives and equalities can be handled on one smaller neighbourhood. This is the exact coherent shrinking scope of that input, not a claim about arbitrary meromorphic objects on a nongood space. Affinoid-domain restriction is flat (NAG-001832), so it preserves the regular multiplication maps.

A regular element avoids every minimal prime, as checked in reviewed F8CR-L. Its image in the domain $A/\mathfrak{q}_i$ is therefore nonzero and regular. F8CR-S and flat actual restrictions supply the corresponding analytic component regularity. The same injection of regular localization proves the cross-product identity. The failure of the last proposed weakening is shown in the algebraic example below. □

In $A = K\langle t, e\rangle/(e^2, te)$, every class has the unique module form $a(t) + ec$, with $a \in K\langle t\rangle$ and $c \in K$. The nilradical is (e), the underlying space is the pure disc, and $\operatorname{ann}(e) = (t, e)$ is an embedded associated prime. At the minimal prime (e), t is invertible and kills e, so the generic length is one. But $A/(t) = K[e]/(e^2)$ has length two at the rigid origin; the reduced component quotient is K. Since $te = 0$ with $e \neq 0$, t is not a Cartier equation. It also cannot be a unit of the ambient total quotient ring: if $t(c/d) = 1$ with d regular, then $tc = d$, and multiplication by e contradicts regularity of d. Componentwise meromorphic invertibility does not solve this.

Appendix G

Stable inertia and original-field models

Let K be a complete nontrivially real-valued field, let $O = K^\circ$, and write $\mathfrak{m}$ and k for its maximal ideal and residue field. The valuation has rank one and need not be discrete. An *F5 model* of a smooth projective geometrically connected curve C/K means a projective, flat, finitely presented nodal O-curve, together with its generic-fibre identification with C, whose special fibre is geometrically connected and reduced. The marking is empty throughout this note. Nodal means at worst nodal of pure relative dimension one; branches need not split over k.

Stable families and their generic-fibre identifications have the conventions of the admitted source 4.14. We use its exact results 4.14.4 and 4.14.5. The example reuses the valued field and extension from C.1.85 and C.1.86.

Lemma G.0.1 (A necessary inertia condition for original-field existence)**.** *Let C/K be as above, of genus $g \geq 2$. Let L/K be finite Galois, with group G, and give L its unique extending absolute value. Put $O' = L^\circ$, let k' be its residue field, and set*

$$I = \ker\bigl(G \longrightarrow \mathrm{Aut}(k'/k)\bigr).$$

Suppose a stable model $\mathcal{Z}/O'$ of C_L is supplied with its generic-fibre identification. Equip it with the unique semilinear G-action of 4.14.5. If C admits an F5 model over O, then every element of I induces the identity morphism on the entire k'-scheme $\mathcal{Z}_{k'}$. No tameness or residue-separability hypothesis is needed for this necessary condition.

Proof. Suppose $f : \mathcal{X} \to \operatorname{Spec} O$ is an F5 model. A nontrivial rank-one valuation ring has only its generic and closed points. Hence all geometric fibres of f are reduced, connected curves of dimension one: the generic fibre is smooth and geometrically connected, and the special fibre has the stated properties. The criterion in Stacks Tag 0E6T, with Stacks Tag 0E6L, makes f a prestable family. The same lemma gives a finite locally free $R^1 f_* \mathcal{O}_{\mathcal{X}}$ with arbitrary base change. Its rank is constant on the connected spectrum of O and equals g at the generic point. Thus this is a prestable family of genus g in the sense of Stacks Tag 0E6V.

Apply the arbitrary-base stabilization theorem Stacks Tag 0E8A. It gives a stable family $\mathcal{Y}/O$ and a morphism $\mathcal{X} \to \mathcal{Y}$ whose fibres contract rational tails and bridges. The smooth geometrically connected generic curve of genus at least two has none, so this morphism identifies $\mathcal{Y}_K$ with C. This use of the stack of stable families requires no new projectivity theorem for $\mathcal{Y}$.

For the scheme convention, the absence of rational tails and bridges on the stable closed fibre gives an ample relative dualizing sheaf on a neighbourhood of the closed point by Stacks Tag 0E74. As the base is local, that neighbourhood is the whole base. The ample sheaf makes $\mathcal{Y}$ a scheme by Stacks Tag 0D32.

Both $\mathcal{Y}_{O'}$ and $\mathcal{Z}$ are stable families of genus g. Their specified generic identifications give a unique isomorphism

$$\alpha : \mathcal{Y}_{O'} \xrightarrow{\sim} \mathcal{Z}$$

by 4.14.4, which applies to arbitrary valuation rings. The canonical semilinear action on the base change $\mathcal{Y}_{O'}$ extends the canonical action on C_L. Transporting it by α must therefore give the specified action on $\mathcal{Z}$, by the uniqueness in 4.14.5.

On the full special fibre $\mathcal{Y}_{k'} = \mathcal{Y}_k \times_k \operatorname{Spec} k'$, the canonical action of $\sigma \in G$ is $\mathrm{id}_{\mathcal{Y}_k} \times \operatorname{Spec}(\overline{\sigma}^{-1})$. For $\sigma \in I$, this is the identity morphism, including the structure sheaf. The equivariant isomorphism $\alpha_{k'}$ transfers that identity to $\mathcal{Z}_{k'}$, as required. □

Proposition G.0.2 (A tame nondiscrete curve with no original-field F5 model)**.** *Use the admitted field and quadratic extension*

$$K = \bigcup_{r \geq 0} \widehat{\mathbf{C}((t^{1/3^r}))}, \qquad v(t) = 1, \qquad L = K(s), \quad s^2 = t.$$

Then $v(K^\times) = \mathbf{Z}[1/3]$ is dense, L/K is tame Galois of degree two, and both residue fields are $\mathbf{C}$. The curve

$$C: \quad Z^4 = t^2(X^4 + Y^4) \ \subset \ \mathbf{P}^2_K$$

is smooth, projective and geometrically connected of genus three. It admits a smooth projective stable model over L°, but admits no F5 model over K°. The geometric dual graph of the supplied stable model has a single vertex and no edges, and is fixed by the Galois action. Thus invariant stable vertices do not imply even existence of some original-field F5 model.

Proof. The field, value group, completeness and extension data are exactly those of C.1.85 and C.1.86, with $k = \mathbf{C}$ and s in place of b. We reuse these facts. In particular $G = \{1, \sigma\}$ with $\sigma(s) = -s$, the residue field does not change, and $I = G$. No assertion that O'/O is finite or etale is being used; the admitted coefficient result in fact proves that O' is not finite over O.

For the homogeneous polynomial $F = Z^4 - t^2(X^4 + Y^4)$ the partial derivatives are

$$-4t^2X^3, \qquad -4t^2Y^3, \qquad 4Z^3.$$

They cannot vanish simultaneously at a projective point over any field extension of K. On each affine chart the dehomogenized partials likewise have no common zero on the curve, by the displayed formula and the degree-four Euler identity. Inverting a nonzero partial gives a standard smooth presentation as in Stacks Tag 00T6; Stacks Tag 00T7 gives smoothness and relative dimension one. Thus C is a geometrically smooth plane quartic. These smooth hypersurfaces are pure one-dimensional and have no embedded points, so Stacks Tag 0BYD applies over K and over every field extension. It gives $H^0(C_E, \mathcal{O}_{C_E}) = E$ and genus $(4-1)(4-2)/2 = 3$. In particular C is geometrically connected: a disconnection over an algebraic closure would give a nontrivial idempotent in that field of global functions. Projectivity is part of its displayed construction.

Let $D/\mathbf{C}$ be the plane quartic $W^4 = X^4 + Y^4$ and put

$$\mathcal{D} = D \times_{\mathbf{C}} \operatorname{Spec} O'.$$

The same computation makes D a smooth projective geometrically connected curve of genus three. Hence $\mathcal{D}$ is a projective smooth family with these geometric fibres. It is stable by Stacks Tag 0E6T and Stacks Tag 0E75: a

smooth connected genus-three curve has no rational tails or bridges. There is an L-isomorphism

$$\phi : C_L \xrightarrow{\sim} D_L, \qquad [X : Y : Z] \longmapsto [X : Y : Z/s].$$

Indeed $s^4 = t^2$, and multiplication of the third coordinate by s gives its inverse. This supplies the required stable model with generic-fibre identification.

Under ϕ, the canonical semilinear action of σ is the coefficient action of σ together with

$$\tau : [X : Y : W] \longmapsto [X : Y : -W].$$

For example, the pullback of $W = Z/s$ is $Z/(-s) = -W$. This action extends to $\mathcal{D}$, since τ is defined over $\mathbf{C}$ and preserves its equation. Uniqueness in 4.14.5 identifies it with the specified action on the stable model. On the special fibre it is τ, which sends $[1 : 0 : 1]$ to the distinct point $[1 : 0 : -1]$. It is therefore not the identity on the special fibre.

If an F5 model of C over O existed, Lemma G.0.1 would force this action to be the identity, a contradiction. Finally, the geometric special fibre of $\mathcal{D}$ is a smooth connected curve, hence has one irreducible component and no nodes. Its geometric dual graph therefore has one vertex and no edges; the action fixes that graph. This graph statement does not assert that its geometric component vertex descends to an original-field F5 vertex. □

Finite model measures and logarithmic integrals

Let K be complete and nontrivially discretely valued, with its specified absolute value, valuation ring R, residue field k, uniformizer π, and

$$\lambda = -\log|\pi| > 0.$$

We do not renormalize λ to one or pass to an algebraic closure. Let X be an integral proper K-variety of dimension $d \geq 2$. Take a proper flat integral normal finite-type R-model $\mathcal{X}$ with identified generic fibre X. Retain explicitly the following local data: every height-one local ring used below is a DVR, and the special fibre has finitely many irreducible components V, all of dimension d. These are hypotheses, not assertions about arbitrary analytic local rings. Smoothness or strict semistability of the model is not required.

Write $A_V = \mathcal{O}_{\mathcal{X},\eta_V}$ and normalize ord_V by a uniformizer of this DVR. Then

$$b_V = \mathrm{ord}_V(\pi) = \mathrm{length}_{A_V}(A_V/\pi A_V) > 0, \qquad [\mathcal{X}_k] = \sum_V b_V[V]. \tag{G.0.1}$$

Thus a nonreduced special fibre is allowed. Its b_V is not discarded. The point $\xi_V \in X^{\mathrm{an}}$ is specified on $K(X)$ by

$$|a(\xi_V)| = |\pi|^{\mathrm{ord}_V(a)/b_V} \quad (a \neq 0). \tag{G.0.2}$$

Distinct components give distinct points: the bounded valuation ring in (G.0.2) has centre η_V on $\mathcal{X}$, so equality of points would give equality of their centres. If the points were equal, their valuations would give the same valuation ring. The two maps from its spectrum to the separated model agree at the generic point. The closed diagonal and integrality of that spectrum force them to agree everywhere, including at the centre. The model ring A_V, the ordinary analytic stalk $\mathcal{O}_{X^{\mathrm{an}},\xi_V}$, and the completed residue field $\mathcal{H}(\xi_V)$ are different objects. Only the first is a DVR hypothesis here.

Choose line bundles $L_1, \ldots, L_d, M$ on X and model lines

$$\mathcal{L}_i|_X \simeq L_i^{\otimes e_i}, \qquad \mathcal{M}|_X \simeq M^{\otimes e_0}, \qquad e_i, e_0 \in \mathbf{Z}_{>0}.$$

Use their continuous root model metrics: a model frame has norm one, and if $s^{\otimes e_0} = ae$ in a model frame e, then $\|s\| = |a|^{1/e_0}$ on the domain reducing to that frame. The model metrics are supplied as part of these data. Put

$$E = \prod_{i=1}^{d} e_i, \quad \delta_V = \deg_{\mathcal{L}_1|_V,\ldots,\mathcal{L}_d|_V,k}(V), \quad \mu_{\mathcal{X}} = \sum_V \frac{b_V\delta_V}{E}\,\delta_{\xi_V}. \tag{G.0.3}$$

The degree is the mixed algebraic degree over k, with its usual full residue-field dimensions. It is not a degree over the field of constants of V followed by omission of that field degree. We use the specified integers δ_V and the finite measure above. The measure may be signed. Positivity requires $\delta_V \geq 0$. Its mass is exactly $E^{-1}\sum_V b_V\delta_V$; identifying this with a generic-fibre degree would use an additional algebraic specialization identity. The mixed convention contains no extra $d!$. For a proper d-dimensional integral k-scheme W and invertible sheaves $M_1,\dots,M_d$, use the mixed degree

$$\delta(W;M_1,\dots,M_d) = \deg_k\big(c_1(M_1)\cdots c_1(M_d)\cap[W]\big).$$

The selected supported operations in NAG-003112 compute the actual multiples of the coordinate divisor cycles, and their push into the ambient support gives the first Chern operation. The degree convention is the one used with NAG-003117.

Let s be a nonzero rational section of M. A model frame at η_V writes $s^{\otimes e_0} = a_V e_V$, and put $c_V = \operatorname{ord}_V(a_V)$. A change of model frame multiplies a_V by a DVR unit, so c_V is well-defined. Write $g_s = -\log\|s\|$ on the dense open where s is regular and nonvanishing.

Theorem G.0.3 (Exact logarithmic integral on a proper model)**.** *Under the standing finite-model data, every ξ_V lies in the analytification of every nonempty Zariski open subset of X. In particular g_s is finite at all the atoms of $\mu_{\mathcal{X}}$ and is integrable with respect to its total variation. The exact formulas are*

$$g_s(\xi_V) = \frac{\lambda c_V}{e_0 b_V}, \tag{G.0.4}$$

$$\int_{X^{\mathrm{an}}} g_s\, d\mu_{\mathcal{X}} = \frac{\lambda}{e_0 E}\sum_V c_V\delta_V, \tag{G.0.5}$$

$$\int_{X^{\mathrm{an}}} |g_s|\, d|\mu_{\mathcal{X}}| = \frac{\lambda}{e_0 E}\sum_V |c_V\delta_V|. \tag{G.0.6}$$

Every proper algebraic closed subset of X has $|\mu_{\mathcal{X}}|$-measure zero. For $a\in K^\times$, replacing s by as changes (G.0.5) by $-\log|a|\,\mu_{\mathcal{X}}(X^{\mathrm{an}})$.

Direct inputs NAG-001707, the standing finite-model data.

Proof. On an affine model neighbourhood of η_V, the valuation in (G.0.2) is nonnegative on the model coordinate ring and extends the given absolute

value on K. Indeed, $\mathrm{ord}_V(u) = 0$ for $u \in R^\times$, and $\mathrm{ord}_V(\pi) = b_V$. The valuation inequality and multiplicativity therefore give an analytic point by NAG-001707. Its kernel in the generic-fibre coordinate ring is zero, since the valuation of each nonzero rational function is finite. Its underlying scheme point is the generic point of X. Hence it belongs to every nonempty Zariski open, including the locus where s is regular and nonvanishing. Formula (G.0.2) and the root metric give (G.0.4). This also shows that an arbitrary value assigned on the omitted divisor does not affect the integral.

A finite sum of distinct Dirac masses has total variation obtained by taking the absolute values of its coefficients. Substituting (G.0.4) into (G.0.3) proves both integral formulas. The positive integer b_V cancels between the mass and the value; it has not been set to one. The zero-mass assertion follows from the generic scheme point of every atom. Finally

$$c_V(as) = c_V(s) + e_0 \,\mathrm{ord}_V(a) = c_V(s) + e_0 b_V \,\mathrm{ord}_R(a).$$

Since $-\log|a| = \lambda \,\mathrm{ord}_R(a)$, substitution proves the last assertion with its stated sign. □

Proposition G.0.4 (Weak convergence does not control the logarithm)**.** *For every $d \geq 2$ and K as in the standing finite-model data there are genuine semipositive product-model measures μ_j of mixed mass one on $X = (\mathbf{P}^1_K)^d$ and a fixed model-metrized line (M, h) with a nonzero regular section s such that*

$$\mu_j \Longrightarrow \delta_o, \qquad \int -\log \|s\|_h \, d\mu_j = j\lambda \longrightarrow +\infty, \qquad o \in Z(s).$$

Thus finite-model integrability and weak measure convergence, even with an unchanged metric on M, do not imply logarithmic integrability of the limit. This does not contradict convergence theorems that also require uniform convergence of the semipositive metrics defining the measures.

Direct inputs NAG-000182, NAG-001707, NAG-001709, NAG-001714, the standing finite-model data, the mixed algebraic degree convention.

Proof. For each $j \geq 1$ use the model $(\mathbf{P}^1_R)^d$ with generic-fibre identification $T_i = \pi^j S_i$, and the model lines $\mathrm{pr}_i^* \mathcal{O}(1)$. They are semipositive: on any special-fibre curve their degrees are nonnegative, since they are generated by global sections. The special fibre has one reduced component, $b = 1$,

and its mixed degree is one, by intersecting the d coordinate divisors at one k-rational product point. Its model measure is therefore $\mu_j = \delta_{\xi_j}$, where

$$\left| \sum_{m \in \mathbf{N}^d} a_m T^m \right| (\xi_j) = \max_m |a_m| \, |\pi|^{j(m_1 + \cdots + m_d)}.$$

Gauss multiplicativity gives the point, and its polynomial evaluations converge to $|a_0|$, the evaluations at the origin o. The evaluation topology in NAG-001707 gives $\xi_j \to o$ in the common affine chart and thus in X^{an}. Consequently the Dirac masses converge against every continuous analytic test, not just radial tests.

Use $M = \mathrm{pr}_1^* \mathcal{O}(\infty)$ with its standard model metric and its global section $s = T_1$ relative to the frame 1 on the finite chart. On that chart

$$\|s(x)\|_h = \frac{|T_1(x)|}{\max(1, |T_1(x)|)}.$$

This extends as a regular section nonzero at infinity, with zero divisor $\{T_1 = 0\}$. At ξ_j the norm is $|\pi|^j$, so the integral is $j\lambda$. At o it is zero and its negative logarithm is infinite. For fixed R, the tails are $(j\lambda - R)_+$ and are unbounded in j. The curvature metrics defining μ_j are moving; their uniform convergence is not claimed. □

Coherent tensor projection for finite analytic maps

Fix a complete field K with its specified real-valued non-Archimedean absolute value. Trivial valuation and generalized affinoid radii are allowed. Spaces in this supplement are good and Hausdorff. Coherent modules live on the analytic G-site. A line bundle means a coherent module which is free of rank one on ordinary open neighbourhoods. The symbol q^* on coherent modules denotes ordinary tensor pullback; it is not a derived functor.

For a norm-admissible finite morphism $q : Y \to X$, the full inverse image of $V = \mathcal{M}(A)$ is $\mathcal{M}(B)$, where B is finite over A with its canonical finite-module norm. If N is finite over B, compose controlled finite free presentations $A^a \twoheadrightarrow B$ and $B^b \twoheadrightarrow N$. Their lifting bounds compare the iterated quotient norm with the canonical finite-A-module norm. Thus restriction of scalars also preserves the canonical topology on N. Every tensor used below between finite modules has its canonical topology. The comparison with the completed analytic tensor is provided by NAG-001565 and NAG-001702. Algebraic finiteness with an unrelated Banach norm would not suffice.

Proposition G.0.5 (Coherent tensor projection)**.** *Let $q : Y \to X$ be norm-admissible and finite. For $\mathcal{F} \in \mathrm{Coh}(Y_G)$ and $\mathcal{E} \in \mathrm{Coh}(X_G)$ there is a canonical isomorphism*

$$q_*(\mathcal{F} \otimes_{\mathcal{O}_Y} q^*\mathcal{E}) \simeq q_*\mathcal{F} \otimes_{\mathcal{O}_X} \mathcal{E}. \tag{G.0.7}$$

It commutes with affinoid-domain restriction and analytic base change. Neither $\mathcal{F}$ nor $\mathcal{E}$ is required to be locally free.

Direct inputs NAG-001565, NAG-001624, NAG-001702, and NAG-001752.

Proof. On $V = \mathcal{M}(A)$ and its full inverse image $\mathcal{M}(B)$, let M and N represent $\mathcal{E}$ and $\mathcal{F}$. The map

$$N \otimes_B (B \otimes_A M) \longrightarrow N \otimes_A M, \qquad n \otimes (b \otimes m) \longmapsto bn \otimes m$$

has inverse $n \otimes m \mapsto n \otimes (1 \otimes m)$. These are maps of finite A-modules, so they are bounded, with bounded inverses, for the canonical norms. The finite-tensor theorem identifies the modules with the analytic completed constructions.

For a bounded affinoid base change $A \to C$, put $D = B \otimes_A C$. The same formulas identify both base changes with $N \otimes_A M \otimes_A C$. In particular they

respect domain restrictions. The finite coherent direct-image theorem and affinoid coherent equivalence therefore glue them to (G.0.7). This argument concerns an isomorphism of tensors, and asserts no exactness for tensoring with an arbitrary $\mathcal{E}$. □

Norm integrals and logarithmic limits for finite models

Theorem G.0.6 (Norm integration under a component-degree criterion)**.** *Let $q : \mathcal{Y} \to \mathcal{X}$ be finite locally free of constant rank $N \geq 1$, with both models in the class of the standing finite-model data and with integral generic fibres Y, X. Give q^*L_i and q^*M their pulled-back model metrics. For each V, set*

$$B_V = (q_*\mathcal{O}_{\mathcal{Y}})_{\eta_V}, \qquad A_V = \mathcal{O}_{\mathcal{X},\eta_V}.$$

Retain the ordinary algebraic local descriptions: B_V is the whole finite free rank-N algebra, and all its maximal localizations are the DVRs $\mathcal{O}_{\mathcal{Y},\eta_W}$ for the components W over V. Let t_V be a uniformizer of A_V, and put

$$r_W = \mathrm{ord}_W(t_V), \quad f_W = [\kappa(W) : \kappa(V)], \quad \delta_W = \deg_{q^*\mathcal{L}_1|_W,\dots,q^*\mathcal{L}_d|_W,k}(W).$$

Assume the finite list of component-degree identities

$$\delta_W = f_W \delta_V \quad (W \mid V). \tag{G.0.8}$$

For a nonzero rational section s of q^*M, use the determinant section $\mathrm{Nm}_q(s)$ of $\mathrm{Nm}_q(q^*M) \simeq M^{\otimes N}$, with the metric induced by the model line $\mathcal{M}^{\otimes N}$ and root exponent e_0. Then

$$q_*^{\mathrm{an}}\mu_{\mathcal{Y}} = N\mu_{\mathcal{X}}, \tag{G.0.9}$$

$$\int_{X^{\mathrm{an}}} -\log\|\mathrm{Nm}_q(s)\|\, d\mu_{\mathcal{X}} = \int_{Y^{\mathrm{an}}} -\log\|s\|\, d\mu_{\mathcal{Y}}. \tag{G.0.10}$$

Both logarithmic integrals are absolutely convergent with respect to total variation. All components, full residue degrees and unreduced DVR quotients are retained, including in inseparable cases. The criterion holds for the coordinate power map $T_i = S_i^{n_i}$ on $(\mathbf{P}^1_R)^d$, with $n_i \geq 1$, $\mathcal{L}_i = \mathrm{pr}_i^*\,\mathcal{O}(1)$, and $e_i = 1$.

Direct inputs `NAG-002543`, `NAG-002552`, Theorem G.0.3, the mixed algebraic degree convention.

Proof. Each local DVR extension gives

$$b_W = r_W b_V, \qquad \sum_{W|V} f_W r_W = N. \tag{G.0.11}$$

The first equality follows by writing $\pi = ut_V^{b_V}$ with u a unit. For the second, apply NAG-002543 to the regular sequence (t_V) in A_V and the full algebra B_V. Its summand at W is $f_W r_W$ because $\operatorname{length}_{\mathcal{O}_{\mathcal{Y},\eta_W}}(\mathcal{O}_{\mathcal{Y},\eta_W}/t_V) = r_W$. This proof does not require a separable residue extension. Equations (G.0.2) and (G.0.11) give $q^{\mathrm{an}}(\xi_W) = \xi_V$. Thus the mass pushed to ξ_V is

$$\sum_{W|V} \frac{b_W \delta_W}{E} = \frac{b_V \delta_V}{E} \sum_{W|V} r_W f_W = N \frac{b_V \delta_V}{E},$$

which proves (G.0.9).

Let $F = K(X)$ and $L = K(Y)$. The generic algebra $B_V \otimes_{A_V} F$ is L, a field extension of full degree N. For $a \in L^\times$, NAG-002552 gives

$$\operatorname{ord}_V \operatorname{Nm}_{L/F}(a) = \sum_{W|V} f_W \operatorname{ord}_W(a). \tag{G.0.12}$$

To include a rational a, choose a nonzero $z \in A_V$ with $za \in B_V$, possible because B_V spans L over F. Apply that lemma to za and to z, and subtract. Multiplication by a on L is invertible even for an inseparable extension; its determinant, rather than a product over distinct embeddings, is the norm used here.

In a local frame e of $\mathcal{M}$, write $s^{\otimes e_0} = aq^*e$. The coefficient of $(\operatorname{Nm}_q s)^{\otimes e_0}$ in $e^{\otimes N}$ is $\operatorname{Nm}_{L/F}(a)$. Indeed, exterior multiplication on the rank-N module gives $\det(m_a)$, while changing e by a unit u multiplies the determinant frame by u^N. These changes are exactly those of $\mathcal{M}^{\otimes N}$, so the construction glues and has the stated pulled-back tensor-power metric. Consequently, if $c_W = \operatorname{ord}_W(a)$, then the downstairs coefficient is $\sum_{W|V} f_W c_W$. Theorem G.0.3 now gives

$$\int -\log \|\operatorname{Nm}_q(s)\| \, d\mu_{\mathcal{X}} = \frac{\lambda}{e_0 E} \sum_V \delta_V \sum_{W|V} f_W c_W = \frac{\lambda}{e_0 E} \sum_W \delta_W c_W.$$

The last expression is the upstairs integral. Absolute convergence is part of the same finite-sum theorem.

For the coordinate power map, the exponent classes $\prod_i S_i^{a_i}$, $0 \le a_i < n_i$, are a free basis on every coordinate chart. They give finite flat rank $N = \prod_i n_i$ and the full special-fibre field degree N, including inseparable degrees. The single reduced component has mixed degree one downstairs. Upstairs the pullback of the ith coordinate line is $\mathrm{pr}_i^* \mathcal{O}(n_i)$. Choose the coordinate

section with divisor $n_i\{S_i = 0\}$ for each i. Their proper intersection at the rational product origin has local algebra

$$k[S_1, \dots, S_d]/(S_1^{n_1}, \dots, S_d^{n_d}),$$

whose monomial basis has length N. This computes the mixed degree as N and verifies (G.0.8) in the stated example. □

Assume in this section that X^{an} is compact Hausdorff; the projective case is supplied by NAG-001714. Let s be a nonzero global regular section of a line bundle M, $D = Z(s)$, and h a continuous metric. Extend $g = -\log \|s\|_h$ by $+\infty$ on D^{an}. It is bounded below. For each j, let h_j be a continuous metric and μ_j a positive finite model measure on X^{an}, with its generic divisorial atoms as above. Let $g_j = -\log \|s\|_{h_j}$ at those atoms, and assume

$$\varepsilon_j = \sup_{x \in X^{\mathrm{an}}} \left| \log \frac{\| \cdot \|_{h_j,x}}{\| \cdot \|_{h,x}} \right| \longrightarrow 0, \qquad \mu_j \Longrightarrow \mu, \tag{G.0.13}$$

where μ is a finite positive Radon measure and convergence is against all real continuous functions. The fibrewise ratio uses any nonzero vector and is independent of that vector.

Theorem G.0.7 (Uniform logarithmic tails suffice)**.** *In the preceding setup write*

$$T_j(R) = \int (g_j - R)_+ \, d\mu_j = \sum_V a_{j,V} \big(g_j(\xi_{j,V}) - R\big)_+, \qquad a_{j,V} = \mu_j(\{\xi_{j,V}\}) \geq 0.$$

Suppose

$$\lim_{R \to \infty} \sup_j T_j(R) = 0. \tag{G.0.14}$$

Then $\mu(D^{\mathrm{an}}) = 0$, $g \in L^1(\mu)$ and

$$\int g \, d\mu = \lim_{j \to \infty} \int g_j \, d\mu_j. \tag{G.0.15}$$

If h_j and the metrics defining μ_j have the common model data of the standing finite-model data, the hypothesis is the explicit coefficient condition

$$\lim_{R \to \infty} \sup_j \sum_V \frac{\delta_{j,V}}{e_{0,j} E_j} \big(\lambda c_{j,V} - e_{0,j} b_{j,V} R\big)_+ = 0. \tag{G.0.16}$$

In particular a common upper bound on $c_{j,V}/(e_{0,j}b_{j,V})$ suffices. More generally, if $g_j \geq C$ at all atoms and for some $\alpha > 0$ and $A < \infty$ one has

$$\sup_j \sum_V a_{j,V}(g_j(\xi_{j,V}) - C)^{1+\alpha} \leq A, \tag{G.0.17}$$

then $T_j(R) \leq A/(R-C)^\alpha$ for $R > C$, so the conclusion holds.

Direct inputs Theorem G.0.3, NAG-001714.

Proof. Because $\|s\|_h$ is continuous and bounded on the compact space, g is bounded below. Each function $g_R = \min(g, R)$ is a finite continuous function, including at D^{an}: it is the continuous capped function of the nonnegative quantity $\|s\|_h$. Metric convergence implies $|g_j - g| \leq \varepsilon_j$ off D^{an} and hence at every model atom by Theorem G.0.3. The sequence ε_j is bounded. Thus all these atom values have a common lower bound C, and g can also be taken at least C. Let $m_j = \mu_j(X^{\mathrm{an}})$. Weak convergence tested on 1 makes m_j bounded. The map $u \mapsto \min(u, R)$ is 1-Lipschitz, so

$$\left| \int \min(g_j, R)\, d\mu_j - \int g_R\, d\mu_j \right| \leq \varepsilon_j m_j. \tag{G.0.18}$$

For fixed R, its left integrals therefore have common limit $I_R = \int g_R\, d\mu$.

Put $I_j = \int g_j\, d\mu_j$ and $T(R) = \sup_j T_j(R)$. The exact identity

$$I_j = \int \min(g_j, R)\, d\mu_j + T_j(R)$$

gives

$$I_R \leq \liminf_j I_j \leq \limsup_j I_j \leq I_R + T(R). \tag{G.0.19}$$

For some fixed sufficiently large R_0, $T(R_0)$ is finite. Since g_{R_0} is bounded and the m_j are bounded, the I_j are bounded above; their lower bound follows from Cm_j. Hence I_R is bounded above as R grows. By the definition of the positive integral, $\sup_R \int (g_R - C)\, d\mu = \int (g - C)\, d\mu$: every bounded nonnegative simple function below $g - C$ lies below $g_R - C$ once $R - C$ exceeds its largest value. Thus g has finite integral. The simple functions $n\, 1_{D^{\mathrm{an}}} \leq g - C$ then force $\mu(D^{\mathrm{an}}) = 0$, and the lower bound gives $g \in L^1(\mu)$. Letting $R \to \infty$ in (G.0.19) proves (G.0.15).

On a common model, substitute $a_{j,V} = b_{j,V}\delta_{j,V}/E_j$ and $g_j(\xi_{j,V}) = \lambda c_{j,V}/(e_{0,j}b_{j,V})$. Since $b_{j,V}, e_{0,j} > 0$ and $\delta_{j,V} \geq 0$, the expression for $T_j(R)$

becomes exactly the sum in (G.0.16). A uniform upper bound on the indicated ratios makes it zero for large R. Finally, for $x \geq C$ and $R > C$,

$$(x - R)_+ \leq \frac{(x - C)^{1+\alpha}}{(R - C)^{\alpha}}.$$

Summing proves the final sufficient condition. □

Lemma G.0.8 (A finite-group orbit tensor with trivial inertia)**.** *Let S be affine, let X/S be separated, and let a finite group G act on X by automorphisms covering automorphisms of S. Let $I \triangleleft G$, and let $C \hookrightarrow X$ be a G-stable closed subscheme on which every element of I acts identically. If $\mathcal{A}$ is relatively ample on X/S, then*

$$\mathcal{N} = \bigotimes_{g \in G} \rho_g^* \mathcal{A} \tag{11}$$

is relatively ample and has its canonical permutation G-linearization. Its restricted I-action on $\mathcal{N}|_C$ is the identity. If $H = G/I$, and $\bar{\rho}_h$ denotes its induced action on C, the underlying restricted invertible sheaf is

$$\mathcal{N}|_C \simeq \bigotimes_{h \in H} (\bar{\rho}_h^*(\mathcal{A}|_C))^{\otimes |I|}. \tag{12}$$

The construction commutes with equivariant pullbacks and specified transition isomorphisms of the input sheaves. It therefore applies to compatible towers. No group order is inverted.

Proof. For $h \in G$, the factors of $\rho_h^* \mathcal{N}$ are $\rho_{gh}^* \mathcal{A}$, indexed by $g \in G$. Reindexing by $g \mapsto gh$ gives λ_h. Associativity of pullback and the usual symmetry of tensor products show that the two maps for any composite agree: both reindex the same factors in the same way. The identity gives the identity map. This proves the linearization, including all noncommutative group relations.

On C, the action factors through H. The factors indexed by a right coset gI are canonically the same invertible sheaf $\bar{\rho}_{gI}^*(\mathcal{A}|_C)$. Grouping these factors gives (12). For $i \in I$, right multiplication by i permutes factors within each such coset. Locally trivialize each of the finitely many coset sheaves. A permutation of copies of a rank-one module fixes the tensor of their chosen generator, and fixes every coefficient because $\rho_i|_C$ is the identity. Hence it is the identity of the full restricted module. This includes nilpotents; no conclusion is being drawn merely from pointwise characters.

Ampleness is unchanged by an isomorphism of schemes. Over the affine base, relative and absolute ampleness agree by Stacks Tag 01VK. Finite tensor products of these ample sheaves are ample: use the external-product assertion Stacks Tag 0DNK over the affine, hence quasi-separated, base, and pull back by the closed diagonal using Stacks Tag 0B3E; then induct on the number of factors. In the section argument for the external-product assertion, sections of powers n and m are first raised to powers m and n, so their product is a section of the common power nm. This is the same ampleness argument used in the audited cyclic orbit construction, with a finite group as index set.

Finally, an equivariant pullback identifies each indexed factor with the corresponding pulled-back factor. Tensoring the given maps on these factors commutes with every permutation above. This proves the asserted transition compatibility and the tower statement. □

Let A be a nonzero Noetherian ring. Set

$$S = A \setminus \bigcup_{\mathfrak{p} \in \operatorname{Min}(A)} \mathfrak{p}, \qquad T(A) = \ker\left(A \longrightarrow \prod_{\mathfrak{p} \in \operatorname{Min}(A)} A_{\mathfrak{p}} \right), \qquad A^{\mathrm{u}} = A/T(A). \tag{1.1}$$

We call $T(A)$ the embedded torsion ideal. No reduction of the generic Artinian local rings is performed.

Supplied hypothesis (SC). For a finite module over a generalized affinoid algebra, the S_1 property of the algebraic localizations is equivalent to the corresponding analytic property. The property is preserved on analytic domains.

Proposition G.0.9 (Coherent embedded torsion quotient; F8U-G)**.** *Assume (SC) and the stated v0.38 coherent-domain interfaces. On a good Hausdorff pure n-dimensional analytic X, the ideals $T(A)$ on affinoid domains glue to a coherent ideal $\mathcal{T}$. The closed subspace*

$$i : X^{\mathrm{u}} = (X, \mathcal{O}_X/\mathcal{T}) \longrightarrow X \tag{3.1}$$

is finite, is a homeomorphism on underlying points, is pure of analytic dimension n, and satisfies S_1. Every regular analytic local function on X remains regular on X^{u}. Pullback sends $\operatorname{Int}(X/K)$ *into* $\operatorname{Int}(X^{\mathrm{u}}/K)$.

Proof. Let $A \to B$ represent an actual nonempty affinoid domain of $\mathcal{M}(A)$. Restriction is exact on coherent sheaves, and NAG-001624 identifies it with $B \otimes_A -$ on finite modules. In particular $TB = T(A) \otimes_A B$ injects into B. The lower-dimensional support bound of NAG-002669 applies to the original torsion ideal. Its support is the restriction of $\operatorname{Supp} T(A)$, so has analytic dimension at most $n-1$, by domain base change NAG-001846 and dimension locality. The domain is pure of dimension n by NAG-002413. Therefore $TB \subseteq T(B)$: a module with smaller-dimensional support has zero localization at every minimal prime of B.

The quotient B/TB is the actual domain algebra obtained by base change from A^{u}, using NAG-001565 and NAG-001846. By Lemma C.1.36, A^{u} is S_1; (SC) makes B/TB S_1 as well. Its underlying space is unchanged by the nilpotent ideal TB and remains pure of dimension n. The image of $T(B)$ in B/TB has support of dimension at most $n-1$. A nonzero submodule of a Noetherian S_1 pure structure module has an associated prime among its

minimal primes, so cannot have smaller-dimensional support. The image is zero, proving

$$T(B) = T(A) \otimes_A B. \tag{3.2}$$

Thus the coherent ideals coincide on all actual affinoid intersections and satisfy the cocycle condition. The coherent sheaf equivalence NAG-001624 glues them, without assuming a finite global cover.

Each local quotient is by a finite nilpotent ideal, as in the actual closed quotient of NAG-001653, so (3.1) is a finite closed immersion and a homeomorphism. Its analytic dimension and purity agree with those of X; (SC) gives the asserted S_1 property. Regularity follows locally from Lemma C.1.36. Finite morphisms are relatively interior by NAG-001701; composition of interiors, NAG-001704, proves the last claim. In particular a boundaryless X gives boundaryless X^{u}. □

Finite logarithmic graph: weights and persistence.

Use the finite logarithmic graph and its notation from the setup preceding the actual source-image lemma. In particular the field, the tuples $h, (g_0, f_0)$, and the domains $V_0, V_{0,S}$ are those specified there.

Lemma G.0.10 (The whole-fibre weight is one; F8GP-4)**.** *For every S, the h-moment chain of $V_{0,S}$ is*

$$\mathrm{Trop}_{h,V_{0,S}}(\mathcal{O}_{V_{0,S}}) = \mathcal{P}|_{\{t\circ F\le S\}}. \tag{3.2}$$

Each full-dimensional product cell that survives truncation has weight one. Lower-dimensional pieces contribute no n-chain.

Proof. Apply the frozen compact-chain theorem to the pure space $V_{0,S}$ and tuple h. Its construction subdivides the actual image and its boundary image, the latter of dimension at most $n-1$. Choose w in the relative interior of an n-cell of P_S, away from that boundary image and from the product's proper faces. Thus the *entire* h-fibre over w is interior over K, and the local image is in one product cell's affine n-plane. These are precisely the two flat-germ hypotheses required by NAG-002362. This use of the frozen theorem is only its existing compact-domain scope. For a factor of type D_i or E_i, set $q_i = T_i$; for a factor of type H_i, set $q_i = T_i - 1$. Adjoin the Z_ν as the remaining coordinates. The tangent lattice of this product cell is carried isomorphically onto $\mathbb{Z}^n$ by these selected moment coordinates: its basis vectors are respectively $(1,1)$, $(0,1)$, $(1,0)$, and the torus coordinate vectors in disjoint coordinate blocks.

The algebra of the *entire* h-fibre over w is the exact-radius Laurent algebra $R_q = A_{K,r(w)}$. To check the assertion as an algebra statement, not just a set equality, express the omitted coordinates and their inverses in R_q. On a D_i-factor, $|q_i| > 1$, and

$$(T_i - 1)^{-1} = q_i^{-1} \sum_{\ell\ge 0} q_i^{-\ell}.$$

On an E_i-factor, $|q_i| < 1$, and

$$(T_i - 1)^{-1} = -\sum_{\ell\ge 0} q_i^{\ell}.$$

On an H_i-factor, $|q_i| < 1$, and

$$T_i^{-1} = (1+q_i)^{-1} = \sum_{\ell\ge 0} (-q_i)^{\ell}.$$

These series converge in the exact-radius norm. The simultaneous level relations give bounded homomorphisms in both directions; they fix all coordinate generators and hence are inverse. All inequalities defining $V_{0,S}$ have fixed values on this whole fibre, so no factor or sheet is removed by them.

The choice of w does not require $t \circ F < S$. If $t \circ F$ is constant on an n-cell and equals S, that whole cell is part of the actual image P_S. The frozen boundary-image dimension bound still permits the same generic interior-fibre choice on it. No equality-level cell is removed.

For the selected transverse coordinates, the lattice divisor is one and the actual Gauss algebra is

$$R_q \widehat{\otimes}_{R_q} H_q = H_q.$$

Its dimension over H_q is one. The frozen module-weight theorem therefore gives weight one at w. This determines the coefficient of every surviving n-cell. The finite-chain theorem, subdivision independence, and lemma C.1.39 give (3.2). □

Theorem G.0.11 (Persistent logarithmic graph; F8GP-1)**.** *For every real S, put*

$$V_{0,S} = \{z \in V_0 : |f_0(z)| \geq e^{-S}\}, \qquad P_S = P \cap \left\{ \lambda + \sum_i m_i s_i + b \cdot x \leq S \right\}. \tag{1.7}$$

Every nonempty $V_{0,S}$ is pure of analytic dimension n. The following chain is defined once, independently of S:

$$C_0 = F_* \mathcal{P}. \tag{1.8}$$

The pushforward counts each full-rank cell with its lattice index and discards cells on which F has rank below n. It is a finite nonnegative integral n-chain, and

$$\boxed{\mathrm{Trop}_{(g_0,f_0),V_{0,S}}(\mathcal{O}_{V_{0,S}}) = C_0|_{\{t \leq S\}}} \tag{1.9}$$

for every S, with zero chain for the empty domain. Its support lies in

$$\left(\kappa + M \left(\prod_i [-A_i, B_i] \times Q \right) \right) \times [t_{\min}, \infty), \quad t_{\min} = \lambda - \sum_i m_i A_i + \min_Q b \cdot x. \tag{1.10}$$

Thus the same finite weighted chain works at all levels, including levels where a full-dimensional cell lies in $\{t = S\}$.

Proof of theorem G.0.11. Purity is lemma C.1.40. On $V_{0,S}$, all entries of h and (g_0, f_0) are units. Their actual moment maps satisfy $t_{(g_0,f_0)} = F \circ t_h$. If $V_{0,S}$ is empty, the actual source image makes $\mathcal{P}|_{\{t \circ F \le S\}}$ zero. The closed-cutoff pushforward then gives the required zero chain. Otherwise adjoin the actual constant units $a, c_1, \dots, c_r$ to h. The whole level algebras and the transverse Gauss dimensions are unchanged, and the saturated tangent lattices embed with zero constant coordinates and index one. The translated formula is now a literal character map for the identity finite map of $V_{0,S}$. Use whole-interior projection off the target absolute boundary image. That lower-dimensional image does not contain any top-dimensional cell of a full-rank image, even at $t = S$. On a common subdivision the finite-module chain and weights identify the closed chains from their generic coefficients. This gives

$$\operatorname{Trop}_{(g_0,f_0),V_{0,S}}(\mathcal{O}) = F_* \operatorname{Trop}_{h,V_{0,S}}(\mathcal{O}).$$

Substitute (3.2), then (3.3), to obtain (1.9). The bounds in (1.10) follow directly from $y_i \in [-A_i, B_i]$, $x \in Q$, and $s_i \ge -A_i$. The finite chain is constructed before any S is chosen. □

Write $A_0 = \mathcal{O}(V_0)$ for the algebra of the specified graph domain.

Theorem G.0.12 (Persistence under covers and perturbations; F8GP-7)**.** *Let $p : V = \mathcal{M}(B) \to V_0 = \mathcal{M}(A_0)$ be finite with its canonical module norm, and suppose B is a locally free A_0-module of constant positive rank e. Assume V is pure of dimension n. Let $u_0, u_1, \dots, u_r \in B^\times$ satisfy*

$$|u_j(z)| = 1 \quad \text{for every } z \in V. \tag{5.1}$$

For

$$f = p^* f_0 \, u_0, \qquad g_\ell = p^* g_{0,\ell} \, u_\ell, \qquad V_S = \{|f| \ge e^{-S}\},$$

the function f is regular, every nonempty V_S is pure of dimension n, and one single chain

$$C = eC_0 \tag{5.2}$$

satisfies

$$\boxed{\operatorname{Trop}_{(g,f),V_S}(\mathcal{O}_{V_S}) = C|_{\{t \le S\}}} \tag{5.3}$$

for every real S. The same bound (4.2) applies. Neither separability, reducedness of V, nor global freeness of B is required.

A concrete sufficient condition for (5.1) is $u_j = 1 + \varepsilon_j$ with $\|\varepsilon_j\| < 1$ in a specified complete submultiplicative affinoid norm on B.

Proof. The norm identities give, on all points,

$$|f| = |p^* f_0|, \qquad |g_\ell| = |p^* g_{0,\ell}|, \qquad V_S = p^{-1}(V_{0,S}). \tag{5.4}$$

Thus no source sheets are selected or omitted. The map on V_S is the actual finite base change; its direct-image module is still locally free of rank e. Purity of V_S follows from domain purity applied to V. Flatness of B over A_0 preserves injectivity of multiplication by f_0. Multiplication by u_0 is invertible, proving regularity of f.

If $V_{0,S}$ is empty, (5.4) makes V_S empty and (1.9) gives (5.3). Otherwise apply whole-interior projection to $p|_{V_S}$ over the original field, using the literal pullbacks of the target tuple and the identity map on the moment coordinates. By (5.4) the norm-one twists have the same moment map and the same whole analytic level domains as those literal pullbacks. The relative interiors of target top cells avoid the target absolute boundary image after a common subdivision. The finite-module chain and weights give equality of the closed finite chains from the generic equalities. This gives

$$\mathrm{Trop}_{(g,f),V_S}(\mathcal{O}_{V_S}) = \mathrm{Trop}_{(g_0,f_0),V_{0,S}}(p_*\mathcal{O}_{V_S}). \tag{5.5}$$

At a generic target cell, let E_Q be its complete transverse Gauss algebra. The tensor of the locally free module $p_*\mathcal{O}_{V_S}$ with E_Q has constant rank e. The finite-dimensional Artinian algebra E_Q is a product of local factors; on each factor a finite locally free module of constant rank e is free of that rank. Consequently

$$\dim_{H_Q}\big(p_*\mathcal{O}_{V_S} \otimes E_Q\big) = e \dim_{H_Q} E_Q.$$

The same lattice divisor occurs in both module-weight formulas. Therefore the right side of (5.5) is $e\,\mathrm{Trop}_{(g_0,f_0),V_{0,S}}(\mathcal{O})$. Equation (1.9) proves (5.3). This dimension calculation retains all Artinian lengths and full residue degrees, including inseparable degrees.

A positive-rank locally free algebra has zero structural kernel, and the finite-image theorem makes p surjective. Thus the bounded unit-moment base in (1.10) is still the actual moment image of V. The scalar e changes weights, not that base or the height bound in (4.2).

Finally, if $\|\varepsilon\| < 1$, the Neumann series $\sum_{\ell\geq 0}(-\varepsilon)^\ell$ converges to the inverse of $1+\varepsilon$. Every bounded multiplicative seminorm satisfies $|\varepsilon(z)| \leq \|\varepsilon\| < 1$; this follows directly by applying boundedness to powers and taking roots. The strong triangle inequality then gives $|1+\varepsilon(z)| = 1$, proving the sufficient condition. □

Fix the original complete non-Archimedean field K and its absolute value; trivial valuation and generalized real radii are allowed. Let X be good, Hausdorff, and pure of analytic dimension $n \geq 1$. Fix $C \Subset \mathrm{Int}(X/K)$, an ordinary open neighbourhood $U \supset C$, and $f \in \mathcal{O}(U)$. Require:

S1. Every ordinary local ring of U satisfies S_1.

S2. Multiplication by f is injective on $\mathcal{O}_{U_G}$. Thus "regular" means an actual non-zero-divisor, not merely a nonzero function on one component.

S3. The actual zero space $D = V(f) \subset U$, with its quotient structure, is empty or pure of analytic dimension $n-1$.

The test η is an ordinary smooth moment form of bidegree $(n-1, n-1)$, with $\operatorname{Supp}\eta \subset C$. We use the structure sheaf coefficients in the scalar PL assertion. An arbitrary coherent coefficient version is not silently substituted. All dimensions here are analytic dimensions. In particular S3 is not a statement about ordinary Krull dimension alone.

Chart condition (IP). For a pure n-dimensional affinoid V, a regular analytic f, nonempty pure $(n-1)$-dimensional D_V, and a unit moment tuple g, assume every actual affinoid-domain algebra in V is S_1. Then for some H, all $H < a < b$ satisfy

$$\mathcal{T}_{(g,f)}\big(\mathcal{O}_{\{e^{-b}\leq|f|\leq e^{-a}\}}\big) = \mathcal{T}_g(\mathcal{O}_{D_V}) \times [a,b]$$

in the last coordinate $-\log|f|$, with full actual quotient weights and the standard interval lattice.

Lemma G.0.13 (Actual chart hypotheses; F8SA-C)**.** *Under S1–S3, choose finitely many affinoid domains $V_i \subset U$ whose ordinary interiors cover C, and unit moment representatives $\eta|_{V_i} = t_{g_i}^{*}\alpha_i$. For every nonempty intersection $V_I = \bigcap_{i\in I} V_i$, the hypotheses of IP hold whenever $D_I = D \cap V_I$ is nonempty. If $D_I = \varnothing$, a sufficiently small f-tube in V_I is empty.*

Proof. Goodness and the ordinary local definition of a smooth moment form [NAG-002424] supply such neighbourhoods; compactness gives a finite family. NAG-002411/NAG-002413 make each nonempty V_I an actual pure n-dimensional affinoid domain. Restricting the injective sheaf map in S2 and taking sections proves that f is a non-zero-divisor in its algebra. Quotient/domain base change NAG-001846 identifies D_I with the actual algebra quotient by f, not its reduction. It is an affinoid domain of D, hence is pure

of dimension $n-1$ by S3 and domain purity. R-S1 [NAG-002765] applied to every affinoid domain of V_I supplies IP's full affinoid-domain S_1 condition. A chosen g_i, $i \in I$, remains a tuple of units upon restriction. If D_I is empty, continuity on compact V_I gives $\min_{V_I} |f| > 0$. □

The ordinary cutoff presentations and the final topologies are those of the two generating families and their comparison. For an open $\Omega \subset \mathbb{R}^N$, let $E^{p,q}(\Omega)$ be the space of smooth ambient superforms with the coefficient seminorms

$$p_{L,m}(\eta) = \max_{I,J,\,|a|\le m} \sup_{u\in L} |\partial^a \eta_{I,J}(u)|, \qquad L \Subset \Omega.$$

Empty coefficient slots give the zero space.

Definition G.0.14 (Local retraction condition)**.** For a closed subset $Z \subset X$, condition (R_d) means that for every $z \in Z$ there are an ordinary neighbourhood $U_z \subset X$, a good Hausdorff space Y_z of local analytic dimension at most d, a closed immersion $i_z : Y_z \hookrightarrow U_z$ whose image contains z, and an analytic retraction $r_z : U_z \to Y_z$. The chosen image need only contain z; it need not contain all of $Z \cap U_z$. The dimension bound means that the smaller affinoid neighbourhoods used in Lemma F.1.6 have dimension at most d.

Theorem G.0.15 (A logarithmic current in the retraction scope)**.** *Let X be good, Hausdorff and pure of analytic dimension $n \ge 1$, and let $\mathcal{F}$ be a coherent $\mathcal{O}_{X_G}$-module. Let $g, h \in \mathcal{O}_X(X)$ be non-zero-divisors in every local ring and put*

$$Z = \{|g| = 0\} \cup \{|h| = 0\}, \qquad u = \log|g/h| \quad \text{on } X \setminus Z.$$

Assume (R_{n-1}) for Z. Then

$$T_{g/h,\mathcal{F}}(\alpha) = \int_{X\setminus Z,\,\mathcal{F}|_{X\setminus Z}} u\alpha \tag{G.0.20}$$

is well-defined and continuous on $(\mathcal{E}^{n,n}(X), \tau_{\mathrm{cut}}) = (\mathcal{E}^{n,n}(X), \tau_{\mathrm{ord}})$. The displayed functional is independent of the representatives of the ordinary test form. It is a current of bidimension (n,n) for this fixed regular quotient.

For each cutoff presentation Q_i, there is $C_i < \infty$ with

$$|T_{g/h,\mathcal{F}}(Q_i\eta)| \le C_i \max_{I,J} \sup_{t_{f_i}(V_i)} |\eta_{I,J}|. \tag{G.0.21}$$

There are smooth functions $u_M \in \mathcal{A}^{0,0}(X)$, $M \ge 0$, formed by constant smooth truncation of $\log|g|$ and $\log|h|$ near their zeros, such that for each i one number M_i satisfies

$$\int_{X,\mathcal{F}} u_M Q_i\eta = T_{g/h,\mathcal{F}}(Q_i\eta) \quad (M \ge M_i,\ \eta \in E^{n,n}(\Omega_i)). \tag{G.0.22}$$

The threshold is uniform over the whole fixed presentation, with no bound on η required.

Proof. Fix a cutoff presentation Q_i and put $K = \operatorname{supp}\chi_i$. For each $z \in K \cap Z$, Lemma F.1.6 applied to its fixed tuple makes every pulled-back (n,n)-form zero on one ordinary neighbourhood of z. A finite union O of these neighbourhoods covers $K \cap Z$. Therefore $K_i = K \setminus O$ is compact in $X \setminus Z$ and contains $\operatorname{supp} Q_i\eta$ for every η. The cutoff presentations span the test space, so every test has compact support in the complement. There g and h are locally analytic units, using NAG-001572 on smaller affinoids as in NAG-002427. Thus u is an ordinary smooth moment function. The product $u\alpha$ has compact support in the complement. The integral exists and is independent of its chart representatives by NAG-002425. Open restrictions are pure of dimension n by NAG-002413. These facts also prove linearity of (G.0.20).

For the fixed i and K_i, by the compact partition scope of NAG-002428, choose $\theta \in \mathcal{A}_c^{0,0}(X)$ supported in $X \setminus Z$ and equal to one near K_i. The function $b = \operatorname{ext}_0(\theta u)$ is ordinary smooth on X, and locality of the baseline integral gives

$$T_{g/h,\mathcal{F}}(Q_i\eta) = \int_{X,\mathcal{F}} b\, Q_i\eta.$$

Compute this integral on a finite affinoid cover of the fixed support of χ_i inside $\operatorname{Int}_{\mathrm{top}}(V_i, X)$, adjoining f_i to representatives of $b\chi_i$. The finite inclusion–exclusion formula the actual compact cover formula of NAG-002416 and the finite-module chain and the finite-cell functional give fixed cells, actual coherent module weights and fixed coefficient multipliers. On each cell, the absolute integral is at most its lattice-normalized volume times the absolute weight times a fixed constant times the right-hand coefficient supremum in (G.0.21), by NAG-002389. The projected coefficient arguments lie in $t_{f_i}(V_i)$. Summing these finitely many bounds proves (G.0.21) and continuity by the definition of the final topology. No positivity or integration by parts enters this estimate.

Choose a smooth real function ρ with $\rho = 0$ on $(-\infty, 0]$ and $\rho = 1$ on $[1, \infty)$, as explicitly constructed in NAG-002427. Put

$$\lambda(s) = s\rho(s+1), \qquad \lambda_M(t) = -M + \lambda(t+M).$$

Thus $\lambda_M(t) = t$ for $t \geq -M$ and is $-M$ for $t \leq -M-1$. For an analytic function a set

$$\ell_M(a)(x) = \begin{cases} \lambda_M(\log|a(x)|), & |a(x)| > 0, \\ -M, & |a(x)| = 0. \end{cases}$$

This is an ordinary smooth function: near a zero it is constant on $\{|a| < e^{-M-1}\}$, and on the nonzero locus it is a smooth function of a unit moment coordinate. The scalar sheaf in NAG-002427 glues these representatives. Set $u_M = \ell_M(g) - \ell_M(h)$.

If K_i is empty, every $Q_i\eta$ is zero and stationarity is immediate. Otherwise, the positive continuous functions $|g|$ and $|h|$ have positive minima on K_i. Choose $M_i \geq 0$ strictly larger than both negatives of the minimum logarithms there. For $M \geq M_i$, $u_M = u$ on a neighbourhood of K_i. Since every $Q_i\eta$ is supported in K_i, the two products agree as ordinary forms after extension by zero. This proves (G.0.22). It also gives absolute finiteness on every finite cell presentation: all coefficients and the logarithms are bounded on the relevant compact supports. No separate representation by Radon measures is required.

□

Proposition G.0.16 (A unit logarithm need not annihilate a positive current)**.** *For every $n \geq 2$, let $z_1, \dots, z_n$ be the coordinates on the analytic split torus over K, write $x_j = -\log|z_j|$ and $t = (x_1, \dots, x_n)$, and set*

$$\Omega = (1,2) \times (0,1)^{n-1}, \qquad U = t^{-1}(\Omega), \qquad h = x_1 = \log|z_1^{-1}|.$$

Then

$$T(\eta) = \int_{U,\mathcal{O}_U} x_1 \eta, \qquad \eta \in \mathcal{E}^{n,n}(U),$$

is a positive native current with an order-zero bound on every fixed coefficient stage. Nevertheless $d'd''h = 0$ and $d'd''(hT) \neq 0$. Thus positivity and these order-zero bounds do not suffice for harmonic frame invariance.

Proof. Closed polyannuli with boxes inside Ω are ordinary affinoid neighborhoods in U. They are integral and have analytic dimension n by NAG-002294; The affine analytification construction NAG-001707 and separated-space theorem NAG-001713 make the ambient torus good and Hausdorff. Thus U is good, Hausdorff and pure of dimension n. For the global units $g = z_1^{-1}$ and $h_0 = 1$, the zero set in NAG-002480 is empty. Its retraction condition is therefore vacuous. That frozen theorem constructs exactly T and its fixed-stage order-zero estimates, on all native top tests. Since $x_1 > 0$, positivity follows from NAG-002425. The unit calculation in Theorem C.1.64 gives $d'd''h = 0$ as a smooth form; its current conclusion is unavailable without closedness of T.

Choose a nonnegative nonzero $\psi \in C_c^\infty(\Omega)$ and use the native test

$$\alpha = \psi(x) \bigwedge_{j=2}^{n} (d'x_j \wedge d''x_j) \in \mathcal{E}^{n-1,n-1}(U).$$

Its support is compact: the inverse image of $\operatorname{supp}\psi$ is closed in a closed polyannulus whose box is compactly contained in Ω. For the coordinate moment map the actual whole-fibre Gauss module is the Gauss field itself, and the tangent lattice map is the identity. Thus its weight is one by NAG-002362, consistently with the degree-one identity case of NAG-002294. The global chain formula the finite-module chain and the finite-cell functional and the lattice convention identify coordinate top integrals with ordinary real integrals of their coefficients, without a factorial or a valuation-normalization factor.

Only the x_1 derivative survives in $d'd''\alpha$. Therefore Theorem C.1.63 gives

$$(d'd''(hT))(\alpha) = \int_\Omega x_1^2\,\partial_1^2\psi\,dx_1\cdots dx_n = 2\int_\Omega \psi\,dx_1\cdots dx_n > 0.$$

The second equality is the one-variable fundamental theorem applied twice, with vanishing boundary terms because ψ is compactly supported; iterated integration is the elementary calculation proved in NAG-002389. No analytic Stokes or Poincaré–Lelong theorem enters this computation. In particular T cannot be closed, by Theorem C.1.64. □

In the local Cartier setting of NAG-002772, use the full quotient $B = A/(f)$ by the given regular equation on the actual affinoid chart. The effective Cartier coefficients are those of that quotient. The purity of the zero space is supplied as stated below.

Theorem G.0.17 (Cartier integration comparison in the pure-zero-space scope; F8ST-I-R1)**.** *Let $D = \mathcal{M}(B)$ be a nonempty pure d-dimensional Cartier zero space as above, and let $g = (g_1, \dots, g_r)$ be analytic units on a neighbourhood of the chart. Put $t_g = -\log|g|$. For $\mathfrak{p} \in \operatorname{Min} B$, let $D_{\mathfrak{p}} = \mathcal{M}(B/\mathfrak{p})$ and $c_{\mathfrak{p}} = \operatorname{length}_{B_{\mathfrak{p}}} B_{\mathfrak{p}}$. Then the frozen integral chains and all their smooth top-form pairings satisfy*

$$\mathcal{T}_g(B) = \sum_{\mathfrak{p} \in \operatorname{Min} B} c_{\mathfrak{p}} \mathcal{T}_{g|D_{\mathfrak{p}}}(B/\mathfrak{p}), \tag{G.0.23}$$

$$\mathcal{I}_{B,g}(\alpha) = \sum_{\mathfrak{p} \in \operatorname{Min} B} c_{\mathfrak{p}} \mathcal{I}_{B/\mathfrak{p},g}(\alpha). \tag{G.0.24}$$

Here α is a smooth (d,d)-superform near the compact moment image. The same equality holds for ordinary compactly supported forms after chart localization and a finite partition. The coefficient $c_{\mathfrak{p}}$ is exactly the analytic Cartier coefficient of Theorem F.1.12.

In particular, on a good Hausdorff pure n-dimensional space, for a regular meromorphic f whose local numerator and denominator zero spaces are empty or pure of dimension $n-1$, the cycles formed from these presentations are independent among such presentations and glue. Their analytic Cartier-cycle pairing agrees with the frozen coherent-cycle pairing on every ordinary $(n-1,n-1)$-test with compact support in $\operatorname{Int}(X/K)$. This purity condition is retained explicitly to match the frozen integrator; it is not deduced here from a relative-dimension theorem. The local coefficient result in Theorem F.1.12 does not require it.

Proof. Take a common finite subdivision of the actual moment images and their boundary images for D and the $D_{\mathfrak{p}}$, using the finite-module chain and weights. At a relative interior point w of a top-dimensional cell, the full analytic moment fibre is interior to D. The local moment image is contained in the affine plane $w + N_{\mathbb{R}}$ for the saturated rank-d tangent lattice N. The boundary images have dimension at most $d-1$, so they miss these relative interiors. For an integral projection Q injective on the tangent lattice N, put

$$E_Q = D_w \widehat{\otimes}_{R_Q} H_Q, \qquad e_Q = [\mathbb{Z}^d : Q(N)].$$

Here D_w is the *actual algebra of the entire moment fibre* and H_Q is the projected polytorus Gauss field, precisely as in NAG-002362. That theorem, with structure module B, gives

$$m_{D,g}(w) = \frac{\dim_{H_Q} E_Q}{e_Q} = \sum_{\mathfrak{p} \in \operatorname{Min} B} c_{\mathfrak{p}}\, m_{D_{\mathfrak{p}},g}(w). \tag{G.0.25}$$

For an empty component fibre its weight is zero. This formula includes all local Artin lengths and residue degrees in E_Q; no separate residue-degree multiplier is attached to $c_{\mathfrak{p}}$. The lattice index is divided out exactly once.

The equality holds on every top cell. Lower-dimensional cells carry no d-chain term, so the finite-module chain and weights give (G.0.23). By the finite-cell functional, integration of the same tangential smooth coefficients on a common subdivision gives (G.0.24). This is a finite sum; no limiting or measurable-integration extension occurs. The ordinary compact integral and compact partitions give the ordinary-form assertion. Actual domain restriction of the coefficients is the effective domain transport in the Cartier theorem, so the local formulas agree on overlaps. For a regular meromorphic function in the stated pure-zero-space scope, subtract the two effective formulas. On each actual common affinoid refinement, quotient/domain base change and domain purity preserve the empty-or-pure dimension $n-1$ condition for all four equations. The antichain clause of the Cartier theorem therefore applies to both cross-products and proves representation independence. A compact test needs finitely many such representatives and partition terms, whose sum is consequently independent of these choices. Closed immersions have compact inverse support on compact sets and are finite and everywhere relatively interior (NAG-001701); interior composition (NAG-001704) therefore shows that a test supported in $\operatorname{Int}(X/K)$ has the required interior support on its zero spaces. □

Field steps in tame descent

PDF-derived transcription. Historical English reader, Section 1.55, printed pages 216–220 and 223. The review record identifies the printed statements, proofs, and cited inputs.

Throughout, a valued field is complete and nontrivially real-valued, with additive valuation v, actual valuation ring F°, maximal ideal $\mathfrak{m}_F$, value group Γ_F, and residue field $\widetilde{F}$. Finite extensions carry their unique extending absolute values. Their existence, uniqueness and completeness are NAG-001450. Simple residue roots lift by NAG-002049.

For a finite separable extension E/K, the *explicit tame hypotheses* in this patch mean all three conditions

$$\begin{gathered} e = [\Gamma_E : \Gamma_K], \qquad f = [\widetilde{E} : \widetilde{K}], \qquad [E : K] = ef, \\ e \in (K^\circ)^\times, \qquad \widetilde{E}/\widetilde{K} \text{ separable.} \end{gathered} \tag{G.0.26}$$

Thus defectlessness is an assumption, not a consequence of the other two conditions. An *actual unramified lift* means the finite separable residue lift constructed by NAG-002050; in the Galois case its valuation rings have the finite free etale torsor property of NAG-002262.

An *exact Kummer step* $F \subset F(s)$ of degree $n \geq 2$ means the precise coefficient class of NAG-002610:

$$\begin{gathered} n \in (F^\circ)^\times, \qquad \zeta \in F^\circ, \qquad \operatorname{ord}(\zeta) = \operatorname{ord}(\bar{\zeta}) = n, \\ s^n \in F^\times, \qquad v(s) > 0, \qquad jv(s) \notin \Gamma_F \quad (0 < j < n). \end{gathered} \tag{G.0.27}$$

Lemma G.0.18 (Corrected radicals and a value basis)**.** *Let E/F be finite with equal residue fields and $[E : F] = [\Gamma_E : \Gamma_F] = e$, where $e \in (F^\circ)^\times$. There is a tower*

$$F = F_0 \subset F_1 \subset \cdots \subset F_r = E, \qquad F_i = F_{i-1}(s_i), \qquad s_i^{n_i} \in F_{i-1}^\times, \tag{G.0.28}$$

with $n_i \geq 2$, $v(s_i) > 0$, and $[F_i : F_{i-1}] = [\Gamma_{F_i} : \Gamma_{F_{i-1}}] = n_i$. The residue fields are unchanged, $\prod_i n_i = e$, and the monomials $\prod_i s_i^{a_i}$, $0 \leq a_i < n_i$, have distinct value classes modulo Γ_F and form an F-basis of E. The empty tower is allowed when $e = 1$.

Every step is exact Kummer if either E/F is Galois or F contains all e-th roots of unity. Moreover, if N/F is finite with $\Gamma_N = \Gamma_F$ in a common valued

overfield, then $E \otimes_F N$ is the field EN, of degree and value index e over N and with residue field $\widetilde{N}$. If N contains all e-th roots of unity, the base-changed tower (G.0.28) *consists of exact Kummer steps of the same degrees.*

Direct inputs NAG-001450, NAG-002049, NAG-002610.

Proof. Suppose F_{i-1} has been constructed and its value group is not Γ_E. Choose $a \in E^\times$ whose value has order $n_i > 1$ in $\Gamma_E/\Gamma_{F_{i-1}}$. Choose $c \in F_{i-1}^\times$ with $v(c) = n_i v(a)$, and choose a unit $u \in F_{i-1}^\circ$ lifting the residue of a^{n_i}/c. This is possible because every intermediate residue field is the common residue field. The integer n_i divides e and is a unit. The simple root 1 of the reduction of $T^{n_i} - a^{n_i}/(cu)$ therefore lifts to $d \in 1 + \mathfrak{m}_E$. Set $s_i = a/d$. Then $s_i^{n_i} = cu$ and $v(s_i) = v(a)$. Multiplying s_i by a sufficiently large positive-value power of any fixed element of F makes its value positive and preserves all these assertions about its class and its power.

The powers $1, s_i, \dots, s_i^{n_i-1}$ have distinct value classes over F_{i-1}. A nonzero linear combination has a unique term of smallest value and cannot vanish. Thus its degree is at least n_i and, by the displayed polynomial, at most n_i. The fundamental inequality Stacks 0ASH now shows that its value index is exactly n_i and its residue degree is one. In particular Γ_{F_i} is exactly the subgroup generated by $\Gamma_{F_{i-1}}$ and $v(s_i)$.

These subgroups strictly increase in the finite quotient Γ_E/Γ_F, so the process stops. Products of the listed powers give distinct representatives of successive group cosets, hence distinct classes modulo Γ_F. At termination their number is e. Their degrees multiply to $e = [E : F]$, so the terminal field is E and they are the required basis. The unique-minimum argument also gives the value of every nonzero basis expansion.

If E/F is Galois, it is normal over every intermediate field, by Stacks 09DW. The minimal polynomial $T^{n_i} - s_i^{n_i}$ therefore splits in E; it has degree n_i and is separable. All n_i-th roots of unity belong to E. Reduction is injective on them: two with the same reduction coincide by uniqueness of simple-root lifts, Stacks 06RR. Their residues lie in $\widetilde{F_{i-1}}$, and Hensel lifting there, with the same uniqueness in E, places all these roots in F_{i-1}. The group of roots is cyclic by Stacks 09HX, since a degree-d polynomial has at most d roots. Hence a primitive root and its reduction both have order n_i. If instead $\mu_e \subset F$, the same conclusion follows because $n_i \mid e$, with reduction injective by Stacks 06RR. In either case the polynomial

splits in F_i, and its root multiplications give the cyclic Galois group. This proves (G.0.27).

Finally the same e monomials remain linearly independent over N, since $\Gamma_N = \Gamma_F$. The multiplication map $E \otimes_F N \to EN$ is therefore injective and has image of N-dimension e; its image is a finite-dimensional domain, hence a field and thus all of EN. Its value group contains Γ_E, of index e over Γ_N. Another application of Stacks 0ASH forces equality of the value index with e and equality of residue fields with $\widetilde{N}$. Applying the same basis argument to each initial segment of (G.0.28) preserves its degree and value index. If $\mu_e \subset N$, each segment has the required roots of unity with unchanged residue order, so is exact Kummer. □

Proposition G.0.19 (An actual unramified base change supplies the steps)**.** *Let E/K satisfy (G.0.26), without assuming it Galois. There is an actual unramified subextension M/K in E with $\widetilde{M} = \widetilde{E}$ and $[M : K] = f$. There is a finite Galois actual unramified extension N/K, containing this M in a common valued overfield, such that EN/N is a tower of exact Kummer steps, of total degree and value index e and with residue field $\widetilde{N}$. For $e = 1$ this tower is empty. Neither a Galois action on a supplied E-model nor a Galois extension EN/K is asserted by this conclusion.*

Direct inputs NAG-002049, NAG-002050, NAG-002052, NAG-002262, NAG-003143.

Proof. Write $k = \widetilde{K}$ and $l = \widetilde{E}$. Use the primitive residue generator and its lifted monic polynomial in the proof of NAG-002050, but lift its simple residue root inside E. This gives $\alpha \in E^\circ$ and $M = K(\alpha)$. The degree is at most f; the residue degree is at least f. The fundamental inequality Stacks 0ASH forces $[M : K] = f$, $\Gamma_M = \Gamma_K$ and $\widetilde{M} = l$. This is the same actual residue lift, with its chosen embedding in E. By (G.0.26), E/M has degree and value index e and unchanged residue field.

Choose a finite Galois residue extension k'/k containing l and all e-th roots of unity. It exists by taking the splitting field of a separable defining polynomial for l/k together with $T^e - 1$, using Stacks 09HU; the latter polynomial is separable because e is a unit. First lift k'/l over M by NAG-002050, obtaining N/M in a common algebraic overfield of E. Thus $[N : K] = [k' : k]$, $\widetilde{N} = k'$ and $\Gamma_N = \Gamma_K$.

To identify N/K as the actual Galois unramified lift, lift a primitive generator of k'/k inside N by Hensel. Its field over K has degree at least $[k' : k]$, by

its residue, and at most that degree, by its lifted polynomial. It is therefore N. All roots of the residue polynomial lift inside N, since its residue is k'; they are distinct and exhaust the roots of the lifted polynomial. Thus N/K is Galois and is precisely the lift of NAG-002052. Its valuation rings have the torsor property in NAG-002262. Hensel also lifts all roots of $T^e - 1$ from k' to N. Lemma G.0.18, applied to E/M and N/M, proves all the assertions about EN/N. The construction supplies field inclusions; it does not supply action maps on a model or assert normality over K. □

Theorem G.0.20 (A Galois-normal sequence of exact Kummer steps)**.** *Let L/K be finite Galois satisfying (G.0.26), with group G. Put $k = \widetilde{K}$ and $l = \widetilde{L}$. Then l/k is Galois, and its actual unramified lift $M \subset L$ satisfies*

$$1 \longrightarrow I = \mathrm{Gal}(L/M) \longrightarrow G \longrightarrow \mathrm{Gal}(l/k) \longrightarrow 1, \qquad |I| = e. \tag{G.0.29}$$

Here I is exactly the kernel of the action on l. It is abelian, and every subgroup of I is normal in G. There is consequently a chain

$$1 = J_0 \subset J_1 \subset \cdots \subset J_r = I, \qquad F_j = L^{J_j}, \qquad L = F_0 \supset \cdots \supset F_r = M, \tag{G.0.30}$$

whose nontrivial factors J_j/J_{j-1} have prime order and whose steps F_{j-1}/F_j are exact Kummer. All fields in (G.0.30) have residue field l. No roots of unity are assumed in K, and no cyclicity of I or splitting of (G.0.29) is assumed.

Direct inputs NAG-001450, NAG-002052, NAG-003143, NAG-003144.

Proof. Take the embedded $M = K(\alpha)$ constructed in Proposition G.0.19; let P be its lifted polynomial of degree f. It is minimal by the degree calculation there. Since L/K is normal, P splits in L. Every root is integral, by the unique extending absolute value and conjugacy. Reducing this factorization shows that the separable minimal polynomial of $\bar{\alpha}$ splits in l. Thus l/k is Galois. Every root of its polynomial lifts inside M, since $\widetilde{M} = l$; these lifts exhaust the roots of P. Consequently M/K is Galois, with reduction identifying its group with $\mathrm{Gal}(l/k)$, just as in NAG-002052. Restriction and Stacks 09DW give (G.0.29). An element fixing M fixes l. Conversely an element acting trivially on l fixes α by Stacks 06RR, hence fixes M. This identifies inertia and proves $|I| = [L : M] = e$.

We give the needed ramification argument to avoid importing a DVR-only cyclicity theorem. For $i \in I$ define

$$\theta_i : \Gamma_L/\Gamma_M \longrightarrow l^\times, \qquad \theta_i(v(a)) = \overline{i(a)/a}. \tag{G.0.31}$$

This is well defined: changing a by an element of the same value changes the ratio by $i(u)/u$ for a unit u, whose residue is one; changing the value by $v(b)$, $b \in M^\times$, has no effect. Multiplication shows that θ_i is a character. Since I fixes l, composition gives a homomorphism $I \to \mathrm{Hom}(\Gamma_L/\Gamma_M, l^\times)$. It is injective. Indeed use the radical tower of Lemma G.0.18 for L/M. If $\theta_i = 1$ and i fixes the previous field, then $i(s_j)/s_j$ is an n_j-th root of unity with residue one. It equals one by Stacks 06RR. Induction fixes every radical and hence all of L. The target of (G.0.31) is abelian, so I is abelian.

All values of (G.0.31) lie in $\mu_e(l)$, since the value quotient has order e. This finite group is cyclic by Stacks 09HX. For $g \in G$, valuation preservation gives

$$\theta_{gig^{-1}}(\gamma) = \bar{g}(\theta_i(\gamma)). \tag{G.0.32}$$

To see this directly, represent γ by a and apply g to $i(g^{-1}a)/(g^{-1}a)$; the value of $g^{-1}a$ is still γ. If $t = |\mu_e(l)|$, the automorphism $\bar{g}$ of this cyclic group is exponentiation by some integer q_g coprime to t. Thus injectivity of (G.0.31) implies $gig^{-1} = i^{q_g}$. Also (G.0.31) implies $i^t = 1$ for every i. Exponentiation by q_g therefore preserves every subgroup of I, proving its normality in G.

A finite abelian group has a series with prime cyclic factors: take a maximal proper subgroup and induct on its order; the quotient is simple abelian, so any nonidentity element generates it and its order is prime. All groups in the resulting series are G-normal by the preceding paragraph. The correspondence Stacks 09DW gives (G.0.30) and its cyclic prime-degree extensions. Their residue fields all equal l, since they lie between M and L. The product of their degrees and the product of their value indices both equal e. Each index is at most its degree by Stacks 0ASH, so equality holds at every step. For a prime-degree step its value quotient has prime order, hence is cyclic. The first radical in Lemma G.0.18 already generates that step; its Galois clause supplies a primitive root with primitive reduction. This is exactly (G.0.27) for each step. □

Proposition G.0.21 (A noncyclic obstruction surviving unramified base change)**.** *Give $\mathbb{Q}(x,y)$ the valuation trivial on $\mathbb{Q}$ with $v(x)=1$ and $v(y)=\sqrt{2}$, defined on polynomials by the least monomial value, and let K be its completion. Then $\Gamma_K=\mathbb{Z}+\sqrt{2}\mathbb{Z}$ and $\widetilde{K}=\mathbb{Q}$. For*

$$L=K(u,w),\qquad u^2=x,\qquad w^2=y, \tag{G.0.33}$$

the field extension is tame Galois, of degree and value index four, with unchanged residue field, and

$$\mathrm{Gal}(L/K)=I\simeq(\mathbb{Z}/2)^2,\qquad \Gamma_L/\Gamma_K\simeq(\mathbb{Z}/2)^2. \tag{G.0.34}$$

The same assertions hold over any actual finite unramified extension N/K after replacing L by LN, with residue field $\widetilde{N}$ and degree four over N. Consequently no such base change converts this into one full-value-index cyclic Kummer step. Two exact quadratic steps suffice. This is a complete rank-one nondiscrete example.

Direct inputs NAG-001450, NAG-002050, NAG-003143.

Proof. Irrationality makes the values of distinct monomials distinct. A polynomial has a unique lowest term, whose product with the lowest term of another polynomial is again uniquely lowest. This proves multiplicativity and extends the valuation to fractions. Its group is $\mathbb{Z}+\sqrt{2}\mathbb{Z}$. A value-zero fraction has numerator and denominator with the same leading exponents; its residue is their rational leading coefficient ratio. Hence its residue field is $\mathbb{Q}$. Completion changes neither value group nor residue field: for a nonzero completed element choose an approximation whose difference has larger value; the two values and their leading residues agree. For value-zero elements this also identifies ordinary residues. The value group is nondiscrete. Indeed the positive numbers $(\sqrt{2}-1)^m$ lie in $\mathbb{Z}+\sqrt{2}\mathbb{Z}$ and tend to zero. It is a nonzero ordered subgroup of $\mathbb{R}$, hence has rank one.

Take the two roots in a finite algebraic extension of K, with its unique extending valuation. The four monomials $1,u,w,uw$ have values in four distinct cosets modulo Γ_K: their values are $0,1/2,\sqrt{2}/2,(1+\sqrt{2})/2$. They are linearly independent by the unique-minimum argument. Their span is closed under multiplication using (G.0.33), and the extension has degree at most four, so they are a basis and $[L:K]=4$. Their values generate $\frac{1}{2}\Gamma_K$, of index four. The fundamental inequality Stacks 0ASH forces this

to be the whole value group and forces residue degree one. Independent sign changes of u, w are four automorphisms, giving (G.0.34); they are all inertia. Residue characteristic zero, equality of degree with value index, and unchanged residue verify all of (G.0.26).

The tower $K \subset K(u) \subset L$ has value index and degree two at each step: the new value classes are represented by $1/2$ and $\sqrt{2}/2$, respectively. Their positive generators and the root -1, of residue order two, satisfy (G.0.27). For any actual unramified N/K, its value group is still Γ_K. Lemma G.0.18 proves $L \otimes_K N = LN$, degree and value index four, and unchanged residue over N. The four sign changes extend on this tensor product, giving the same noncyclic inertia and value quotient. A single (G.0.27) step of degree four has a cyclic value quotient of order four and a cyclic Galois group. Both conflict with (G.0.34). This proves the asserted obstruction, even if N contains a primitive fourth root of unity. □

The toric Gauss section and smooth tests

Let K be algebraically closed, complete and nontrivially valued, with its fixed absolute value and $v = -\log|\cdot|$. Throughout,

$$d \geq 2, \qquad X = (\mathbf{P}^1_K)^d, \qquad T = (\mathbf{G}_{m,K})^d, \qquad L_i = \mathrm{pr}_i^*\,\mathcal{O}(m_i\infty), \quad m_i \geq 1.$$

We use the usual good Hausdorff analytification, pure of dimension d. Put $t_i = -\log|T_i|$ on T^{an}, and let $\bar{t} : X^{\mathrm{an}} \to \overline{\mathbf{R}}^{,d}$ be its continuous extension, where $\overline{\mathbf{R}} = [-\infty, +\infty]$; zero maps to $+\infty$ and infinity to $-\infty$. The lattices are $N = M = \mathbf{Z}^d$ in the coordinate dual bases, and dt has covolume one.

Choose $\phi_i \in C^\infty(\mathbf{R})$ convex, with exact tails

$$\phi_i(t) = -m_i t + c_i^- \quad (t \leq A_i), \qquad \phi_i(t) = c_i^+ \quad (t \geq B_i), \qquad A_i < B_i. \tag{G.0.35}$$

The frame $e_{i,0} = 1$ of L_i has weight $\phi_i(t_i)$, and $e_{i,\infty} = T_i^{m_i} e_{i,0}$ has weight $\phi_i(t_i) + m_i t_i$. Both are constant near their respective boundary points. These define global metrics h_i in both the ordinary moment-smooth convention and the primary algebraic tropical smooth convention. Explicit examples are $\phi_i(t) = m_i \int_t^\infty (s-t)\rho_i(s)\,ds$, with $\rho_i \in C_c^\infty((A_i, B_i))$, $\rho_i \geq 0$, $\int \rho_i = 1$.

Set

$$\theta_i = d'd''\phi_i(t_i), \quad \theta = \bigwedge_{i=1}^{d} \theta_i, \quad W(t) = \prod_i \phi_i''(t_i), \quad D = \prod_i m_i, \quad S = \prod_i \operatorname{supp}(\phi_i''). \tag{G.0.36}$$

Use the positive generator $\omega_d = \bigwedge_i (d't_i \wedge d''t_i)$, so that $\theta = t^*(W\omega_d)$ and $\int a\omega_d = \int a(t)dt$. There is no $d!$ in this mixed wedge and no rescaling of the valuation. The curvature is zero near $X^{\mathrm{an}} \backslash T^{\mathrm{an}}$. If a finite box B contains S in its interior, then the whole compact polyannulus $Q = t^{-1}(B)$ is an ordinary neighbourhood of its support. All frozen chart weights use full fibres and actual canonical Banach algebras.

For $w \in \mathbf{R}^d$, let $\rho(w)$ be the Gauss point

$$\left| \sum_{m \in \mathbf{Z}^d} a_m T^m \right|_{\rho(w)} = \max_m |a_m| e^{-\langle m, w \rangle} \quad \text{on finite Laurent polynomials.} \tag{G.0.37}$$

Write $\Gamma = \rho(\mathbf{R}^d)$.

In the primary algebraic tropical convention used below, the germ is read by tangential restriction on the faces of the actual tropical chart, after subdivision. The ordinary convention uses the actual smooth moment germs.

Lemma G.0.22 (Local cancellation forces rank drop)**.** *The map ρ extends continuously to a section $\bar{\rho} : \overline{\mathbf{R}}^{,d} \to X^{\mathrm{an}}$ of $\bar{t}$. Its image $\bar{\Gamma}$ is closed, and $\Gamma = \bar{\Gamma} \cap T^{\mathrm{an}}$. For every $x \in T^{\mathrm{an}} \setminus \Gamma$ there is an ordinary open neighbourhood $U_x \subset T^{\mathrm{an}}$ and a finite union H_x of proper integral-normal affine hyperplanes in $\mathbf{R}^d$ such that*

$$t(U_x) \subset H_x.$$

Consequently any smooth moment form $t^*\alpha$ with α of bidegree (d,d) has zero germ at x, in both the frozen ordinary moment convention and the primary algebraic tropical convention. In particular the two versions of θ in (G.0.36) satisfy

$$\operatorname{supp} \theta \subset \rho(S). \tag{G.0.38}$$

Proof. The weighted Gauss norm is multiplicative by NAG-000182. On a finite coordinate chart of X, allow some radii to be zero and first quotient by those coordinate variables. The Gauss norm in the remaining variables gives a point on that chart. These constructions agree under inversion of nonzero coordinates and give $\bar{\rho}$. Evaluation on a polynomial is a finite maximum of

continuous monomial functions of the radii, including zero radii. This proves continuity in each analytic coordinate chart, hence globally. The equality $\bar{t}\bar{\rho} = 1$ follows directly. The domain is compact and X^{an} is Hausdorff; thus $\bar{\rho}$ is a homeomorphism onto its closed image. A finite tropical coordinate has positive finite radius, so its image is in T^{an}, proving the assertion about Γ.

Fix $x \notin \Gamma$, and put $w = t(x)$. Distinct points of the torus analytification are distinct multiplicative seminorms on its Laurent coordinate ring. The ultrametric inequality always gives $|f(x)| \leq |f(\rho(w))|$. Hence some Laurent polynomial $f = \sum_m a_m T^m$, with like terms collected, satisfies

$$|f(x)| < M_f(t(x)), \qquad M_f(u) = \max_m |a_m| e^{-\langle m,u\rangle}.$$

Both sides are continuous and M_f is positive. The same strict inequality defines an ordinary open neighbourhood U_x. At every $y \in U_x$ the largest term in f cannot be unique: a unique largest summand has the absolute value of the entire sum in a valued field, and the same statement holds in the completed residue field at y. At least two distinct exponents m, n therefore satisfy

$$v(a_m) + \langle m, t(y)\rangle = v(a_n) + \langle n, t(y)\rangle.$$

These are finitely many proper affine hyperplanes with nonzero integer normal $m - n$. Their union is the required H_x.

For the frozen germs, choose an ordinary affinoid neighbourhood of x inside U_x, using the neighbourhood construction in NAG-002424. Its actual T-moment image is finite polyhedral. Subdivision along H_x puts every face in dimension at most $d - 1$. Restriction of an alternating d-covector to each tangent space is zero. Thus the representative $t^*\alpha$ is tangentially zero on every face, which is exactly a zero germ in the frozen definition.

For the primary convention the same argument can be placed on an explicit algebraic tropical chart. If $f(x) \neq 0$, put $g = f$. If $f(x) = 0$, choose $a \in K^\times$ with $|a| < M_f(w)$ and put $g = f - a$. Then $g(x) \neq 0$, $M_g(w) = M_f(w)$ and $|g(x)| < M_g(w)$. The very affine open $T \setminus V(g)$ has unit coordinates T_i, g, possibly augmented to its canonical unit tuple. On its tropical open subset defined by $|g| < M_g(t)$, projection to the T_i coordinates lands in the finite union of hyperplanes just proved. Subdivide its polyhedral faces accordingly. On every face the projected tangent space has rank at most $d - 1$, so the pullback of α is zero by polyhedral restriction. This gives the zero primary smooth germ without an approximation of analytic moment maps.

Finally θ is already zero off $t^{-1}(S)$ in the torus and near the toric boundary. The argument just given removes every remaining point outside Γ. Since $\rho(S)$ is compact and closed, the support inclusion (G.0.38) follows. □

Let $\mathcal{A}$ be the real algebra of global ordinary smooth moment functions on X^{an}. Let $\mathcal{A}_{\mathrm{com}}$ be its subalgebra of functions also smooth on primary algebraic tropical charts.

Lemma G.0.23 (A common smooth algebra is uniformly dense)**.** *The algebra $\mathcal{A}_{\mathrm{com}}$ separates points of X^{an} and contains the constants. Both $\mathcal{A}_{\mathrm{com}}$ and $\mathcal{A}$ are uniformly dense in $C(X^{\mathrm{an}})$.*

Proof. For any positive multi-degree $\ell = (\ell_1, \dots, \ell_d)$, the line $L(\ell) = \bigotimes_i \mathrm{pr}_i^* \mathcal{O}(\ell_i \infty)$ has a common smooth metric with weight $\sum_i (\ell_i/m_i)\phi_i(t_i)$ on the torus. If s is a nonzero global algebraic section and $\chi \in C^\infty(\mathbf{R})$ is constant at both sufficiently large positive and negative arguments, then

$$u_{s,\chi}(x) = \chi(-\log \|s(x)\|) \tag{G.0.39}$$

is a common smooth function. At a zero of s, use the constant value $\chi(+\infty)$. This extends continuously and is locally constant there. Off the zero set, in an algebraic frame $s = fe$ its argument is $-\log|f| - \log\|e\|$, a smooth function of algebraic unit moments. Near a zero, one may make a tropical neighbourhood explicit by replacing the vanishing regular coefficient f with $f - a$, where $a \neq 0$ is small, and imposing a strict upper bound on $|f - a|$ larger than $|a|$. After shrinking the other moment bounds, this lies in the region on which (G.0.39) is constant. At a coordinate boundary the same construction with $T_i - b$ or $T_i^{-1} - b$ describes the region where the metric weight has its constant tail. Removing the zeros of these finitely many nonvanishing algebraic units gives a very affine chart. Thus these functions have the required representatives in both conventions. Sums and products are computed using joint moment tuples.

Take distinct $x, y \in X^{\mathrm{an}}$. For each coordinate choose $a_i \in K$ different from any rigid projection of x or y to that factor. This is possible since at most two values are excluded and K is infinite. Then both points lie in $U = \prod_i (\mathbf{P}^1 \setminus \{a_i\}) \simeq \mathbf{A}^d$, with affine coordinates $z_i = (T_i - a_i)^{-1}$. Some $f \in K[z_1, \dots, z_d]$ has $|f(x)| \neq |f(y)|$, because points of this analytification are polynomial seminorms. Choose positive ℓ_i at least the degree of f in z_i. There is a section s_0 of $L(\ell)$ with divisor $\sum_i \ell_i \{T_i = a_i\}$, and $s_f = f s_0$ extends

to a global section by the degree bound. The section s_0 is nonvanishing at x and y. If its norms there differ, use it in (G.0.39), with χ taking different values at the two logarithmic norms. If its norms agree, the norms of s_f differ and the same construction with s_f separates the points. This also covers a zero value of f, using the constant tail of χ.

Here is a complete compact-space density argument. Let Y be a compact Hausdorff space and $A \subset C(Y, \mathbf{R})$ a unital point-separating algebra. Its uniform closure B is an algebra. It is closed under absolute values: on a compact interval, polynomial approximation of $|r|$ follows from the Bernstein polynomials

$$B_n h(t) = \sum_{k=0}^{n} h(k/n) \binom{n}{k} t^k (1-t)^{n-k}.$$

Indeed, for continuous h on $[0,1]$, the binomial mean and variance give, for every $\delta > 0$,

$$|B_n h(t) - h(t)| \le \omega_h(\delta) + \frac{\|h\|_\infty}{2n\delta^2},$$

uniformly in t. Choose $\delta = n^{-1/4}$ and use uniform continuity. Rescaling proves the required approximation of $|r|$. Polynomial composition therefore puts $|b|$ in B for every $b \in B$. Thus B is closed under finite maxima and minima.

Given $u \in C(Y)$ and $\epsilon > 0$, for any $x, y \in Y$ a suitable affine function of a separating element of A takes the values $u(x), u(y)$ at x, y; for $x = y$ use a constant. Denote it by a_{xy}. For fixed x, the open sets where $a_{xy} > u - \epsilon$ cover Y. Choose finitely many y and let b_x be the maximum of the corresponding a_{xy}. Then $b_x \in B$, $b_x > u - \epsilon$ everywhere and $b_x(x) = u(x)$. Hence $b_x < u + \epsilon$ on a neighbourhood of x. Finitely many such neighbourhoods cover Y. The minimum b of their b_x satisfies $u - \epsilon < b < u + \epsilon$ on Y and belongs to B. Thus $u \in B$. Apply this argument to the algebra generated by the functions (G.0.39) and the constants. It is contained in $\mathcal{A}_{\mathrm{com}} \subset \mathcal{A}$, proving both density claims. □

Radon determination on the toric Gauss section

Use the same standing product, curvature and chart conventions.

Theorem G.0.24 (When radial Radon data determines the full measure)**.** *Let ν be a finite positive Radon measure on $\overline{\mathbf{R}}^{d}$ and μ a finite positive Radon measure on X^{an} with $\bar{t}_*\mu = \nu$. Then*

$$\mu = \bar{\rho}_*\nu \quad \Longleftrightarrow \quad \mu(X^{\mathrm{an}} \setminus \bar{\Gamma}) = 0. \tag{G.0.40}$$

If ν gives zero mass to the tropical boundary and to every proper affine hyperplane in $\mathbf{R}^d$ with nonzero integer normal, the right-hand condition follows automatically. In particular it follows for $\nu = W(t)dt$ from (G.0.36). In this case for every $u \in C(X^{\mathrm{an}})$,

$$\int u\, d\mu = \int u(\rho(t))W(t)\, dt. \tag{G.0.41}$$

No countability condition on the value group or the set of analytic points is needed. Positivity and Radon regularity are hypotheses.

Proof. On $\bar{\Gamma}$ the map $\bar{\rho}\bar{t}$ is the identity. If μ is concentrated there, then for every continuous u,

$$\int u\, d\mu = \int u \circ \bar{\rho} \circ \bar{t}\, d\mu = \int u \circ \bar{\rho}\, d\nu.$$

This proves the forward identification of measures; the converse concentration is immediate from the image of $\bar{\rho}$.

Now impose the additional hypotheses on ν. The analytic toric boundary has μ-mass zero because its image is in the tropical boundary. For each $x \in T^{\mathrm{an}} \setminus \Gamma$, the neighbourhood in Lemma G.0.22 has mass zero: positivity gives

$$0 \le \mu(U_x) \le \mu(t^{-1}(H_x)) = \nu(H_x) = 0.$$

Every compact subset of the open set $T^{\mathrm{an}} \setminus \Gamma$ is covered by finitely many such U_x, hence has mass zero. Inner regularity therefore makes the entire open set have mass zero. This finite-cover argument is essential; it does not take a countable union over all Laurent polynomials. Equation (G.0.40) now applies. An absolutely continuous measure $W dt$ assigns zero mass to all the specified hyperplanes, which proves (G.0.41). □

Normalizers in exact Kummer descent

PDF-derived transcription. Historical English reader, Section 1.55, Lemma 1.55.4, printed pages 220–221. The standing context is from printed pages 216–217. The historical original TeX remains unlocated.

The lemma uses the valued-field convention, the exact Kummer step (K*) and the action convention below. The remaining definitions record the surrounding historical terminology.

Standing context

Throughout, a valued field is complete and nontrivially real-valued, with additive valuation v, actual valuation ring F°, maximal ideal $\mathfrak{m}_F$, value group Γ_F, and residue field $\widetilde{F}$. Finite extensions carry their unique extending absolute values. Their existence, uniqueness and completeness are NAG-001450. Simple residue roots lift by NAG-002049.

For a finite separable extension E/K, the *explicit tame hypotheses* in this patch mean all three conditions

$$\begin{gathered} e = [\Gamma_E : \Gamma_K], \qquad f = [\widetilde{E} : \widetilde{K}], \qquad [E : K] = ef, \\ e \in (K^\circ)^\times, \qquad \widetilde{E}/\widetilde{K} \text{ separable.} \end{gathered} \tag{Tg}$$

Thus defectlessness is an assumption, not a consequence of the other two conditions. An *actual unramified lift* means the finite separable residue lift constructed by NAG-002050; in the Galois case its valuation rings have the finite free etale torsor property of NAG-002262.

An *exact Kummer step* $F \subset F(s)$ of degree $n \geq 2$ means the precise coefficient class of NAG-002610:

$$\begin{gathered} n \in (F^\circ)^\times, \qquad \zeta \in F^\circ, \qquad \operatorname{ord}(\zeta) = \operatorname{ord}(\bar{\zeta}) = n, \\ s^n \in F^\times, \qquad v(s) > 0, \qquad jv(s) \notin \Gamma_F \quad (0 < j < n). \end{gathered} \tag{K*}$$

Its integral extension is faithfully flat but need not be finite. We use left scheme actions ρ_g covering $\operatorname{Spec}(g^{-1})$, and linearizations $\rho_g^*\mathcal{L} \simeq \mathcal{L}$, as in the frozen mixed packet. Identity on a special fibre always means identity on the entire scheme or restricted module, including its structure sheaf.

Lemma G.0.25 (Retaining a normalizer action at a Kummer step)**.** *Let F/E be an exact Kummer step with group Q. Let a finite group P act on F by isometric field automorphisms preserving E, with $Q \triangleleft P$, and suppose its restriction to Q is the specified Galois action. Let Z/F° be projective, flat, finitely presented and nodal of relative dimension one, with a compatible semilinear P-action. Suppose Q acts identically on the entire special scheme. Then the canonical Q-descent Z_E/E° carries a canonical semilinear P/Q-action, and its base-change comparison is P-equivariant.*

A P-linearized relatively ample invertible sheaf with identity Q-action on its full residue module descends to a relatively ample P/Q-linearized invertible sheaf on Z_E. Both descents are functorial for equivariant isomorphisms with their specified comparisons. The action of P/Q on E need not be faithful; there is no unramified hypothesis on any lower field.

Proof. The exact input NAG-002908 supplies Z_E and its projective nodal structure. Its construction is that of NAG-002683, from the invariant rings of a finite Q-invariant affine cover. Adjoin the finitely many P-translates and all their nonempty finite intersections. Normality of Q preserves invariance; separatedness over the affine base makes the intersections affine. Write

$$D_U = \Gamma(U, \mathcal{O}_Z), \qquad C_U = D_U^Q.$$

The cited gluing theorem gives $F^\circ \otimes_{E^\circ} C_U \simeq D_U$ by multiplication and identifies invariant overlap rings with the actual overlaps of the descended charts.

Pullback by $\rho_p : U \to \rho_p U$ maps $D_{\rho_p U}$ to D_U and $C_{\rho_p U}$ to C_U, because conjugation preserves Q. It restricts on E° to $(p|_E)^{-1}$ and commutes with restriction maps. These maps glue to an action on Z_E; its group laws hold already on the invariant rings. Every $q \in Q$ fixes each U and its invariant ring, so the action factors through P/Q. The multiplication comparisons commute with these maps and are therefore P-equivariant.

The input NAG-002906 descends the bundle and its relative ampleness. On the charts its modules are $\Gamma(U, \mathcal{L})^Q$. Linearized pullbacks transport these modules by the same conjugation argument and commute with restriction. They glue to a linearization factoring through P/Q, with the required comparison. An equivariant isomorphism transports both invariant rings and modules; intersecting covers gives the same maps, by the canonical overlap comparisons. This proves functoriality and uniqueness with a specified comparison.

Only invariant descent in the exact Kummer class was used; no integral ramified torsor was presumed. □

Appendix H

Quotient action in the mixed tame tower

All valuation rings below are the actual valuation rings, with the specified extending absolute values. Fix the following supplied field configuration, denoted (T):

$$K \subset M \subset L, \qquad O = K^{\circ}, \quad A = M^{\circ}, \quad B = L^{\circ}, \qquad k = \widetilde{K}, \quad l = \widetilde{M}. \tag{T}$$

The field K is complete and nontrivially real-valued. The extension M/K is the finite unramified Galois lift of a finite Galois extension l/k, in the exact sense of 4.43.1. The extension L/K is finite Galois, with group G, and restriction gives the exact sequence

$$1 \longrightarrow I = \mathrm{Gal}(L/M) \longrightarrow G \longrightarrow H = \mathrm{Gal}(M/K) \longrightarrow 1. \tag{8}$$

The extension L/M satisfies the exact class of C.1.53: for $e = |I| \geq 2$,

$$\begin{gathered} e \in A^{\times}, \quad \zeta \in A, \quad \mathrm{ord}(\zeta) = \mathrm{ord}(\bar{\zeta}) = e, \qquad L = M(s), \quad s^e = c \in M^{\times}, \\ \gamma = v(s) > 0, \qquad j\gamma \notin v(M^{\times}) \quad (0 < j < e). \end{gathered} \tag{9}$$

Thus I is generated by $s \mapsto \zeta s$, $\widetilde{L} = l$, and $A \to B$ is faithfully flat, possibly not finite. In contrast, $O \to A$ is finite free, faithfully flat and etale, and

$$A \otimes_O A \simeq \prod_{h \in H} A, \qquad a \otimes b \longmapsto (a\, h(b))_h. \tag{10}$$

These facts are outputs of the two exact coefficient results just cited. No splitting of (8), invertibility of $|H|$, or discreteness of the value group is assumed.

Scheme actions are left actions ρ_g covering $\mathrm{Spec}(g^{-1})$. Linearizations are isomorphisms $\lambda_g : \rho_g^*\mathcal{L} \simeq \mathcal{L}$ compatible with composition. The induced left action on functions and sections is formed using $\rho_{g^{-1}}^*$ and $\lambda_{g^{-1}}$, so its coefficient action is g. Identity on a special scheme or module always means scheme-theoretic identity on the entire restriction.

Lemma H.0.1 (The quotient action on the inertia descent)**.** *Assume (T). Let Y_B/B be projective, flat, finitely presented, and at-worst-nodal of relative dimension one, with a semilinear G-action. Suppose I acts identically on $C = (Y_B)_l$. The canonical I-descent Y_A/A carries a canonical semilinear H-action, and its comparison*

$$Y_A \times_A B \simeq Y_B \tag{13}$$

is G-equivariant, where g acts on Y_A through gI and on the coefficient ring B as specified. The model Y_A is projective, flat, finitely presented and nodal of relative dimension one.

If $\mathcal{L}_B$ is a G-linearized relatively ample invertible sheaf whose restricted I-action on C is the identity, then its inertia descent $\mathcal{L}_A$ carries a canonical H-linearization, is relatively ample, and (13) identifies its pullback equivariantly with $\mathcal{L}_B$. Both constructions are functorial for equivariant isomorphisms and retain their specified comparison maps.

Proof. Apply E.0.1 to the I-action over B/A. Its descent is the invariant-affine gluing of C.1.81, so it gives the asserted projective model and the I-equivariant comparison (13). We prove the extra equivariance rather than presuming an integral Galois torsor for B/A.

Choose the finite I-invariant affine cover furnished by that gluing theorem. Adjoin all its G-translates and all nonempty finite intersections. Normality of I makes every translated open I-invariant; separatedness makes the intersections affine. For a member U, put

$$D_U = \Gamma(U, \mathcal{O}_{Y_B}), \qquad E_U = D_U^I, \qquad U_A = \operatorname{Spec} E_U. \tag{14}$$

The gluing theorem identifies $B \otimes_A E_U$ with D_U by multiplication and identifies invariant overlap rings with the actual overlaps of the U_A.

For $g \in G$, pullback along $\rho_g : U \to \rho_g U$ maps $D_{\rho_g U}$ to D_U and maps $E_{\rho_g U}$ to E_U: conjugation by g preserves I. On A this map is $(g|_M)^{-1}$. It commutes with every restriction map and hence glues to an automorphism of

Y_A covering $\mathrm{Spec}((g|_M)^{-1})$. The multiplication comparisons commute with these pullbacks, which proves the claimed G-equivariance of (13). The group law follows already on the invariant coordinate rings. For $i \in I$, the map on each E_U is the identity and $\rho_i U = U$, so the action factors through H, independently of a choice of coset lifts.

The given bundle has the inertia descent $\mathcal{L}_A = (p_*\mathcal{L}_B)^I$ by C.1.83, with $p : Y_B \to Y_A$. That result supplies its invertibility, ampleness and comparison. On (14), its sections are $\Gamma(U, \mathcal{L}_B)^I$. The linearized pullbacks send these invariant sections to invariant sections by the same conjugation calculation, and commute with restriction. They therefore define a G-linearization of $\mathcal{L}_A$ over the just constructed action. Every $i \in I$ is the identity on these invariant modules, so the linearization factors through H as well.

An equivariant isomorphism transports the invariant-affine data and their invariant modules. Intersecting either cover with the transported other cover gives a common invariant affine refinement; the canonical gluing comparisons agree there. This proves the stated functoriality and independence of the cover. Uniqueness of a comparison can also be checked after the faithfully flat base change, using the faithful part of Stacks Tag 02W0 for schemes and the faithful part of Stacks Tag 023T for their sheaves. □

Theorem H.0.2 (The mixed inertia criterion)**.** *Assume (T), and let Y_B/B be a supplied projective, flat, finitely presented nodal curve of relative dimension one with a semilinear G-action. Then the following are equivalent:*

1. *I acts identically on the entire scheme $(Y_B)_l$.*
2. *There is a projective, flat, finitely presented nodal O-scheme Y of relative dimension one with a G-equivariant isomorphism $Y \times_O B \simeq Y_B$, for the coefficient action.*

This descent, with its comparison, is unique up to the unique compatible isomorphism. If a G-linearized relatively ample invertible sheaf $\mathcal{L}_B$ is supplied, it descends with its linearization to a relatively ample invertible sheaf on Y if and only if its entire special-fibre I-action is the identity. There is no requirement of identity for the residual H-action.

Proof. Assume condition 1. Lemma H.0.1 constructs Y_A and its semilinear H-action. Equation (10) turns this action into an actual descent datum for $\mathrm{Spec}\, A \to \mathrm{Spec}\, O$: the two pullbacks are identified on the components

indexed by H, and the group law is exactly the cocycle condition on the triple product. Since this base map is surjective finite locally free and Y_A/A is projective, Stacks Tag 0CCJ makes the datum effective as an ordinary scheme Y/O.

Properness and finite presentation descend by Stacks Tag 02L1 and Stacks Tag 02L0. Flatness and nodality of relative dimension one descend by Stacks Tag 0C5E. To retain projectivity, note that $q : Y_A \to Y$ is finite locally free and surjective, as a base change of $\operatorname{Spec} A \to \operatorname{Spec} O$. The affine base and projectivity give an ample invertible sheaf on Y_A. The finite locally free case of Stacks Tag 0BD4 gives an ample invertible sheaf on Y. Properness over the affine base now gives projectivity by Stacks Tag 0B45. No division by $|H|$ occurs.

Combining $Y \times_O A \simeq Y_A$ with (13) gives the required G-equivariant comparison over B. Conversely, in any such comparison the special fibre is $Y_k \times_k l$. The subgroup I acts trivially on l by (9), and acts on the coefficient factor only. Hence it is the identity on the whole special scheme. This proves necessity.

Suppose now that $\mathcal{L}_B$ has the stated residual I-identity. The preceding lemma gives an H-linearized relatively ample $\mathcal{L}_A$ on Y_A. Equation (10), after base change to Y, makes this a genuine fpqc sheaf descent datum. Effectivity and full faithfulness in Stacks Tag 023T give a quasi-coherent sheaf $\mathcal{L}$ on Y with the specified pullback. By Stacks Tag 05B2 it is finite locally free; its rank is one because rank is unchanged by residue-field extension and q is surjective. It is therefore invertible. Relative ampleness descends by Stacks Tag 0D2P. Conversely, a bundle pulled back from Y has identity I-action on its full special-fibre module, for the same coefficient reason as above. Thus the actual supplied bundle descends, with no further power.

The inertia comparison is unique by the cited invariant descent and isomorphism functoriality; unramified descent is fully faithful by Stacks Tag 02W0, and sheaf descent by Stacks Tag 023T. Any two final descents therefore have a unique compatible comparison. In particular the special scheme C has the resulting full semilinear H-descent datum over l/k, and $Y_k \times_k l \simeq C$ respects it. This datum, rather than identity of the H-action or mere invariance of vertices, is what is used in the unramified step. □

Lemma H.0.3 (Closed subspace neighbourhood; F8RC-N)**.** *Let X be an analytic space, $Z \hookrightarrow X$ a closed analytic subspace, and $W \subset X$ an analytic domain containing $|Z|$. Then W contains an ordinary open neighbourhood of $|Z|$.*

Proof. For $z \in Z$, the domain universal property identifies $Z \times_X W$ with Z, since the entire map $Z \to X$ factors through W.

For the closed immersion into W, one may check the pullback on actual affinoid domains of W subordinate to affinoid charts of X. On these charts the canonical finite tensor of the closed ideal quotient is the actual closed quotient. This verifies the closed immersion by the target-local criterion NAG-001653.

Both maps $(Z, z) \to (X, z)$ and $(Z, z) \to (W, z)$ are closed immersions of analytic germs. By NAG-001978, their maps on reductions are isomorphisms. Functoriality makes $\mathcal{R}(W, z) \to \mathcal{R}(X, z)$ an isomorphism.

The reduction functor NAG-001972 identifies the reduction of (W, z) with an open subspace of the reduction of (X, z). The isomorphism above makes this subspace the whole reduction. By the subdomain classification NAG-001973, (W, z) and (X, z) are the same subdomain germ of (X, z). Thus some ordinary open neighbourhood of z in X lies in W. Taking the union over z proves the assertion. □

Lemma H.0.4 (The ordinary moment-image tube)**.** *Let $V = \mathcal{M}(A)$ be affinoid over the specified complete non-Archimedean field, let $f \in A$, and let g be a finite unit tuple on V. Suppose the nonempty actual zero space $D = \mathcal{M}(A/(f))$ has analytic dimension at most d, and put $P_0 = t_g(D)$. Then for some $\rho > 0$,*

$$t_g(\{|f| < \rho\}) \subseteq P_0. \tag{H.0.1}$$

If D is empty, a sufficiently small tube is empty. Arbitrary positive affinoid radii and the trivial absolute value are allowed.

Proof. By NAG-002358, P_0 is a compact finite integral affine polyhedral set of dimension at most d. The inverse image of each compact cell is an actual affinoid Laurent domain: integral affine inequalities become bounds on monomials in the units g_i, with positive real radii. Their finite union $W_0 = t_g^{-1}(P_0)$ is an analytic domain, obtained from its finite quasi-net of affinoid pieces along their actual intersections by the domain calculus. It contains the closed

subspace D. Lemma H.0.3 gives an ordinary neighbourhood O of D contained in W_0. On the compact complement $V \setminus O$, $|f|$ has a positive minimum, if the complement is nonempty. This proves (H.0.1) for a sufficiently small positive ρ.

If D is empty and V is nonempty, $|f|$ has a positive minimum on the compact V. If V is empty, every positive ρ works. □

Proposition H.0.5 (Fixed-test logarithmic integrability; F8RC-L)**.** *Let X be good, Hausdorff, and pure of dimension n, and let f be a regular analytic function on an open neighbourhood of the compact support of an ordinary smooth form β. If one of its bidegrees is n, then β vanishes on an ordinary neighbourhood of $\{f = 0\}$. In particular, for an ordinary compact (n, n)-test α, the pairing*

$$L_f(\alpha) = \int_{X \setminus \{f=0\}} \log |f| \, \alpha$$

is well-defined by the frozen ordinary compact integral. For every fixed such test, bounded continuous truncations agreeing with $\log |f|$ above $-R$ give the same value for all sufficiently large R. If η is ordinary smooth of bidegree $(n-1, n-1)$, then $d''\eta$ and $d'd''\eta$ vanish near $\{f = 0\}$.

Proof. Work on the open set where f is given. At a zero outside $\operatorname{supp} \beta$ the form already vanishes nearby. At a zero in the support, choose a common ordinary affinoid neighbourhood V on which f is regular and β has one unit-moment representative $t_g^*\gamma$, using the ordinary moment sheaf. The affinoid is pure of dimension n by domain purity. Regularity avoids every minimal prime. Apply dimension drop to the nonzero image of f on each integral ambient component. The component zero spaces cover the support of the full actual zero quotient $D = \mathcal{M}(\mathcal{O}(V)/(f))$, so its dimension is at most $n - 1$; for $n = 0$ it is empty. The ordinary moment-image tube for this actual quotient puts the g-image of a sufficiently small strict sublevel of $|f|$ in $t_g(D)$, of dimension at most $n-1$ when nonempty. Intersect that sublevel with the ordinary interior of V in X. The restriction of γ to every face is zero when one exterior degree is n. Thus its ordinary pullback is zero on this neighbourhood. This is an assertion about the actual ordinary germ and its representative, not just about a vanishing integral. It is local at every point of the zero scheme.

For compactly supported α, its closed support is therefore disjoint from the zero scheme. On this compact support $|f|$ has a positive lower bound

and a finite upper bound. The logarithm is bounded there and is an ordinary smooth function where f is a unit. Adjoin the unit f to the chart tuple on the unit locus near the compact support. Multiplication gives a compact ordinary form, extended by zero across the neighbourhood where α is zero. Its integral is the displayed value by the ordinary compact integral. Choose R so that $\log|f| > -R$ on this support. Then the truncation agrees with the smooth unit logarithm on a neighbourhood of the support. The product agrees as an ordinary compact form and is zero where the fixed test is zero. The final assertions follow by applying the same argument to $d''\eta$ and $d'd''\eta$, whose bidegrees are $(n-1,n)$ and (n,n), on the open set where they and f are defined. Neither S_1 nor purity of the zero scheme is needed for this proposition. □

Appendix I

Descent of the polarized mixed tower

Use the valuation-ring tower (T) and the action conventions of Chapter H.

Theorem I.0.1 (Descent of a compatible mixed equivariant tower)**.** *Assume (T), choose $0 \neq \pi \in \mathfrak{m}_O$, and put $B_n = B/\pi^n B$. Suppose given a cartesian tower of proper, flat, finitely presented B_n-schemes X_n with compatible semilinear G-actions. Assume that $C = X_1 \times_{B_1} l$ is at-worst-nodal of pure dimension one and that I acts identically on the entire scheme C.*

Choose any ample $\mathcal{A}_C$, compatible ample lifts $\mathcal{A}_n$, and put $\mathcal{N}_n = \bigotimes_{g\in G} \rho_{g,n}^* \mathcal{A}_n$. There exist a projective, flat, finitely presented nodal O-scheme Y of relative dimension one and a relatively ample invertible sheaf $\mathcal{P}$, with compatible equivariant polarized identifications

$$(Y, \mathcal{P}) \times_O B_n \simeq (X_n, \mathcal{N}_n) \qquad (n \geq 1). \tag{15}$$

The chosen polarized tower determines this pair uniquely up to its unique compatible polarized isomorphism. Its residue polarization is characterized after extension to l by

$$\mathcal{P}|_{Y_k} \otimes_k l \simeq \bigotimes_{h\in H} (\bar{\rho}_h^* \mathcal{A}_C)^{\otimes e}, \tag{16}$$

with the H-descent datum induced by the orbit linearization. An equivariant realization of the underlying tower over O necessarily has the stated whole-special-scheme I-identity.

Proof. The exact result B.1.2 supplies $\mathcal{A}_C$ and its compatible ample lifts, or lifts any prescribed ample $\mathcal{A}_C$. Apply Lemma G.0.8 at every level. Its naturality makes the tensor transition maps G-equivariant, and the full I-action on $\mathcal{N}_n|_C$ is the identity. Formula (12) gives the right side of (16); it is not replaced by $\mathcal{A}_C^{\otimes|G|}$.

Apply B.1.3 to the ordinary polarized tower. This constructs a projective, flat, finitely presented nodal pair $(Y_B, \mathcal{N}_B)$ over the complete valuation ring B. Rank-one completeness gives $B = \varprojlim B_n$. For each $g \in G$, the given tower automorphism and its linearization are compatible polarized isomorphisms into the base twist. The passing exact lemma D.0.2 algebraizes them uniquely. For every g, h, their appropriate composite and the map for gh have the same reductions; faithfulness makes them equal. The identity relation is checked in the same way. Thus this is a full G-action and linearization, including relations in a possibly nonsplit extension (8). Reduction at level one shows the required entire residual I-identities on the scheme and the bundle.

Theorem H.0.2 now applies to the actual algebraic pair. It descends the scheme and the existing $\mathcal{N}_B$ to $(Y, \mathcal{P})$, without a second orbit tensor. Reducing the algebraic comparisons gives (15), all transition compatibilities, and (16). The corresponding $O/\pi^n O$ tower consists of the reductions of this actual proper flat finitely presented polarized scheme. Neither ramified residual descent nor a valuation-ring module theorem has been applied to the quotient rings B_n.

For uniqueness, two such pairs become algebraizations of the same polarized tower over B. Polarized full faithfulness gives the unique comparison there; it is G-equivariant because its equivariance equations hold at every level. Inertia functoriality and fully faithful unramified descent descend that comparison uniquely. Finally, if the underlying tower is already the equivariant base change of an O-model, its residue scheme is obtained by extending k to l, on which I acts trivially. This proves the last assertion. □

Primitive cuts on a projective DVR model

Let K be complete and nontrivially discretely valued, with valuation ring R, residue field k, uniformizer π, and fixed absolute value. Set

$$v = \operatorname{ord}_R : K^\times \longrightarrow \mathbf{Z}, \qquad \lambda = -\log|\pi| > 0, \qquad -\log|a| = \lambda v(a).$$

We put $v(0) = +\infty$ when taking contents. No algebraic closure or rescaling of the absolute value is used. Fix a free R-module E of rank $d+1$, $d \geq 2$. Our common model is $\mathbf{P}(E)$, with projective points interpreted as lines, so its linear sections are elements of E^*. This is a proper flat normal model with one reduced special component $V = \mathbf{P}(E_k)$. At every induction stage we reuse E for a free module of rank $r+1$, $0 \leq r \leq d$, and reuse the corresponding projective-model notation. The initial stage is $r = d$.

For $0 \leq i \leq r$, choose

$$m_i \in \mathbf{Z}_{>0}, \qquad c_i \in \mathbf{Q}, \qquad L_i = \mathcal{O}(m_i), \qquad s_i = \ell_i^{m_i}, \qquad \ell_i \in E_K^*.$$

The rows ℓ_i form an invertible matrix A in an R-basis of E. Thus every subfamily is independent over K; the generic divisors meet properly and all $r+1$ supports have empty total intersection. Use the metric

$$\|s_i([z])\|_i = |\pi|^{c_i} \frac{|\ell_i(z)|^{m_i}}{(\max_j |z_j|)^{m_i}}. \tag{I.0.1}$$

The homogeneous expression is interpreted on analytic coordinate charts, or with coordinates in the completed residue field of an analytic point. It is independent of rescaling z.

These are algebraic root model metrics. Choose $e_i \geq 1$ with $e_i c_i \in \mathbf{Z}$ and use $\mathcal{O}(e_i m_i)$ on $\mathbf{P}(E)$, whose standard model frame is identified generically with $\pi^{-e_i c_i}$ times the standard frame. Taking the e_ith root gives (I.0.1). The special-fibre line is $\mathcal{O}(e_i m_i)$ and is generated by global sections, hence has nonnegative degree on every vertical curve. Thus the metrics are semipositive. The rational shifts change the metric identification, not that special-fibre positivity. Changing the clearing denominator e_i does not change the metric.

For a nonzero row $\ell \in E_K^*$ write

$$a = \min_j v(\ell_j), \qquad u = \pi^{-a}\ell \in E^*.$$

The row u is primitive: at least one coefficient is a unit. Its integer content a is independent of the chosen R-basis.

Lemma I.0.2 (Primitive cuts and determinant recursion)**.** *Assume $r \geq 1$. There is an R-basis $e_0, \dots, e_r$ of E with $u(e_0) = 1$ and $E' = \ker u = Re_1 \oplus \cdots \oplus Re_r$. The horizontal model cut is $\mathbf{P}(E') \simeq \mathbf{P}_R^{r-1}$. For $r \geq 1$, a section $s = \ell^m$ with metric shift c and clearing exponent e as above has normalized model divisor*

$$\frac{1}{e}\,\mathrm{cyc}\big(\mathrm{div}_{\mathcal{O}(em)}(s^{\otimes e})\big) = m[\mathbf{P}(E')] + (ma + c)[V]. \tag{I.0.2}$$

The generic divisor is $m[\mathbf{P}(E'_K)]$. A negative $ma+c$ is allowed as a rational vertical coefficient. All coefficients are computed by ordinary algebraic DVR orders, with actual quotient lengths.

If $\ell = \ell_i$ is a row of an invertible $(r+1)$-row matrix A, the other rows restrict to an invertible r-row matrix A_i on E'_K, and

$$v(\det A) = a_i + v(\det A_i). \tag{I.0.3}$$

The restricted standard metric is the standard metric for the lattice E', with the same shift c_j and exponent m_j for every remaining line. No primitivity of these restricted rows is assumed.

Elementary integral row reduction; ordinary DVR length convention of NAG-002552. The proof does not invoke the pending model log/divisor packet or a general intersection product.

Proof. Permute the coordinates to make a unit coefficient first, divide that coordinate vector by the unit, and subtract multiples of it from the other coordinate vectors. These are invertible R-operations and give the displayed basis. The content is the fractional ideal generated by the row coefficients, so this ideal and a are invariant under an invertible R-basis change. The primitive equation is now $z_0 = 0$. Its model quotient is a polynomial projective hyperplane over R, which proves the claim about $\mathbf{P}(E')$.

In a model frame, the coefficient of $s^{\otimes e}$ has a factor $\pi^{e(ma+c)}u^{em}$. At the generic point of the horizontal hyperplane its order is em, and at the generic point of V its order is $e(ma+c)$. These are the only components of the divisor. At a DVR with parameter t, the successive powers in $A/(t^n)$ give length n; for a rational coefficient one subtracts the lengths of numerator and denominator. Thus no nilpotent layer in $u^{em} = 0$ is removed. Divide the coefficients by e to obtain (I.0.2).

Move row i to the first position and use the constructed basis. The matrix becomes

$$\begin{pmatrix} \pi^{a_i} & 0 \\ * & A_i \end{pmatrix}.$$

Row permutation and the basis matrix have determinant a unit up to sign, proving (I.0.3); its nonzero determinant also proves that A_i is invertible over K. Finally, a matrix in $\mathrm{GL}_{r+1}(R)$ and its inverse both have operator norm at most one for the maximum norm over every valued extension of K.

Consequently the maximum norm is unchanged. Restriction to the direct summand E' gives exactly the standard metric in its basis. □

DVR divisor coefficients and conditional model recursion

Let K be complete and nontrivially discretely valued, with its specified absolute value, valuation ring R, residue field k, uniformizer π, and

$$\lambda = -\log|\pi| > 0.$$

We do not renormalize λ to one or pass to an algebraic closure. Let X be an integral proper K-variety of dimension $d \geq 2$. Take a proper flat integral normal finite-type R-model $\mathcal{X}$ with identified generic fibre X. Retain explicitly the following local data: every height-one local ring used below is a DVR, and the special fibre has finitely many irreducible components V, all of dimension d. These are hypotheses, not assertions about arbitrary analytic local rings. Smoothness or strict semistability of the model is not required.

Write $A_V = \mathcal{O}_{\mathcal{X},\eta_V}$ and normalize ord_V by a uniformizer of this DVR. Then

$$b_V = \mathrm{ord}_V(\pi) = \mathrm{length}_{A_V}(A_V/\pi A_V) > 0, \qquad [\mathcal{X}_k] = \sum_V b_V[V]. \tag{I.0.4}$$

Thus a nonreduced special fibre is allowed. Its b_V is not discarded.

Choose line bundles $L_1, \ldots, L_d, M$ on X and model lines

$$\mathcal{L}_i|_X \simeq L_i^{\otimes e_i}, \qquad \mathcal{M}|_X \simeq M^{\otimes e_0}, \qquad e_i, e_0 \in \mathbf{Z}_{>0}.$$

Let s be a nonzero rational section of M. A model frame at η_V writes $s^{\otimes e_0} = a_V e_V$, and put $c_V = \mathrm{ord}_V(a_V)$. A change of model frame multiplies a_V by a DVR unit, so c_V is well-defined.

Proposition I.0.3 (Horizontal and vertical divisor coefficients)**.** *Assume the height-one DVR hypotheses given above also for the horizontal prime divisors. Then, as codimension-one cycles on $\mathcal{X}$ with rational coefficients,*

$$\frac{1}{e_0}\,\mathrm{cyc}\big(\mathrm{div}_{\mathcal{X}}(s^{\otimes e_0})\big) = \overline{\mathrm{cyc}(\mathrm{div}_X(s))} + \sum_V \frac{c_V}{e_0}[V]. \tag{I.0.5}$$

Here the bar means coefficientwise closure of the horizontal prime cycles. At any height-one point with DVR A, a local coefficient $f = a/b \in \mathrm{Frac}(A)^\times$, $a, b \in A \setminus \{0\}$, has order

$$\mathrm{ord}_A(f) = \mathrm{length}_A(A/aA) - \mathrm{length}_A(A/bA). \tag{I.0.6}$$

For an effective local equation f, its coefficient is $\operatorname{length}_A(A/fA)$*, using the actual quotient, including its nilpotents. This is algebraic Cartier-to-cycle compatibility; it does not identify an analytic current or an F8 tropical end cycle.*

Proof. If t is a uniformizer and $a = t^m u$ with u a unit, the chain of powers of t in $A/(t^m)$ has m simple quotients, each its residue field. Thus $\operatorname{length}_A(A/aA) = m$; a unit has quotient zero and length zero. Subtracting the two orders proves (I.0.6), independently of the chosen fraction. In particular replacing $A/(t^m)$ by its reduction would incorrectly replace m by one when $m > 0$.

A height-one prime of $\mathcal{X}$ is either a vertical component V or horizontal. For a horizontal prime H, the element π is already a unit in $\mathcal{O}_{\mathcal{X},\eta_H}$. Localizing the model to its generic fibre therefore leaves this DVR unchanged. If H_K is the corresponding prime divisor of X, the local coefficient of $s^{\otimes e_0}$ has order $e_0 \operatorname{ord}_{H_K}(s)$. At V its order is c_V by definition. Comparing these coefficients proves (I.0.5).

There is no special-fibre factor b_V in a horizontal coefficient. For a finite residue extension, a simple residue-field factor has length its full field dimension after restriction of scalars; this is exactly the convention in NAG-002543 and NAG-002552. It counts inseparable degrees as well as separable degrees, without counting embeddings. □

Let Z have dimension $r \geq 2$, and suppose a proposed class of normal proper models and sections supplies the following operations for the data in question:

- $\mathcal{H}_i Z$ is the normalized horizontal divisor cycle of s_i, with actual multiplicities, and the required model data on its components;
- $\mathcal{V}_Z(i; J)$ is the normalized vertical term for cutting with s_i and retaining the metrics indexed by J;
- $H_C(J)$ is already defined, linear on the required cycles in lower dimensions, symmetric in its remaining entries, and satisfies the same horizontal–vertical recursion there.

All restrictions are required to be defined; no component is silently reduced or deleted. The operations and the vertical term are extended linearly to

cycles. On a common normal DVR model the proposed vertical term, in integer model data, is

$$\mathcal{V}_Z(i;J)=\frac{\lambda}{e_i\prod_{j\in J}e_j}\sum_V \operatorname{ord}_V(s_i^{\otimes e_i})\deg_{(\mathcal{L}_j)_{j\in J},k}(V). \tag{I.0.7}$$

This display specifies the algebraic term to be compared; it does not assume the pending packet's general logarithmic identification.

Lemma I.0.4 (The interchange defect)**.** *Let $i\neq j$, let J index the other $r-1$ entries, and put*

$$R_i=H_{\mathcal{H}_iZ}(j,J)+\mathcal{V}_Z(i;j,J),\qquad R_j=H_{\mathcal{H}_jZ}(i,J)+\mathcal{V}_Z(j;i,J).$$

Under the preceding explicit operation and lower-dimensional recursion hypotheses, their difference is exactly

$$\begin{aligned}R_i-R_j=\;&H_{\mathcal{H}_j\mathcal{H}_iZ-\mathcal{H}_i\mathcal{H}_jZ}(J)\\&+\mathcal{V}_{\mathcal{H}_iZ}(j;J)-\mathcal{V}_{\mathcal{H}_jZ}(i;J)\\&+\mathcal{V}_Z(i;j,J)-\mathcal{V}_Z(j;i,J).\end{aligned} \tag{I.0.8}$$

Consequently equality of the horizontal codimension-two cycles and the vertical interchange identity

$$\mathcal{V}_{\mathcal{H}_iZ}(j;J)+\mathcal{V}_Z(i;j,J)=\mathcal{V}_{\mathcal{H}_jZ}(i;J)+\mathcal{V}_Z(j;i,J) \tag{I.0.9}$$

are sufficient for equality of the two first choices. Without that horizontal-cycle equality, vanishing of the full right side of (I.0.8) *is the exact necessary and sufficient condition. If the appropriate identities hold at every node, and the curve/point base cases are compatible, the recursion is independent of its order.*

Proof. Apply the lower-dimensional recursion to $H_{\mathcal{H}_iZ}(j,J)$ and to $H_{\mathcal{H}_jZ}(i,J)$. Their horizontal terms are respectively $H_{\mathcal{H}_j\mathcal{H}_iZ}(J)$ and $H_{\mathcal{H}_i\mathcal{H}_jZ}(J)$, and their vertical terms are the first two vertical expressions in (I.0.8). Subtract, use cycle linearity, and retain the two original vertical terms. This proves the exact formula and both stated criteria. Induct on dimension for every possible first choice, using the criteria to compare any two first choices and the induction hypothesis for later choices. The separately assumed curve and point cases start this induction. No equality of Chow classes is substituted for a required cycle or functional identity. □

Determinant norms and Cartier sections

Here $q : Y \to X$ may be any norm-admissible finite morphism between the fixed K-spaces, with $q_*\mathcal{O}_Y$ locally free of constant rank $n \geq 1$ on ordinary opens. In particular this applies to the finite constant-extension map above. We work with algebraic determinants of coherent modules, before introducing any metric on a norm bundle.

Define the *determinant norm line*

$$\mathrm{Nm}_q(\mathcal{L}) = \det(q_*\mathcal{L}) \otimes \det(q_*\mathcal{O}_Y)^\vee. \tag{I.0.10}$$

Here det is the nth exterior power. Exterior powers and the displayed line are constructed on ordinary local frames and glued by their determinant transition maps. This also defines the norm of an isomorphism.

Proposition I.0.5 (Norm projection)**.** *For line bundles $\mathcal{L}$ on Y and $\mathcal{M}$ on X, there is a canonical isomorphism*

$$\mathrm{Nm}_q(\mathcal{L} \otimes q^*\mathcal{M}) \simeq \mathrm{Nm}_q(\mathcal{L}) \otimes \mathcal{M}^{\otimes n}. \tag{I.0.11}$$

In particular $\mathrm{Nm}_q(q^*\mathcal{M}) \simeq \mathcal{M}^{\otimes n}$. The formulas commute with analytic base change. Consequently the kernel of $\mathrm{Pic}(X) \to \mathrm{Pic}(Y)$ is killed by n.

Direct inputs Proposition G.0.5, Lemma C.2.10, `NAG-001752`.

Proof. The tensor projection isomorphism gives $q_*(\mathcal{L} \otimes q^*\mathcal{M}) \simeq q_*\mathcal{L} \otimes \mathcal{M}$. For any rank-$n$ locally free module E, local exterior multiplication gives

$$\det(E \otimes \mathcal{M}) \simeq \det(E) \otimes \mathcal{M}^{\otimes n}.$$

Changing a frame of $\mathcal{M}$ by a multiplies the top wedge by a^n, and changing a frame of E by a matrix multiplies both sides by the same determinant. These local maps therefore glue canonically. Cancel $\det(q_*\mathcal{O}_Y)$ to obtain (I.0.11). The norm line of $\mathcal{O}_Y$ has its canonical trivialization, which gives the specialization.

Finite coherent direct image commutes with analytic base change, including nonflat base change. Exterior powers of locally free modules and the displayed frame maps do too. This proves the stated compatibility. If $q^*\mathcal{M}$ is trivial, apply its determinant norm and the specialization to get $\mathcal{M}^{\otimes n} \simeq \mathcal{O}_X$. No injectivity of the unadorned Picard pullback is asserted. □

Atomic calibration and projective model induction

Use the same projective DVR and root-metric data.

Write ξ_E for the divisorial point of V. On a coordinate chart $z_0 = 1$ it is the unit-radius Gauss point. For $r = 0$ it is the unique point of $\mathbf{P}^0_K$.

For these model data the finite model measure is specified by its atom at ξ_E. Its weight is the mixed special-fibre degree of the root model lines divided by the product of their clearing exponents, with the multiplicity of the special component included. Here that multiplicity is one.

The comparison with the primary induction refers to the supplied recursion below when it has the same cycle, finite model measure and dimension-zero value.

$$H_Z(s_i, \text{remaining data}) = H_{\mathrm{cyc}(\mathrm{div}_Z\, s_i)}(\text{remaining data}) + \int_{Z^{\mathrm{an}}} -\log \|s_i\|\, d\mu_{\text{remaining data}}. \tag{I.0.12}$$

Proposition I.0.6 (Atomic calibration on the projective model)**.** *For any set J of r remaining lines on $\mathbf{P}(E)$, the specified mixed model measure and its mass are*

$$\mu_J = D_J \delta_{\xi_E}, \qquad D_J = \prod_{j \in J} m_j = \deg_{(L_j)_{j\in J},K}(\mathbf{P}(E_K)). \tag{I.0.13}$$

The empty product in dimension zero is one. For a further nonzero row ℓ_i of content a_i,

$$\int_{\mathbf{P}(E_K)^{\mathrm{an}}} -\log \|s_i\|_i\, d\mu_J = \lambda(m_i a_i + c_i) D_J. \tag{I.0.14}$$

The logarithm is finite at the atom, and every proper algebraic closed subset has measure zero. For $r \geq 1$ the normalized horizontal coefficient is m_i. For $r = 0$ the generic divisor is empty and the horizontal part is zero. The normalized vertical coefficient is $m_i a_i + c_i$, and the special-fibre multiplicity is one. There is no additional factorial.

NAG-000182 and NAG-001707 for Gauss seminorms and analytification; Lemma I.0.2; the specified finite model-measure definition. The coordinate quotient calculation below calibrates the algebraic degrees and unreduced lengths directly.

Proof. For projective space, the dimension of homogeneous polynomials of degree nq is $\binom{nq+r}{r}$, with leading term $n^r q^r / r!$. Thus $\deg_{\mathcal{O}(n)} \mathbf{P}^r = n^r$. Polarizing this polynomial shows that the mixed degree of $\mathcal{O}(n_1), \ldots, \mathcal{O}(n_r)$ is

$\prod_j n_j$: the coefficient of $t_1 \cdots t_r$ in $(\sum_j n_j t_j)^r$ is $r! \prod_j n_j$. The same normalization has a direct complete-intersection check. Choose the r coordinate equations $z_j^{n_j} = 0$, $1 \le j \le r$. They meet at $[1 : 0 : \cdots : 0]$, and their local algebra is

$$k[t_1, \dots, t_r]/(t_1^{n_1}, \dots, t_r^{n_r}).$$

Its monomials with exponents smaller than n_j form a basis of size $\prod_j n_j$. These are regular successive coordinate powers, and the quotient retains all nilpotents. Its residue field is k, so no residue-degree factor is suppressed. The same calculation holds over K.

For the root model lines $\mathcal{O}(e_j m_j)$, this mixed special-fibre degree is $\prod_j e_j m_j$. The BPS defining atomic weight divides by $\prod_j e_j$ and multiplies by the special-fibre multiplicity, which is one. This proves (I.0.13) independently of the chosen clearing exponents. The constant shifts do not change these special-fibre lines.

The Gauss seminorm is multiplicative by NAG-000182. Its kernel on the affine coordinate ring is zero, so its scheme point is generic; this proves the zero-mass assertion. The Gauss value of the row ℓ_i is the maximum absolute value of its coefficients, namely $|\pi|^{a_i}$. The denominator in (I.0.1) is one in this chart. Hence $-\log \|s_i(\xi_E)\| = \lambda(m_i a_i + c_i)$. Integrating a finite value against the one-atom measure proves (I.0.14). For $r = 0$ the row is a nonzero scalar and the same calculation applies. □

Define a model functional recursively on these tuples. In dimension zero, define it to be the negative logarithm of the nonzero section's norm. In dimension $r \ge 1$, choose any index i, take the primitive horizontal model $\mathbf{P}(E_i)$ of Lemma I.0.2, and set

$$H_E^{(i)}((L_j, s_j)_{j=0}^r) = m_i H_{E_i}((L_j|_{E_i}, s_j|_{E_i})_{j \ne i}) + \lambda(m_i a_i + c_i) \prod_{j \ne i} m_j. \quad \text{(I.0.15)}$$

Every subsequent stage again chooses an index. The first term uses the actual generic divisor cycle $m_i[\mathbf{P}(E_{i,K})]$, and the second is the full model logarithmic integral, not a guessed correction.

Theorem I.0.7 (Symmetric projective model induction)**.** *The recursion is defined at every stage for every permutation of the indices. Every order gives*

$$H_E = \lambda \left(D\, v(\det A) + \sum_{i=0}^{r} c_i \frac{D}{m_i} \right), \qquad D = \prod_{i=0}^{r} m_i. \quad \text{(I.0.16)}$$

It is therefore symmetric in the labelled pairs (L_i, s_i), independent of the chosen integral bases and primitive complements, and independent of the clearing exponents e_i. The value changes by $\lambda q D/m_i$ if c_i is increased by $q \in \mathbf{Q}$. Replacing ℓ_i by $b_i\ell_i$, $b_i \in K^\times$, changes the value by $-D\sum_i \log|b_i|$.

This is a self-contained model recursion on the stated projective class. It identifies the restriction of the primary BPS induction to this class because its base value, divisor cycle and measure are the same. No native smooth-integral comparison, analytic adjointness, metric limit, model-change invariance or extension to arbitrary pseudo-divisors is part of the assertion.

Lemmas and formulas I.0.2–I.0.6; induction and determinant arithmetic. The reference to the primary induction is a comparison of specified definitions, not an imported symmetry theorem.

Proof. The dimension-zero value is $\lambda(m_0 v(\ell_0)+c_0)$, which is (I.0.16). Suppose the formula has been proved in dimension $r-1$, for all choices of data and orders. The matrix of remaining rows on E_i is invertible, so the induction hypothesis applies after any first choice i. Writing $D_i = D/m_i$, the first term of (I.0.15) is

$$m_i\lambda\left(D_i v(\det A_i) + \sum_{j\neq i} c_j \frac{D_i}{m_j}\right) = \lambda\left(Dv(\det A_i) + \sum_{j\neq i} c_j \frac{D}{m_j}\right).$$

Its second term is $\lambda(Da_i + c_i D/m_i)$. Equation (I.0.3) gives precisely (I.0.16). This proves the claim for every first index and every later order, without assuming order-independence in dimension r.

Permuting rows changes the determinant by a sign of absolute value one; a change of R-basis multiplies it by a unit. The norms and the child lattices have the basis compatibilities proved in Lemma I.0.2. The formula itself contains no e_i. The two change rules follow by replacing c_i and by multiplying the matrix rows by b_i, respectively. Finally, the primary induction (I.0.12), if evaluated on this class, has exactly the same finite base value and exactly the two terms in (I.0.15). Finite induction identifies its value with the displayed formula; the new proof of symmetry did not use that primary theory. □

Proposition I.0.8 (Generic avoidance does not make model cuts proper)**.** *Fix $d \geq 2$ and $n \geq 1$ on $\mathbf{P}^d_R$, with unshifted standard metrics and $m_i = 1$. Take*

$$\ell_0 = z_0, \qquad \ell_i = z_0 + \pi^n z_i \quad (1 \leq i \leq d). \tag{I.0.17}$$

Every model section avoids the generic point of the special component. Every generic-fibre subfamily meets properly, and the full generic intersection is empty. Nevertheless the simultaneous model zero scheme has special-fibre support $\{z_0 = 0\} \simeq \mathbf{P}^{d-1}_k$, so it is not a finite vertical intersection to which a final quotient-length formula could be applied. The symmetric model recursion is finite and has value $dn\lambda$.

After the first horizontal cut $z_0 = 0$, each remaining section has vertical order n. Its restriction to that vertical component is the zero section. Thus using the remaining restricted sections themselves to cut that vertical component fails; its contribution must use the mixed line-bundle degree, with the correct multiplicities.

Theorem I.0.7; explicit model equations. This is an obstruction to the proposed naive cut procedure, not to known refined intersection theory or to the primary local height.

Proof. Each row is primitive, so its order at the generic point of the special fibre is zero. Subtract row zero from all other rows. The determinant is π^{nd}, hence all rows are independent over K and their hyperplanes meet properly there. The simultaneous ideal is

$$(z_0, \pi^n z_1, \ldots, \pi^n z_d).$$

Modulo π, its support is the stated projective hyperplane; its dimension is $d - 1 > 0$. For instance on $z_1 = 1$ it contains the quotient $R[z_2, \ldots, z_d]/(\pi^n)$ after setting $z_0 = 0$, which has positive-dimensional special support. Thus a finite local intersection length is not supplied by the whole tuple.

On the horizontal model $z_0 = 0$, the remaining rows are $\pi^n z_i$. Each therefore contributes the vertical component with order n and vanishes identically when restricted to that component. Its line-bundle restriction is still $\mathcal{O}(1)$, whose required mixed degree is one; the zero section is not a Cartier equation for that degree. Equation (I.0.16) gives $H = \lambda v(\pi^{nd}) = dn\lambda$. Equivalently, the first logarithmic term is zero, and the later d stages, including the final point, each contribute $n\lambda$. □

Cartier sections under determinant norm

Use the same finite locally free rank and determinant norm conventions.

Corollary I.0.9 (Pulled-back Cartier sections)**.** *Let s be a section of a line bundle $\mathcal{M}$ which is a non-zero-divisor in every local trivialization. Then q^*s is again a Cartier section. The determinant of multiplication by q^*s gives a section of $\mathrm{Nm}_q(q^*\mathcal{M})$ which, under (I.0.11), is $s^{\otimes n}$. Its effective Cartier divisor is $n\ \mathrm{div}(s)$.*

Direct inputs Proposition I.0.5, `NAG-001624`; finite local freeness of q.

Proof. Choose an affinoid neighbourhood $V = \mathcal{M}(A)$ on which $\mathcal{M}$ and $q_*\mathcal{O}_Y$ are trivial. The frame coefficient a of s is a non-zero-divisor in A: its multiplication kernel sheaf has zero ordinary stalks, so the affinoid coherent equivalence makes its section kernel zero. The free A-algebra module $B = \Gamma(q^{-1}V, \mathcal{O}_Y)$ preserves this injection. The action of a on the rank-n module $q_*\mathcal{O}_Y$ is aI_n, with determinant a^n. These equations agree on changes of frame, proving the assertion on sections. The local Cartier equation a^n is precisely that of $n\ \mathrm{div}(s)$. □

Use the data X, C, U, f, D, η and the actual chart cover V_i of the preceding chart lemma. There is no claim that $\eta|_{V_i}$ has support in $\mathrm{Int}(V_i/K)$. It can reach the original boundary of that chart. The finite union $Q = \bigcup_i V_i$ is a compact ordinary neighbourhood of C; it need not itself be good. The frozen finite-chart integrator covers exactly this situation. No locally finite partition, global paracompactness, or extension of a chart unit outside its domain is needed. On an overlap select one restricted representative; joint-tuple comparison is made only on that actual overlap.

Supplied fixed-test interface (IL). For a fixed ordinary compact form with one bidegree n, regularity of f implies vanishing on an ordinary neighbourhood of its zero space. The scalar logarithmic pairing on top forms is then the frozen ordinary compact integral away from that space. In particular this applies to $d''\eta$ and $d'd''\eta$, and later to the cut test. This interface needs neither S1 nor S3.

Proposition I.0.10 (Fixed-test stabilization; F8SA-E)**.** *Assume IL. For every fixed compact ordinary top form β supported in C, there is R_β such that the continuous truncation $\ell_R = \max(\log|f|, -R)$, extended by $-R$ at D, satisfies*

$$\ell_R\beta = \log|f|\,\beta \quad (R \geq R_\beta),$$

where the right side is extended by zero across a neighbourhood on which $\beta = 0$. These sufficiently deep products are ordinary smooth compact forms, and their scalar integrals are exactly equal.

More specifically, fix a smooth χ equal to one sufficiently far left and zero for $x \geq b_0$. Set $\eta_1 = \chi(\log|f|)\eta$, extending $\chi(\log|f|)$ by one at D. Given $b > b_0$, there exists finite $a_* < b_0$ such that for every $a \leq a_*$,

$$L_f(d'd''\eta_1) = \int_{Q\cap\{e^a\leq|f|\leq e^b\}} \log|f|\,d'd''\eta_1. \tag{I.0.18}$$

Both $d''\eta_1$ and $d'd''\eta_1$ vanish on an ordinary neighbourhood of the removed lower cap.

Proof. IL [NAG-002806] makes the closed compact support of β disjoint from D. Hence $|f|$ has a positive minimum on that support. Choose the cut strictly below this minimum. Outside the support the form is locally zero, so the asserted equality is equality of ordinary forms after zero extension, not just of integrals.

The cut scalar is smooth near D, because it is locally constant there; away from D, f is a unit and its logarithm is an ordinary smooth moment function. Define its product with η on U, and extend by zero on $X \setminus C$. These definitions agree on their ordinary open overlap. All resulting supports remain in C. Apply IL [NAG-002806] to the two indicated derivatives. Their compact supports avoid D, so one positive lower bound for $|f|$ works for both. Choose a_* strictly below its logarithm and in the constant-one range of χ. They vanish on a neighbourhood of $Q \cap \{|f| \leq e^{a_*}\}$. They also vanish wherever $\log|f| > b_0$. Compact-neighbourhood independence of the frozen integral [NAG-002425] now gives (I.0.18), including its closed endpoints. □

Fix a complete non-Archimedean field K, possibly trivially valued, with its specified absolute value. Affinoids are generalized affinoids with their canonical quotient and finite-module norms. An analytic space is good and Hausdorff, and purity always means *analytic* pure dimension. A regular function means a non-zero-divisor in the relevant affinoid rings, or equivalently the stated injectivity of its coherent sheaf multiplication when working locally. The zero ring and empty spaces contribute zero. We take $n \geq 1$.

For an affinoid $X = \mathcal{M}(A)$ pure of dimension n, write

$$\operatorname{Min} A = \{\mathfrak{q}_1, \dots, \mathfrak{q}_s\}, \qquad X_i = \mathcal{M}(A/\mathfrak{q}_i), \quad i_i : X_i \hookrightarrow X, \quad m_i = \operatorname{length}_{A_{\mathfrak{q}_i}} A_{\mathfrak{q}_i}. \tag{I.0.19}$$

All m_i are positive integers. For regular $f \in A$, put $f_i = f|_{X_i}$, $D = \mathcal{M}(A/(f))$, and $D_i = \mathcal{M}(A/(\mathfrak{q}_i, f))$, retaining their actual quotient structures. The following interfaces are deliberately separate.

Proposition I.0.11 (Weighted component formula for native integrals; F8CR-N)**.** *For every ordinary compact (n,n)-form ω on the affinoid X of (I.0.19),*

$$\int_X \omega = \sum_{i=1}^{s} m_i \int_{X_i} i_i^* \omega. \tag{I.0.20}$$

The same formula holds with ω replaced by $\phi\omega$ for every ordinary smooth scalar ϕ on X. No boundary support assumption, zero-space purity, or scalar PL is used.

Proof. Here is the restriction check needed to keep the original m_i when different moment representatives are used. Let $V = \mathcal{M}(B)$ be an actual affinoid domain of X. The map $A \to B$ is flat by ordinary single-domain flatness. If $\mathfrak{r} \in \operatorname{Min} B$, then $\mathfrak{q} = \mathfrak{r} \cap A$ is minimal in A: flat going down (the already registered algebraic input Stacks 00HS) would otherwise give a prime properly below $\mathfrak{r}$. The local flat map $A_{\mathfrak{q}} \to B_{\mathfrak{r}}$ has Artinian source and target. Tensor a composition series of $A_{\mathfrak{q}}$ with $B_{\mathfrak{r}}$. Exactness gives

$$\operatorname{length}_{B_{\mathfrak{r}}} B_{\mathfrak{r}} = m_{\mathfrak{q}} \operatorname{length}_{B_{\mathfrak{r}}}(B_{\mathfrak{r}}/\mathfrak{q}B_{\mathfrak{r}}). \tag{I.0.21}$$

For every other $\mathfrak{q}_i \in \operatorname{Min} A$, choose an element of $\mathfrak{q}_i \setminus \mathfrak{q}$. It is invertible in $B_{\mathfrak{r}}$, so $(B/\mathfrak{q}_i B)_{\mathfrak{r}} = 0$. Consequently (I.0.21) is exactly

$$\operatorname{length}_{B_{\mathfrak{r}}} B_{\mathfrak{r}} = \sum_i m_i \operatorname{length}_{B_{\mathfrak{r}}}(B/\mathfrak{q}_i B)_{\mathfrak{r}}.$$

In particular no assertion that a flat fibre has length one has entered this calculation.

Apply the generic finite-module weight formula NAG-002362 to these modules on V, and then its global chain construction closed finite-module chain. For any chosen unit tuple g on V, it gives

$$\mathcal{T}_g(B) = \sum_i m_i \mathcal{T}_g(B/\mathfrak{q}_i B).$$

Actual domain base change NAG-001846 and finite tensor comparison NAG-001565 identify $\mathcal{M}(B/\mathfrak{q}_i B)$ with $V \times_X X_i$, retaining its full structure. This is an actual domain of X_i, hence pure of dimension n when nonempty by NAG-002293. The compact finite-pushforward formula, on this single actual affinoid domain and for this closed immersion and the identity map on the common moment coordinates, identifies its integral with the target finite-module integral. There is no lattice or residue factor in addition to the recorded chain weights.

Represent ω on a finite actual affinoid cover of a compact neighbourhood of its support. Use the same cover pulled back to each X_i, discarding empty pieces. All actual intersections have the same calculation. The finite inclusion–exclusion integral NAG-002416, followed by NAG-002425, gives (I.0.20). No unit tuple is extended beyond its chart; joint tuples and their projection pullbacks are used only on actual overlaps. The argument applies verbatim to the compact form $\phi\omega$. □

Fix a complete non-Archimedean field K, possibly trivially valued, with its specified absolute value. Affinoids are generalized affinoids with their canonical quotient and finite-module norms. An analytic space is good and Hausdorff, and purity always means *analytic* pure dimension. A regular function means a non-zero-divisor in the relevant affinoid rings, or equivalently the stated injectivity of its coherent sheaf multiplication when working locally. The zero ring and empty spaces contribute zero. We take $n \geq 1$.

For an affinoid $X = \mathcal{M}(A)$ pure of dimension n, write

$$\operatorname{Min} A = \{\mathfrak{q}_1, \dots, \mathfrak{q}_s\}, \qquad X_i = \mathcal{M}(A/\mathfrak{q}_i), \quad i_i : X_i \hookrightarrow X, \quad m_i = \operatorname{length}_{A_{\mathfrak{q}_i}} A_{\mathfrak{q}_i}. \tag{I.0.22}$$

All m_i are positive integers. For regular $f \in A$, put $f_i = f|_{X_i}$, $D = \mathcal{M}(A/(f))$, and $D_i = \mathcal{M}(A/(\mathfrak{q}_i, f))$, retaining their actual quotient structures. The following interfaces are deliberately separate.

Supplied hypothesis $\mathbf{ZP}_{\mathrm{loc}}$. In each affinoid localization used here, D and every D_i are empty or pure of analytic dimension $n-1$.

Proposition I.0.12 (Cartier cycles with full generic weights; F8CR-C)**.** *For X, f as above, assume ZP_{loc}. Then, with the actual analytic Cartier coefficients and native pure-cycle integrals,*

$$\operatorname{div}_X(f) = \sum_i m_i (i_i)_* \operatorname{div}_{X_i}(f_i), \qquad \int_D \eta|_D = \sum_i m_i \int_{D_i} (i_i^* \eta)|_{D_i} \tag{I.0.23}$$

for every compact ordinary $(n-1, n-1)$-form η. The effective local length formula itself does not require ZP; its use here as a common pure-cycle identity does.

Proof. First check that no extra component is hidden in the right side. If $\mathfrak{r}$ is minimal over $(\mathfrak{q}_i, f)$, choose $\mathfrak{p} \subseteq \mathfrak{r}$ minimal over (f) [Stacks 00E0(4)]. $\mathrm{ZP}_{\mathrm{loc}}$ makes both integral affinoids $\mathcal{M}(A/\mathfrak{p})$ and $\mathcal{M}(A/\mathfrak{r})$ have analytic dimension $n-1$. A strict inclusion would contain a nonzero element of the domain $A/\mathfrak{p}$; the dimension-drop bound NAG-002374 would give dimension at most $n-2$ for the latter zero locus (empty when $n-1=0$). This is impossible. Thus $\mathfrak{r} = \mathfrak{p}$. Conversely, if $\mathfrak{p} \in \operatorname{Min}_A(f)$ contains $\mathfrak{q}_i$, no prime strictly between them can contain f, so $\mathfrak{p}/\mathfrak{q}_i$ is minimal over (f_i). Every $\mathfrak{p}$ contains at least one minimal prime of A. This establishes the exact component correspondence, allowing the same Cartier component to occur for several i.

At each such $\mathfrak{p}$, Proposition C.1.14 gives the coefficient identity with every local Artin length. The frozen effective Cartier comparison NAG-002772

identifies each of these algebraic lengths with the length of the actual analytic quotient stalk at a maximal-Abhyankar point of that zero-space component. More explicitly, NAG-002769 applies to the pure quotient affinoids $A/(f)$ and $(A/\mathfrak{q}_i)/(f_i)$ and their finite structure modules; its ordinary and pointed-domain Artinian length comparisons retain the full closed fibre. Its regular local comparison, not flatness alone, is what justifies that bridge. No S_1 property of A is required by either of these effective coefficient assertions. On the common reduced component the closed immersion has identical quotient $A/\mathfrak{p}$ and generic residue field, hence generic degree one.

Finally NAG-002778 identifies the full quotient integration with these analytic Cartier coefficients and their intrinsic component chains. Its pure-zero-space hypothesis is exactly the one retained here. Finite chart localization and its ordinary compact-form clause give the second equality in (I.0.23). No additional tropical multiplicity, lattice index, or reduced-fibre replacement is allowed. □

The tame inertia criterion for the supplied model

PDF-derived transcription. Historical English reader, Section 1.55, Theorem 1.55.5, printed pages 221–222. The historical original TeX remains unlocated.

Theorem I.0.13 (The full tame inertia criterion for a supplied model)**.** *Let L/K be finite Galois satisfying (Tg), put $O = K^\circ$, $B = L^\circ$, and let G, I, l be as in Theorem 1.55.3. Let Y_B/B be a supplied projective, flat, finitely presented nodal scheme of relative dimension one with a semilinear G-action. There is a projective, flat, finitely presented nodal O-scheme Y of relative dimension one and a G-equivariant comparison*

$$Y \times_O B \simeq Y_B \tag{22}$$

if and only if I acts identically on the entire scheme $(Y_B)_l$. Such a descent is unique up to the unique isomorphism compatible with (22).

A supplied G-linearized relatively ample invertible sheaf $\mathcal{L}_B$ descends, with its specified linearization and comparison, if and only if its entire special-fibre I-action is the identity. Its descent is relatively ample and unique with that comparison. There is no identity requirement on the residue Galois quotient G/I and no further tensor power of $\mathcal{L}_B$ is needed.

Proof. Assume the whole-special-scheme identity. Take (19) and descend from F°_{j-1} to F°_{j} successively using Lemma 1.55.4, with $P = G/J_{j-1}$ and $Q = J_j/J_{j-1}$. Normality in G makes these groups and their actions on the corresponding fields well defined. At each step projectivity, flatness, finite presentation and nodal relative dimension one are retained. Every coefficient residue field is l. Reducing the actual equivariant comparison therefore identifies the new special scheme, with its remaining inertia action, with the previous one. The remaining inertia is still the identity. This argument uses the constructed comparison; it does not assume that invariants commute with reduction.

If $r \geq 1$, it suffices to perform the first $r-1$ steps. The last field configuration $K \subset M \subset F_{r-1}$ then satisfies exactly (T) of `NAG-003009`: M/K is its actual unramified Galois lift, F_{r-1}/K is Galois, and F_{r-1}/M is one exact Kummer step. That frozen theorem performs the final Kummer and unramified descents. Composing the comparisons proves (22).

For completeness, when $I = 1$ the field $L = M$ itself is the actual unramified lift. The torsor identity in `NAG-002262` turns the full G-action into an fpqc descent datum. It is effective for this projective scheme by Stacks 0CCJ. Properness and finite presentation descend by Stacks 02L1 and Stacks 02L0, and flatness and nodal relative dimension one by Stacks 0C5E. The finite locally free surjective pullback has an ample invertible sheaf; Stacks 0BD4 gives one downstairs. Properness over the affine base then gives projectivity by Stacks 0B45.

If $\mathcal{L}_B$ has full residual I-identity, apply the bundle part of Lemma 1.55.4 at these same steps. The new residual module is identified with the old one by the actual bundle comparison, so the required identity persists. For $r \geq 1$ the bundle clause of `NAG-003009` finishes the descent of this very bundle. In the unramified case $I = 1$, fpqc sheaf descent Stacks 023T is effective; finite local freeness descends by Stacks 05B2, and its rank is one by surjective base change. Relative ampleness descends by Stacks 0D2P.

Conversely, (22) identifies the special scheme with $Y_k \times_k l$. Inertia fixes l and acts only on coefficients, so acts identically on that whole scheme. The same calculation on a pulled-back line bundle gives identity on its full residue module. Uniqueness follows at each ramified step from the canonical invariant descent and its functoriality. At the unramified step it is full faithfulness in Stacks 02W0 and Stacks 023T. This also proves independence of the chosen

series and Kummer generators. The quotient G/I retains its semilinear action on the complete special scheme, which is the descent datum used over l/k. □

Descent of the supplied equivariant tower

PDF-derived transcription. Historical English reader, Section 1.55, Corollary 1.55.6, printed page 222. The historical original TeX remains unlocated.

Corollary I.0.14 (The supplied equivariant tower interface)**.** *Keep the field hypotheses and notation of Theorem 1.55.5, and choose* $0 \neq \pi \in \mathfrak{m}_K$. *Put* $B_n = B/\pi^n B$. *Let* X_n/B_n *be a supplied cartesian tower of proper, flat, finitely presented schemes, with compatible semilinear* G*-actions. Suppose* $C = X_1 \times_{B_1} l$ *is nodal of pure dimension one and* I *acts identically on the entire scheme* C. *Choose an ample* $\mathcal{A}_C$ *and compatible ample lifts* $\mathcal{A}_n$, *and put* $\mathcal{N}_n = \bigotimes_{g\in G} \rho_{g,n}^* \mathcal{A}_n$. *Then there is a projective, flat, finitely presented nodal pair* $(Y, \mathcal{P})$ *over* O, *with* $\mathcal{P}$ *relatively ample, and compatible equivariant polarized identifications*

$$(Y, \mathcal{P}) \times_O B_n \simeq (X_n, \mathcal{N}_n). \tag{23}$$

It is unique with these comparisons. The residue polarization, after extension to l, *is*

$$\mathcal{P}|_{Y_k} \otimes_k l \simeq \bigotimes_{h\in G/I} (\bar{\rho}_h^* \mathcal{A}_C)^{\otimes |I|}, \tag{24}$$

with the quotient descent datum. An equivariant realization over O *necessarily has the stated entire-special-scheme inertia identity.*

Proof. The exact input NAG-002910 supplies the indicated ample sheaf and any requested compatible lifts. The general finite-group lemma NAG-003007 makes $\mathcal{N}_n$ compatible and G-linearized, with identity I-action on its entire restriction to C; its coset formula is (24). This lemma does not assume cyclic inertia or invertibility of $|G/I|$.

Apply NAG-002911 to this ordinary polarized tower over the complete valuation ring B. It gives a projective flat finitely presented nodal pair over B. For each g, the maps of the polarized tower into its base twist algebraize uniquely by NAG-002985. The base twists preserve $\pi^n B$ because g fixes K. Full faithfulness makes all group and linearization equations hold: both sides have the same reduction at every level. Thus the actual algebraic pair has

its full G-action and full residual I-identities. Theorem 1.55.5 descends that pair and that existing polarization without another orbit tensor, giving (23) and (24).

Two such realizations become algebraizations of the same polarized tower over B. Polarized full faithfulness gives the unique comparison there and ensures its G-equivariance. The uniqueness and functoriality in Theorem 1.55.5 descend it. Necessity follows by reducing an equivariant O-realization to l, where inertia has trivial coefficient action. The ramified affine theorem has been used only over valuation rings after algebraization, never over the nonreduced rings B_n. □

Meromorphic pairings and line-bundle frames

Let K be complete and non-Archimedean with its specified absolute value; trivial valuation and generalized affinoid radii are allowed. Let X be good, Hausdorff, and pure of analytic dimension $n \geq 1$. Fix an ordinary open $U \subseteq \mathrm{Int}(X/K)$ on which all ordinary local rings are S_1. All identities below are on U. This also handles a single compact test on X: choose such a neighbourhood of its support and restrict the data there. No S_1 claim outside that neighbourhood is needed. Ordinary open subspaces retain purity by NAG-002413; NAG-001630 and NAG-001704 show that every point of U, and of its ordinary open subspaces, is interior over K. Compact supports in these subspaces are therefore genuine analytic-interior supports.

Use the ordinary moment sheaf NAG-002424, the native integral NAG-002425, and the interleaved positive generator $d't_1 \wedge d''t_1 \wedge \cdots \wedge d't_n \wedge d''t_n$ of NAG-002388. There is no additional factor of 2, 2π, or a change from $+\log|f|$. We use the following exact inputs.

R-SPL (supplied hypothesis) For a regular analytic a on an ordinary neighbourhood of the compact support of an ordinary $(n-1, n-1)$-test η,

$$L_a(d'd''\eta) = \int_{V(a)} \eta, \qquad L_a(\alpha) = \int_{U \setminus V(a)} \log|a|\, \alpha. \tag{I.0.24}$$

Regular means injective multiplication on the analytic G-structure sheaf. The full actual quotient $\mathcal{O}/(a)$ occurs on the right. The review retains the good Hausdorff pure S_1 category and ordinary compact interior tests.

R-ZP (supplied hypothesis) Actual zero spaces of such regular functions on pure affinoid refinements are empty or pure of dimension $n-1$, with the full quotient structure. This also applies to products and to every actual common refinement. Its proof does not require S_1, but no non-S_1 scalar PL is inferred here.

Frozen inputs. NAG-002772/002778 compare and glue Cartier coefficients and native cycle integrals in their pure-zero-space scope. NAG-002806 gives actual neighbourhood vanishing of an ordinary form with one bidegree n near the zeros of a regular analytic function. NAG-002427/002428 give ordinary smooth cutoffs and finite compact partitions.

A regular meromorphic function is a section locally represented on ordinary opens by a/b, with both a, b regular in the above G-sheaf sense. This

is the unit part of the meromorphic sheaf in the good-space scope of frozen NAG-002772: its proof supplies ordinary quotient representatives and shrinking of coherent kernels. We do not replace a regular denominator by an arbitrary nonzero element. A line bundle is a coherent $\mathcal{O}_{U_G}$-module free of rank one on ordinary open neighbourhoods, matching the established project category. A regular meromorphic section is a framewise regular meromorphic unit; its existence is data, not asserted for every line bundle.

Proposition I.0.15 (Quotient independence and full Cartier gluing; F8MG-Q)**.** *For a regular meromorphic f on U, the local native pairings $L_{a/b} = L_a - L_b$ define a unique linear pairing $L_f : \mathcal{A}^{n,n}_{U,c} \to \mathbb{R}$. It is additive under multiplication of regular meromorphic functions. The local full Cartier cycles* $\operatorname{div}(a) - \operatorname{div}(b)$ *glue to* $\operatorname{div}(f)$*, and their native pairings on compact ordinary $(n-1,n-1)$-tests glue independently of presentations. The cycle assertion uses R-ZP and the exact frozen restricted Cartier comparison; the logarithmic pairing does not need R-SPL or a new measure representation.*

For local regular quotient representatives, use the ordinary quotient charts. The logarithmic pairing argument uses actual compact top tests and supplied regular quotient factors. In that argument the compact integral and finite ordinary localization apply without an S_1 hypothesis. The Cartier comparison below retains the stated ambient and R-ZP hypotheses.

Proof. For a compact top test in one quotient neighbourhood, frozen NAG-002806 makes its closed support disjoint from the zeros of both a and b. On that support both logarithms are bounded, ordinary smooth functions, and their products with the test have well-defined native compact integrals, extended by zero where the test vanishes. If $a/b = c/d$, refine to actual common affinoid neighbourhoods. Localization at regular elements is injective, so $ad = bc$ there. The test vanishes near the zeros of all four factors, and on the remaining support $\log|a| - \log|b| = \log|c| - \log|d|$. Thus the pairings agree. This also proves logarithmic additivity for a product, after adjoining its finitely many regular factors.

For a general compact top test α, take a finite ordinary partition ρ_j subordinate to quotient neighbourhoods, summing to one near $\operatorname{Supp}\alpha$, and set $L_f(\alpha) = \sum_j (L_{a_j} - L_{b_j})(\rho_j\alpha)$. Two choices are compared by the finite product partition $\rho_j\rho'_k$. Its supports lie on actual common neighbourhoods, where the preceding equality applies. Their sums equal the original test as ordinary

sections. This proves independence and linearity; no countable partition or limiting interchange is used.

For cycles, R-ZP makes every numerator, denominator, and regular cross-product zero space empty or pure of one common dimension $n-1$ on each common affinoid. The antichain hypothesis of NAG-002772 is then satisfied: a strict containment between two component primes of that analytic dimension would contradict NAG-002374. Its scoped product additivity applied to $ad = bc$ gives equality of the divisor differences, including all generic lengths. Domain compatibility and ordinary gluing in that same theorem give the cycle; NAG-002778 supplies its native pairings with the full coherent coefficients. It does not replace these by reduced supports or count geometric points. The compact partition argument proves the asserted pairing independence. □

Theorem I.0.16 (Meromorphic scalar PL from the reviewed analytic input; F8MG-P)**.** *Under R-SPL and R-ZP in the category above, every regular meromorphic f satisfies, for every ordinary $\eta \in \mathcal{A}_{U,c}^{n-1,n-1}$,*

$$L_f(d'd''\eta) = \delta_{\mathrm{div}(f)}(\eta), \qquad \delta_D(\eta) := \int_D \eta. \tag{I.0.25}$$

This is first an equality of fixed-test pairings, before a continuity claim is made.

Apply the supplied scalar identity (I.0.24) to each regular factor on its actual compact quotient chart. The resulting differences refer to the two comparisons in Proposition I.0.15.

Proof. Use quotient neighbourhoods and a finite compact smooth partition ρ_j near $\operatorname{Supp}\eta$. Put $\eta_j = \rho_j\eta$. Each η_j has compact support in its ordinary quotient neighbourhood and in the true analytic interior. R-SPL applies separately to a_j and b_j on that neighbourhood. Subtract:

$$L_f(d'd''\eta_j) = \int_{V(a_j)} \eta_j - \int_{V(b_j)} \eta_j = \delta_{\mathrm{div}(f)}(\eta_j).$$

Here $\operatorname{Supp} d'd''\eta_j \subseteq \operatorname{Supp}\eta_j$, so the local pairing agrees with the global pairing of Proposition I.0.15. Since $\eta = \sum_j \eta_j$ as ordinary sections, differentiation gives $d'd''\eta = \sum_j d'd''\eta_j$. In particular the terms

$$d'd''(\rho_j\eta) = \rho_j d'd''\eta + d'\rho_j \wedge d''\eta - d''\rho_j \wedge d'\eta + d'd''\rho_j \wedge \eta$$

are all retained. Their sums, rather than individual terms, use $\sum \rho_j = 1$ near the support. Adding the finite identities proves (I.0.25). No component reduction, new annular Green assertion, or limit in a current topology enters this proof. □

Proposition I.0.17 (Frame gluing and its signs; F8MG-B)**.** *Let $\mathcal{L}$ have ordinary local frames e_i on U_i, with $e_j = u_{ij}e_i$ on overlaps, u_{ij} analytic units. A smooth metric means a norm on each one-dimensional $\mathcal{H}(x)$-fibre whose weights $h_i = -\log\|e_i\|$ are ordinary smooth scalar functions. The compatibility equation is*

$$h_j = h_i - \log|u_{ij}|. \tag{I.0.26}$$

For a regular meromorphic section $s = f_i e_i$, one has $f_j = u_{ij}^{-1} f_i$. Its full divisor D_s glues from $\operatorname{div}(f_i)$, its ordinary smooth curvature form glues as

$$c_1(\overline{\mathcal{L}})|_{U_i} = d'd''h_i,$$

and the local top-test pairings

$$G_{s,i}(\alpha) = \int_{U_i} h_i\alpha - L_{f_i}(\alpha) \tag{I.0.27}$$

glue independently of frames and compact partitions. Off the local zero and pole loci this is the potential $g_s = -\log\|s\| = h_i - \log|f_i|$.

Unit frame changes use the ordinary joint unit coordinates. Apply the ordinary zero-neighborhood vanishing to the actual top-test support on each regular quotient chart.

Proof. The metric rule $\|ae_i(x)\| = |a|\exp(-h_i(x))$ is independent of the frame precisely when (I.0.26) holds. On any smaller unit moment neighbourhood, $\log|u_{ij}|$ is the negative of one moment coordinate. Its mixed second differential is zero as an ordinary form. Thus $d'd''h_j = d'd''h_i$, and the sheaf property NAG-002424 glues the curvature; it is killed by both d' and d''. No PL theorem is needed to prove this unit identity.

The section transformation follows by comparing $f_i e_i = f_j e_j$. The divisor of a unit is zero, so Proposition I.0.15 and frozen Cartier additivity give the same full divisor on overlaps. For local top tests, logarithmic additivity gives $L_{f_j} = L_{f_i} - L_{u_{ij}}$, and $L_{u_{ij}}(\alpha) = \int \log|u_{ij}|\alpha$, since the unit has no zero. Equation (I.0.26) therefore proves equality of (I.0.27) on every admissible

local top test. In a common regular-quotient chart the actual support avoids the regular numerator and denominator zero loci, by the ordinary top-form vanishing used in the quotient pairing. The larger compact set used to choose the charts may meet those loci. Finite compact partitions and their product refinements glue it just as in Proposition I.0.15. This proves independence, rather than merely a pointwise equality off a divisor. □

We now specify the topology rather than infer continuity from the preceding fixed-test equalities. Write $\mathcal{E}^{r,s}(U) = \mathcal{A}^{r,s}_{U,c}$. A frozen cutoff presentation $i = (V, g, \Omega, \chi)$ has an actual affinoid $V \subset U$, analytic units g on V, an open $\Omega \supset t_g(V)$, and ordinary smooth compact χ with support in $\mathrm{Int}_{\mathrm{top}}(V, U)$. Its map is

$$Q_i\alpha = \mathrm{ext}_0(\chi t_g^*\alpha), \qquad t_g = -\log|g|.$$

The coefficient space $E^{r,s}(\Omega)$ has the usual seminorms $p_{L,m}(\alpha) = \max_{I,J,|a|\le m} \sup_L |\partial^a \alpha_{I,J}$ Definition NAG-002472 defines τ_{cut} by those seminorms P on $\mathcal{E}$ for which every PQ_i is continuous. Frozen NAG-002473 proves that this equals the final ordinary compatible-presentation topology τ_{ord}. We use that comparison without reproving it. The topology on interior tests is this construction on U; no unproved identification with a subspace topology on boundary-reaching tests of X is made.

Proposition I.0.18 (Order-zero coefficient representations; F8MG-O)**.** *For every cutoff presentation, each applicable pairing*

$$L_f \quad (r = s = n), \qquad G_s \quad (r = s = n), \qquad \delta_D \quad (r = s = n-1), \qquad T_\omega(\alpha) = \int \omega\wedge\alpha$$

(where ω is a fixed ordinary smooth complementary form) has a bound

$$|T(Q_i\alpha)| \le C_i p_{t_g(V),0}(\alpha), \qquad C_i < \infty. \tag{I.0.28}$$

Here D is any of the locally finite Cartier differences above. More precisely, the functional on each coefficient presentation has a finite representation

$$T(Q_i\alpha) = \sum_{\ell,I,J} \int_{\sigma_\ell} b_{\ell,IJ}(w)\alpha_{IJ}(P_\ell w)\, d\lambda_\ell(w), \qquad P_\ell(\sigma_\ell) \subseteq t_g(V), \tag{I.0.29}$$

with fixed compact polytopes, lattice-normalized real cell integrals, and fixed smooth bounded densities. They retain all actual integer cycle weights and finite-cover signs. This is a local order-zero representation on coefficient

spaces*; no native signed Radon measure on the analytic space is assumed or constructed here.*

For a globally represented quotient $f = a/b$, smooth constant truncations of the two logarithms give pairings exactly equal to L_f on the entire image of each fixed top-degree Q_i, once the truncation is sufficiently deep. The threshold depends on i. The logarithmic parts of this proposition require regular factors and the frozen logarithmic lemma, not ambient S_1 or scalar PL.

The logarithmic step for supplied regular factors uses the logarithmic pairing argument of NAG-002989. The Green pairing uses Proposition I.0.17 where applicable. The compact cells use the finite-cell functional and unit augmentation on the same affinoid, with exact finite-cover inclusion–exclusion.

Proof. First suppose $f = a/b$ on a neighbourhood of $\operatorname{Supp}\chi$. For every constant ambient basis form $e_{IJ} = d't_I \wedge d''t_J$ of bidegree (n,n), put $\beta_{IJ} = Q_i e_{IJ}$. There are finitely many of these fixed compact ordinary forms. By frozen NAG-002806, each vanishes on an ordinary neighbourhood of $V(a) \cup V(b)$. Hence

$$K_i = \bigcup_{I,J} \operatorname{Supp}\beta_{IJ}$$

is compact and disjoint from these zero loci. Every $Q_i\alpha = \sum_{I,J} \alpha_{IJ}(t_g)\beta_{IJ}$ has support in this *same* K_i, independently of the variable coefficients. This finite-basis argument is the uniform step; fixed-test integrability alone would not suffice. If there are no coefficient slots, the entire presentation is zero.

The logarithms are bounded on K_i. Choose a smooth compact cutoff θ, supported where both factors are units and equal to one near K_i, using NAG-002427/002428. The zero extension $b_0 = \operatorname{ext}_0(\theta \log|a/b|)$ is an ordinary smooth function and $L_f(Q_i\alpha) = \int b_0 Q_i \alpha$. For a meromorphic function given only locally, choose finitely many quotient neighbourhoods and a fixed smooth partition ρ_j near $\operatorname{Supp}\chi$. Apply the same argument to the finitely many fixed basis forms $\rho_j\beta_{IJ}$ on those neighbourhoods. It produces finitely many fixed smooth multipliers b_j and reduces $L_f Q_i$ to integrals of $b_j\rho_j Q_i\alpha$. These functions and their support bounds are chosen before α. In particular this argument uses no result from the unreviewed component packet.

For any fixed smooth multiplier or complementary form, cover the fixed compact support by finitely many actual ordinary affinoid neighbourhoods inside V, and take joint unit tuples representing that fixed data and g. The vari-

able coefficient appears only as $\alpha_{IJ}(Pw)$, where P is projection to the original g-coordinates. The native finite-chart integral NAG-002405/002416/002425 supplies finitely many compact cells. Restriction of the two covector factors to a lattice tangent basis contributes fixed minors. Multiplying those minors, the fixed coefficient functions, actual weights, and inclusion– exclusion signs gives the densities in (I.0.29). This proves that formula for L_f, T_ω, and therefore G_s after a finite frame partition. For δ_D, the same construction is made on the actual pure $(n-1)$-dimensional zero spaces, using R-ZP and NAG-002778. Closed-immersion pullback preserves compact support because its underlying image is closed. Its moment coordinates are the restricted g, and the full quotient weights are retained.

Every summand is bounded in absolute value by $\lambda_\ell(\sigma_\ell)\|b_{\ell,IJ}\|_\infty p_{t_g(V),0}(\alpha)$. The finite sum gives (I.0.28). These integrals also make sense for continuous coefficient functions on the compact moment image: the continuous real polytope integral is constructed in frozen NAG-002389, with a boundary-box estimate and uniform continuity. Smooth restrictions are uniformly dense in continuous functions on a compact subset of Ω: take finitely many Euclidean smooth bumps of small support, normalize their sum near the compact set, and use the value of the continuous function at one point in each small piece. Uniform continuity bounds the error. Thus (I.0.29) extends the coefficient functional uniquely in its zeroth-order norm. This is distinct from allowing arbitrary measurable multipliers in the frozen grid integral or from representing all these refinements by one analytic-space measure.

For the final assertion choose a smooth $\lambda_M : \mathbb{R} \to \mathbb{R}$ which equals t for $t \geq -M$ and is the constant $-M$ for $t \leq -M-1$; the real smooth profile in NAG-002427 supplies one. Define $\ell_M(a) = \lambda_M(\log|a|)$ on the nonzero locus and $-M$ at its zeros. It is ordinary smooth, being constant on a neighbourhood of the zeros and a smooth function of a unit moment coordinate elsewhere. Set $u_M = \ell_M(a) - \ell_M(b)$. On the common K_i the two logarithms have fixed finite lower bounds. For all sufficiently large M, $u_M = \log|a/b|$ there, so their products with every $Q_i\alpha$ are identical. The cutoff presentations span compact tests by the finite partition theorem; hence this also gives eventual equality on every individual top test. No threshold uniform over varying presentations is asserted. □

I.1 Whole fibres on the original source

Fix a complete non-Archimedean field K with its specified real-valued absolute value, possibly trivial. Affinoids may have arbitrary positive real presentation radii. Finite maps are norm-admissible finite, with their canonical finite-module topologies. All domains, analytic fibres, nilpotents and residue fields are retained.

Let Ω be a good Hausdorff K-analytic space, and let $f = (f_1, \dots, f_n)$, $n \geq 1$, be global analytic units. Write

$$\phi : \Omega \longrightarrow T = (\mathbb{G}_m^n)^{\mathrm{an}}, \qquad t = \mathrm{trop} \circ \phi = -\log |f|.$$

For a closed rectangular box $P \subset \mathbb{R}^n$, put $T_P = \mathrm{trop}^{-1}(P)$ and $\Omega_P = t^{-1}(P)$, with the latter inverse image taken in *all of the intended source* Ω. The exact polytorus is T_w, its Gauss point is η_w, and $F_w^{\Omega} = t^{-1}(w)$.

Interior on the actual charts. For an affinoid domain X of the good source Ω, the formulas used below are

$$\mathrm{Int}(\Omega/T) = \mathrm{Int}(\Omega/K), \qquad \mathrm{Int}(X/K) = X \cap \mathrm{Int}(\Omega/K) \cap \mathrm{Int}_{\mathrm{top}}(X, \Omega). \quad (1)$$

For the first formula take a Laurent affinoid neighbourhood of the target point with all bounds strict at that point, and an ordinary affinoid neighbourhood of the source point mapping into it. The target point is absolutely interior by this presentation. The source-factor inclusion and forward composition give the equivalence on these two affinoids. The ordinary local test then gives the asserted equivalence on the good spaces.

For the second formula, let $y \in X$, choose an ordinary affinoid neighbourhood W of y in Ω, and choose an affinoid neighbourhood V of y in X contained in the ordinary interior of W. Both domain presentations use the induced analytic structure, so V is an affinoid domain of W. Absolute interiority in X is equivalent to absolute interiority in V by the ordinary local test. The source-factor inclusion for $V \to W \to \mathcal{M}(K)$ then gives relative interiority in V/W. The affinoid domain criterion makes V an ordinary neighbourhood at y in W. Thus y is ordinary interior in X, and the local test on W and Ω gives absolute interiority in Ω. Conversely, if y is ordinary interior in X and absolutely interior in Ω, take one ordinary affinoid neighbourhood of y in Ω contained in X and use the local test on both spaces.

Theorem I.1.1 (A criterion for an affinoid containing the whole interior fibre)**.** *Assume $w \in t(\Omega)$, and suppose that for one closed full-dimensional box P_0, with $w \in \mathrm{int}(P_0)$, the whole domain Ω_{P_0} is compact Hausdorff. The following conditions are equivalent.*

1. *There is an affinoid domain $X \subset \Omega$ such that*
$$F_w^{\Omega} \subset \mathrm{Int}(X/K). \tag{2}$$
2. *Every point of F_w^{Ω} is in $\mathrm{Int}(\Omega/T)$, and for* every *analytic point $a \in T_w$ the underlying set of the entire analytic fibre Ω_a is finite. Empty fibres are allowed.*
3. *There is a closed full-dimensional box $P \subset \mathrm{int}(P_0)$, with $w \in \mathrm{int}(P)$, such that*
$$\phi : \Omega_P \longrightarrow T_P \quad \textit{is norm-admissible finite.} \tag{3}$$
In particular Ω_P is affinoid and $F_w^{\Omega} \subset \mathrm{Int}(\Omega_P/K)$.

The boxes in condition 3 may be made arbitrarily small about w. Restriction to any analytic point of T_P, or any exact polytorus $T_v \subset T_P$, retains the entire original-source analytic fibre with its actual algebra and canonical norm.

If Ω is boundaryless over K, the relative-interior part of condition 2 is automatic. Alternatively, if $\Omega_{P_0} \to T_{P_0}$ is analytically proper, it supplies both compactness and the required relative interiority at the central level. In either case the finite-fibre condition still quantifies over all of T_w, not only η_w. No flatness assumption is made.

Proof. Assume condition 1. The whole moment fibre in X at w is exactly F_w^{Ω}, since that entire set lies in X. The frozen theorem 5.38.4 therefore gives a finite collar in X for the original tuple f. For every $a \in T_w$, its fibre is the entire fibre in Ω; hence its underlying set is finite, by 2.35.1. Equation (1) propagates the absolute interiority from X to Ω, and identifies it with relative interiority for ϕ. This proves condition 2. The whole-fibre finite collar theorem itself is inherited rather than resubmitted.

Assume condition 2 and set $A_0 = \Omega_{P_0}$. This analytic domain is good: intersect an ordinary affinoid neighbourhood in Ω with the finitely many bounds on f_j and f_j^{-1}. The intersection is an actual affinoid domain and is an ordinary neighbourhood in A_0. Thus A_0 is a compact good Hausdorff analytic space. The map $p_0 : A_0 \to T_{P_0}$ is compact: every compact target

domain is closed in the Hausdorff target, and its inverse image is closed in the compact source.

Fix $a \in T_w$. Its fibre under p_0 is the entire Ω_a. At every point of that fibre, both $A_0 \subset \Omega$ and $T_{P_0} \subset T$ are ordinary neighbourhoods, since all box inequalities are strict at weight w. Ordinary local testing transfers the relative interiority in condition 2 to p_0. The frozen lemma 5.56.1 therefore supplies an ordinary open neighbourhood $N_a \subset T_{P_0}$ over which the *full* restriction of p_0 is finite. This includes the empty-fibre case. The union $N = \bigcup_{a \in T_w} N_a$ contains the entire exact polytorus, and $p_0^{-1}(N) \to N$ is finite by target locality. No branch or Gauss lift has been selected.

The compact set $T_{P_0} \setminus N$ has compact tropical image, and that image misses w. Choose a closed box P about w, inside $\mathrm{int}(P_0)$, avoiding that image and lying in any prescribed real neighbourhood of w. Then $T_P \subset N$. Finite base change yields the finite map

$$p_0^{-1}(T_P) = \Omega_P \longrightarrow T_P.$$

Its source is affinoid by the definition of a finite analytic morphism, and its Banach algebra has the canonical finite norm. For $y \in F_w^{\Omega}$, the target point is absolutely interior in T_P, and the finite map is relatively interior. The affinoid composition formula gives $y \in \mathrm{Int}(\Omega_P/K)$. This proves condition 3. Condition 3 immediately implies 1.

All source identifications are inverse-image domain identities, using 2.40.11. Actual finite base change and 2.33.11 give the stated analytic fibre identifications; finite tensor comparison preserves the complete algebras. In particular, neither reduction nor a selection of a local Artinian factor occurs.

If Ω is boundaryless, (1) proves the final interior assertion. For an analytically proper p_0, compactness is part of properness and every source point is relatively interior. At the central level ordinary local testing again transfers that interiority to Ω/T. This is exactly the project convention 2.53.1; topological compactness alone does not include boundarylessness. □

Theorem I.1.2 (Whole-fibre capture in a boundaryless affinoid exhaustion)**.** *Suppose that Ω is boundaryless over K and has increasing affinoid domains $U_1 \subset U_2 \subset \cdots$ whose ordinary interiors in Ω cover Ω. Let f be any tuple of global analytic units and let $w \in t(\Omega)$. If Ω_{P_0} is compact for some closed full-dimensional box P_0 with $w \in \mathrm{int}(P_0)$, then there are an index m and*

arbitrarily small closed full-dimensional boxes $P \subset \mathrm{int}(P_0)$*, with* $w \in \mathrm{int}(P)$*, such that*

$$\Omega_P \subset \mathrm{Int}_{\mathrm{top}}(U_m, \Omega), \qquad \Omega_P \longrightarrow T_P \quad \textit{is norm-admissible finite}, \qquad F_w^{\Omega} \subset \mathrm{Int}(\Omega_P/K). \tag{4}$$

The inverse images are full inverse images in Ω*. The fibre-finiteness assertion in condition 2 of Theorem I.1.1 is a consequence here, not an additional hypothesis.*

This applies, in particular, to the analytification of an affine finite-type K*-scheme, provided the whole weight-box inverse image is compact. The unit functions may be global analytic functions; no algebraicity of the tuple is required.*

Proof. The fibre F_w^{Ω} is a closed subset of the compact Ω_{P_0}. Finitely many of the interiors of the U_j cover it. Taking the largest index gives

$$F_w^{\Omega} \subset \mathrm{Int}_{\mathrm{top}}(U_m, \Omega).$$

Boundarylessness and (1) imply $F_w^{\Omega} \subset \mathrm{Int}(U_m/K)$. Theorem I.1.1 applies and gives a full finite collar in Ω. To put the collar inside the specified U_m, use the compact set

$$C = \Omega_{P_0} \setminus \mathrm{Int}_{\mathrm{top}}(U_m, \Omega).$$

Its tropical image is compact and misses w. Shrink the finite collar box to avoid $t(C)$, still keeping w in its interior. This proves every assertion of (4). In particular, the same compact argument controls escape outside U_m; no completeness over Ω is inferred merely from a collar inside U_m.

For $\Omega = (\mathrm{Spec}\, B)^{\mathrm{an}}$, choose a finite algebra presentation $B = K[X_1, \ldots, X_N]/I$. The exact radius-piece construction 2.33.23 gives affinoid domains with $|X_j| \leq R_m$, for any increasing sequence $R_m \to \infty$. Every point has all coordinates strictly below some R_m, so their ordinary interiors cover. The construction is good and Hausdorff, and 2.33.27 supplies absolute boundarylessness. The preceding argument uses only these properties and the stated compactness of the full inverse image. It places no extra restriction on the global analytic unit tuple. □

Proposition I.1.3 (A full-rank Gauss lift and a vertical projective fibre)**.** *Over any complete field K as above, put $T_{\mathrm{alg}} = \operatorname{Spec} K[T_1^{\pm 1}, T_2^{\pm 1}]$ and define the closed projective incidence surface*

$$Y = \{(T_1, T_2, [U : V]) \in T_{\mathrm{alg}} \times \mathbf{P}^1_K : (T_1 - 1)V = (T_2 - 1)U\}. \tag{5}$$

Let $\Omega = Y^{\mathrm{an}}$, and let $\phi : \Omega \to (\mathbb{G}_m^2)^{\mathrm{an}}$ be the projection, with moment tuple $f = (T_1, T_2)$ and weight $w = (0, 0)$. Then Ω is good, Hausdorff and boundaryless, ϕ is proper, and every whole weight-box inverse image is compact. The fibre over the torus Gauss point η_w consists of one point x, with unchanged completed residue field and graded moment rank two. Nevertheless no affinoid domain in Ω contains the entire F_w^{Ω}.

Moreover, there is a pure two-dimensional affinoid domain $X \subset \Omega$ containing x in its absolute interior for which

$$F_w^X \not\subset \operatorname{Int}(X/K). \tag{6}$$

It has the actual presentation, on the chart $U \neq 0$ with $z = V/U$,

$$X = \left\{ \tfrac{1}{2} \leq |T_1|, |T_2| \leq 2, \quad |z| \leq 2, \quad T_2 = 1 + (T_1 - 1)z \right\}. \tag{7}$$

Thus even a good moment chart about an interior full-rank Gauss lift in a proper boundaryless ambient source need not have an interior whole moment fibre. The restriction of the proper ambient map to this cut is compact but has relative boundary at weight w; it is not analytically proper.

Proof. On the chart $U \neq 0$, the equation eliminates T_2 and gives the affine ring

$$K[T_1, z, T_1^{-1}, (1 + (T_1 - 1)z)^{-1}]. \tag{8}$$

The chart $V \neq 0$ has the symmetric description. These charts give a finite-type separated scheme, and its projection to the torus is projective by (5). The exact analytification results 2.33.23, 2.33.29, and 2.33.27 give goodness, Hausdorffness, and boundarylessness of both the structural map and the projection. The compactness theorem 2.33.30 makes ϕ compact, hence proper. In particular the inverse image of each compact polyannulus T_P is compact. No proper-pushforward or integration result is used.

Away from $p = (1, 1)$, the inverse to the projection is explicitly

$$(T_1, T_2) \longmapsto (T_1, T_2, [T_1 - 1 : T_2 - 1]).$$

At η_w, both $|T_j - 1|$ are one, so this point is outside p, and ϕ is an analytic isomorphism on an ordinary neighbourhood of it. It follows that its entire Gauss fibre is $\{x\}$ and $\mathcal{H}(x) = \mathcal{H}(\eta_w)$. The initial forms of T_1, T_2 at the weighted Gauss point are algebraically independent over $\widetilde{K}^{\mathrm{gr}}$: a nonzero homogeneous Laurent polynomial has the prescribed Gauss norm and cannot vanish in the graded field. Thus the graded moment rank is two. In chart (8), $|z(x)| = |T_2 - 1|/|T_1 - 1| = 1$.

The fibre over p, by contrast, is the whole $E = (\mathbf{P}^1_K)^{\mathrm{an}}$, with its actual analytic structure: the incidence equation becomes zero. It is a closed analytic subspace of Ω and is contained in F^{Ω}_w. If an affinoid domain $A \subset \Omega$ contained all of F^{Ω}_w, the pullback of the closed immersion $E \hookrightarrow \Omega$ to A would identify E with a closed analytic subspace of an affinoid. Hence E would itself be affinoid. It is boundaryless over K, so 2.43.8 would make it finite over K. Its spectrum would then be a finite set. This is impossible: the weighted Gauss points in its affine line chart, indexed by all radii $\rho > 0$, are distinct because the value of the affine coordinate is ρ. This proves the failure of any affinoid container for the whole original moment fibre.

We now verify the cut, rather than presuming its boundary behaviour. The domain (7) has affinoid algebra

$$D = K\{2^{-1}T_1, 2^{-1}S_1, 2^{-1}T_2, 2^{-1}S_2, 2^{-1}z\}/(T_1S_1-1, T_2S_2-1, T_2-1-(T_1-1)z). \tag{9}$$

The domain universal property, applied in chart (8), identifies this with the actual indicated analytic domain, including its Banach structure. Equivalently, it is the generalized rational domain of the bidisc $|T_1|, |z| \leq 2$ cut out by the lower bound on T_1 and the two bounds on $1 + (T_1 - 1)z$. The Gauss norm makes the bidisc integral. Its completed residue fields are completions of fields generated by at most two coordinate classes, so 3.22.3 bounds their residual dimensions by two. The weighted Gauss field attains two by 3.22.4; 3.22.7 therefore gives analytic dimension two. The frozen domain-purity theorem 5.35.3 therefore makes the nonempty X pure of dimension two.

All inequalities in (7) are strict at x. The chart is ordinary open in Ω, so X contains an ordinary neighbourhood of x. Since Ω is boundaryless, (1) gives $x \in \mathrm{Int}(X/K)$. For $\rho > 0$, let y_ρ be the Gauss point of radius ρ on the exceptional affine chart $T_1 = T_2 = 1$, with coordinate z. Then $y_2 \in X$, whereas $y_\rho \notin X$ for $\rho > 2$. As $\rho \downarrow 2$, these points converge to y_2. Indeed polynomial evaluations are the continuous functions $\max_j |a_j|\rho^j$; on any fixed larger closed disc, uniform polynomial approximation gives the same

continuity for all analytic functions, which determine the spectrum topology. These are actual points over the original field, also when its absolute value is trivial.

Thus $y_2 \notin \mathrm{Int}_{\mathrm{top}}(X, \Omega)$. Equation (1) gives $y_2 \notin \mathrm{Int}(X/K)$, but $t(y_2) = (0, 0)$. This proves (6). The map from X to the target polyannulus of (7) is compact. At y_2 the target bounds are strict, so the affinoid composition formula identifies relative interiority there with absolute interiority in X. Consequently that map has relative boundary and is not proper. Likewise no full collar $(t|_X)^{-1}(P) \to T_P$, with w strictly inside P, can be finite: finite-map innerness and target innerness would make y_2 absolutely interior in that domain and, by composition, in X, a contradiction. □

Meromorphic Cartier coefficients

Quotient representatives must be regular on actual ordinary charts. Use the verified effective coefficient comparison and actual-domain transport. The pairing below uses the full pure zero-space integral.

Theorem I.1.4 (Meromorphic coherent-cycle comparison; F8CA-I)**.** *Let X be good, Hausdorff, and pure of analytic dimension $n \geq 1$. Let f be regular meromorphic and admit ordinary local presentations a/b, with a, b regular and their actual zero spaces empty or pure of dimension $n-1$. Restrict comparisons to such presentations. Then the differences of the effective Cartier cycles are independent of presentation, glue on actual common domains, and have the coherent-cycle integration pairing asserted in the pure-dimensional clause of F8ST-I, on ordinary $(n-1, n-1)$-tests with compact support in* $\mathrm{Int}(X/K)$.

Proof. Two representatives can be restricted to an actual common ordinary affinoid neighbourhood, say $\mathcal{M}(A)$, where their four equations a, b, c, e are defined and regular and $a/b = c/e$. The zero spaces of these restricted equations are actual affinoid domains in the original zero spaces, by quotient/domain base change NAG-001702, 001846. Frozen domain purity NAG-002413 makes each one empty or pure of dimension $n-1$. Thus Lemma C.1.57 applies to (a, e) and (b, c), and also to any further products used for a common denominator.

Localization at regular elements is injective, so equality of the fractions gives $ae = bc$ in this actual common ring. Theorem F.1.13 now gives

$$\mathrm{div}(a) + \mathrm{div}(e) = \mathrm{div}(ae) = \mathrm{div}(bc) = \mathrm{div}(b) + \mathrm{div}(c).$$

Subtracting proves independence. The already verified effective actual-domain comparison makes these equalities agree on refinements and gives ordinary gluing. For triple overlaps use a common further affinoid refinement; the same equality is transitive there.

The effective chain identity of F8ST-I retains the actual whole Gauss algebra, all generic lengths, full residue degrees, and one lattice-index division. Subtract its two effective formulas. The independence just proved now justifies the finite localization and partition sum for a compact test, using NAG-002425 and 002428. Its restriction to each zero space is compact and inside that space's analytic interior: a closed immersion is finite and relatively

interior, and NAG-001704 composes interiors. No boundary term, logarithmic limit, or test-space convergence is introduced. □

Full facet values and finite covers

The complete non-Archimedean field K keeps its specified absolute value. Trivial valuation and generalized positive real radii are allowed. Let X be good, Hausdorff, and pure of analytic dimension $n \geq 1$, and let $\mathcal{F}$ be coherent on X_G. All forms are ordinary smooth moment forms. All coefficients integrated in this packet are smooth or continuous coefficients on finitely many compact polyhedra. No measurable extension of the frozen grid integral is used.

The frozen convention NAG-002388 has all generators anticommuting. The involution J exchanges primed and double-primed generators and fixes functions; $d'' = Jd'J$. On an integral r-plane with coordinates $y_1, \dots, y_r$, the positive generator is

$$\omega_r = d'y_1 \wedge d''y_1 \wedge \cdots \wedge d'y_r \wedge d''y_r = s_r\, d'y_1 \wedge \cdots \wedge d'y_r \wedge d''y_1 \wedge \cdots \wedge d''y_r, \qquad s_r = (-1)^{r(r-1)/2}.$$

Thus $J\omega_r = (-1)^r \omega_r$. A symmetric (p,p)-form means $J\alpha = (-1)^p \alpha$ in this convention. The different convention

Let $V = \mathcal{M}(A)$ be pure of dimension n, M a finite A-module, and g a tuple of units. Put $C = \mathcal{T}_g(M)$. Choose a finite common subdivision of its actual moment image and boundary image. For every $(n-1)$-face τ, choose a basis $v_1, \dots, v_{n-1}$ of its tangent lattice. The primitive normal $u_{\sigma/\tau}$ points *into* the incident n-cell σ. Set

$$b_C(\tau) = \sum_{\sigma \supset \tau} m_\sigma u_{\sigma/\tau} \pmod{(N_\tau)_{\mathbb{R}}}, \qquad \epsilon_n = (-1)^{n(n+1)/2}.$$

For a smooth ambient $(n-1,n)$-form $\widetilde{\beta}$, define

$$\lambda_{C,\tau,w}(\widetilde{\beta}) = \epsilon_n \widetilde{\beta}_w(v'_1, \dots, v'_{n-1}; v''_1, \dots, v''_{n-1}, b_C(\tau)''), \tag{I.1.1}$$

$$\Phi_C(\widetilde{\beta}) = \sum_\tau \int_\tau \lambda_{C,\tau,w}(\widetilde{\beta})\, d\mu_\tau(w). \tag{I.1.2}$$

Here μ_τ gives the chosen tangent basis covolume one. Alternation removes dependence on the normal lift, and the two determinant factors remove orientation dependence. NAG-002389 gives the proved identity

$$\Phi_{\mathcal{T}_g(M)}(\widetilde{\beta}) = \mathcal{I}_{M,g}(d'\widetilde{\beta}). \tag{I.1.3}$$

Every facet is included, including unbalanced interior facets and original analytic-boundary images. Nothing has yet been set equal to zero.

The weights in this formula are $m_\sigma = \dim_{H_Q}(M \otimes_A E_Q)/[\mathbb{Z}^n : Q(N_\sigma)]$ on a complete transverse Gauss fibre, in the notation of NAG-002362. Thus full module lengths, nilpotents, and full residue degrees enter once. No selected geometric lift, reduced fibre, or separable degree is substituted. Coherent modules, and finite integer linear combinations of their chains, are allowed. No real-weight analytic cycle extension is asserted.

> **R-F7.** On a good Hausdorff pure n-dimensional analytic space, for coherent $\mathcal{F}$, an ordinary $(n-1,n)$-form β with compact support in $\mathrm{Int}(X/K)$ satisfies $\int_{X,\mathcal{F}} d'\beta = 0$; the corresponding d'' statement holds in bidegree $(n, n-1)$.

Theorem I.1.5 (The full ordinary boundary functional; F8AG-T)**.** *For $\beta \in \mathcal{A}^{n-1,n}_{X,c}(X)$, the finite facet construction below gives a canonical linear functional $\mathcal{B}_{X,\mathcal{F}}(\beta)$ with*

$$\mathcal{B}_{X,\mathcal{F}}(\beta) = \int_{X,\mathcal{F}} d'\beta. \tag{I.1.4}$$

With R-F7, it factors through the actual ordinary trace map

$$r_{\partial X} : \mathcal{A}^{n-1,n}_{X,c}(X) \longrightarrow \prod_{z \in \partial_K X} \mathcal{A}^{n-1,n}_{X,z}, \qquad \beta \longmapsto (\beta_z)_z. \tag{I.1.5}$$

That is, there is a unique functional on $\operatorname{im} r_{\partial X}$ whose composite is $\mathcal{B}_{X,\mathcal{F}}$. This is a full boundary-germ functional, not an assertion that a boundary trace vanishes.

Proof. Let $S = \operatorname{Supp}\beta$. Choose finitely many ordinary affinoid neighbourhoods V_i, whose ordinary interiors cover S, such that $\beta|_{V_i} = t_{g_i}^* \widetilde{\beta}_i$. Their union Q is a compact analytic neighbourhood of S. For each nonempty index set I, put $V_I = \bigcap_{i \in I} V_i$, and use one $i \in I$ to restrict its tuple and representative to V_I. The coefficient module is the actual $M_I = \Gamma(V_I, \mathcal{F})$. Define

$$\mathcal{B}_{X,\mathcal{F}}(\beta) = \sum_{I \neq \varnothing} (-1)^{|I|+1} \Phi_{\mathcal{T}_{g_i|V_I}(M_I)}(\widetilde{\beta}_i). \tag{I.1.6}$$

Empty intersections contribute zero. Domain purity supplies the correct analytic dimension for every nonempty intersection, even if its moment image has lower dimension.

Apply (I.1.3) term by term. Exterior differentiation is well-defined on ordinary forms by NAG-002424, and $\mathrm{Supp}(d'\beta) \subset S$. The finite compact integration theorem NAG-002416 identifies the sum with $\mathcal{I}_{Q,\mathcal{F}}(d'\beta)$, and NAG-002425 identifies this with the right side of (I.1.4). Those theorems prove independence of the choice of i, all representatives, subdivisions, the presenting cover, and the compact neighbourhood. Thus the explicit facet construction has the claimed intrinsic value. A single global moment representative on an affinoid recovers (I.1.2) itself.

The kernel of (I.1.5) consists exactly of the compact sections zero on an ordinary neighbourhood of the actual analytic boundary. Such a section has compact support in $\mathrm{Int}(X/K)$. R-F7 makes its right side in (I.1.4) zero. Elementary linear factorization proves the boundary-germ assertion. This factor is defined only on the image of the trace map; it does not assign values to arbitrary incompatible germs along the boundary. □

Theorem I.1.6 (Full trace inclusion–exclusion; F8AG-C)**.** *Let Q be a finite union of affinoid domains in a good Hausdorff pure n-dimensional analytic space. Let $\mathcal{F}$ be coherent on Q_G and let β be compatible finite moment-chart data of degree $(n-1,n)$ on Q. Its facet construction defines $\mathcal{B}_{Q,\mathcal{F}}(\beta) = \mathcal{I}_{Q,\mathcal{F}}(d'\beta)$. For any finite affinoid-domain cover $V_1,\dots,V_s$ of Q,*

$$\mathcal{B}_{Q,\mathcal{F}}(\beta) = \sum_{\varnothing \neq I \subseteq \{1,\dots,s\}} (-1)^{|I|+1} \mathcal{B}_{V_I,\mathcal{F}|V_I}(\beta|V_I), \qquad V_I = \bigcap_{i\in I} V_i. \tag{I.1.7}$$

This holds with different unit tuples on different members. Every term is a full trace on its own actual domain. It does not require or imply that the individual terms vanish. It is unchanged under finite refinements and applies to the flux in Green.

Proof. All intersections are actual affinoid domains, by NAG-002411; all nonempty ones are pure of dimension n, by NAG-002413. The coefficient on an intersection is the single actual restriction of $\mathcal{F}$, equivalently $M_i \otimes_{\mathcal{O}(V_i)} \mathcal{O}(V_I)$ in a finite-module presentation. It is not an independently chosen multiplicity.

For a cover on which β has one representative per member, apply frozen finite inclusion–exclusion NAG-002416 to $d'\beta$, then (I.1.3) on each intersection. This is (I.1.7). On V_I, the two unit tuples from any two chosen members are both defined and can be adjoined. Their joint pullbacks represent the same ordinary form; their derivatives have equal tangential top restrictions

by NAG-002422/002424. Global chain coordinate augmentation NAG-002405 gives the same integral. No unit is extended outside its actual domain.

For two arbitrary finite covers (V_i) and (W_j), refine on $V_I \cap W_J$. The same frozen formula gives the finite double sum with coefficient $(-1)^{|I|+|J|}$. Its forms, derivatives, and coherent modules are restrictions of the same data on every actual intersection. Interchanging these finite sums recovers either cover. This also permits a nonpresenting member to be replaced by its finite presenting cover, proving the formula as stated. Triple overlaps are handled by the same actual restrictions; no unmatched jets are identified across unrelated closed pieces.

If one tuple and representative are defined on all of an affinoid Q, NAG-002401 gives equality of the weighted top chains on one common real subdivision. Applying the linear normal expression (I.1.1) gives facetwise cancellation there. With different tuples, the invariant assertion is (I.1.7); joint-coordinate comparisons are made on actual overlaps. Intersecting unrelated moment images is not a substitute for intersecting the source domains. □

Fixed-stage logarithmic truncation

Write U for a good Hausdorff analytic space over a complete non-Archimedean field, with arbitrary valuation. For an application with interior tests, take U to be an ordinary open subset of the true analytic interior of the ambient space. Put $E = \mathcal{A}_c^{p,q}(U)$, with the frozen ordinary moment sheaf and actual ordinary compact supports. The two final topologies of NAG-002472 are equal by NAG-002473; denote their common value by τ_a. A cutoff generator has the form

$$Q_i : E^{p,q}(\Omega_i) \longrightarrow E, \qquad Q_i\eta = \operatorname{ext}_0(\chi_i t_{f_i}^* \eta), \qquad t_{f_i} = -\log|f_i|.$$

Here V_i is affinoid, f_i is a unit tuple, Ω_i contains $t_{f_i}(V_i)$, and $\operatorname{supp}\chi_i$ is compact in $\operatorname{Int}_{\mathrm{top}}(V_i, U)$. The coefficient space has all compact C^∞ seminorms. A seminorm on E is τ_a-continuous exactly when all its composites with Q_i are continuous. The images of the Q_i span E.

Assume now that U is pure of dimension $n \geq 1$ and $\mathcal{F}$ is a coherent analytic module. Let $g, h \in \mathcal{O}_U(U)$ be non-zero-divisors in every local ring, set $Z = V(g) \cup V(h)$, and assume the exact condition (R_{n-1}) of NAG-002479: for each $z \in Z$ there is an ordinary neighbourhood W_z, a good Hausdorff

analytic space Y_z of local dimension at most $n-1$, a closed immersion into W_z whose image contains z, and an analytic retraction onto Y_z. The image need not contain the rest of $Z \cap W_z$. This is a stated hypothesis, not an existence assertion for arbitrary singular divisors.

Put $u = \log|g/h|$ off Z. Use the smooth truncation of the frozen NAG-002480: choose $0 \le \rho \le 1$ smooth, zero on $(-\infty, 0]$ and one on $[1, \infty)$, and define

$$\lambda_M(t) = -M + (t+M)\rho(t+M+1).$$

Extend $\lambda_M(\log|a|)$ by the constant $-M$ at zeros of a; write the result as $\ell_M(a)$. Set $u_M = \ell_M(g) - \ell_M(h)$ and

$$T(\alpha) = \int_{U\setminus Z,\mathcal{F}} u\alpha, \quad T_M(\alpha) = \int_{U,\mathcal{F}} u_M\alpha, \quad D_M = T_M - T.$$

Here $E = \mathcal{A}_c^{n,n}(U)$, and the integral is the frozen native continuous coefficient integral. No arbitrary measurable multiplier is assigned a grid integral.

Theorem I.1.7 (Strong truncation in the frozen retraction scope)**.** *Under the preceding exact hypotheses, T_M and T are continuous for τ_a, and $T_M = T$ on each τ_a-bounded test set for all sufficiently large real M.*

More quantitatively, every cutoff presentation admits constants $C_i, H_{i,g}, H_{i,h} \ge 0$, with $H_i = \max(H_{i,g}, H_{i,h})$, such that

$$|D_M Q_i\eta| \le A_i(M)p_i(\eta), \qquad A_i(M) \le C_i\big((H_{i,g}-M)_+ + (H_{i,h}-M)_+\big), \tag{I.1.8}$$

where $p_i(\eta) = \max_{I,J} \sup_{t_{f_i}(V_i)} |\eta_{I,J}|$. For each $a > 0$, the weights

$$w_i = 1 + C_i(H_{i,g} + H_{i,h})e^{aH_i}$$

define a continuous gauge P_a by (8.15.6) and give

$$\sup_{\alpha\in B} |(T_M - T)(\alpha)| \le e^{-aM} \sup_{\alpha\in B} P_a(\alpha) \tag{I.1.9}$$

on every τ_a-bounded set B. All coherent-cycle weights, lattice volumes, cutoff coefficients, pullback minors and finite inclusion–exclusion terms enter C_i.

Proof. The frozen NAG-002480 supplies T, its continuity, and a compact $K_i \subset U \setminus Z$ containing the supports of all $Q_i\eta$. It also supplies eventual equality on the whole presentation, uniformly in its unrestricted coefficients. Multiplication by the fixed smooth u_M and the finite native cell formula give

continuity of $T_M Q_i$; hence T_M is continuous by finality. Theorem 8.15.12 already proves uniform eventual equality on bounded sets.

For the explicit constants, choose a fixed smooth cutoff equal to one near K_i and supported where g, h are units. Use finitely many actual joint moment charts there, adjoining f_i, g, h and representations of this cutoff and χ_i. The native finite cell formula has the form

$$D_M Q_i \eta = \sum_{\sigma,I,J} \epsilon_\sigma m_\sigma \int_\sigma b_{\sigma,I,J}(w)\eta_{I,J}(P_\sigma w)\big(\delta_M(l_{g,\sigma}(w)) - \delta_M(l_{h,\sigma}(w))\big)\, d\lambda_\sigma, \tag{I.1.10}$$

where $\delta_M(t) = \lambda_M(t) - t$, the cells are fixed and compact, $\epsilon_\sigma \in \{1, -1\}$ are the finite cover signs, m_σ are the actual integer coherent-cycle multiplicities, λ_σ is lattice-normalized volume, and the smooth fixed coefficients b include the covector pullback minors. The maps P_σ are the coefficient-coordinate projections, with images in $t_{f_i}(V_i)$, and $l_{g,\sigma}, l_{h,\sigma}$ are the finite affine logarithms of the adjoined unit coordinates. The formula uses only the frozen native integration leaves NAG-002389, NAG-002405, NAG-002416 and NAG-002425, on the fixed zero-avoiding support.

Writing $s = t + M$ shows directly that

$$0 \le \delta_M(t) \le (-t - M)_+.$$

Indeed it vanishes for $s \ge 0$, and for $s < 0$ it is $(-s)(1 - \rho(s+1))$. Define

$$A_i(M) = \sum_{\sigma,I,J} |m_\sigma| \int_\sigma |b_{\sigma,I,J}|\big((-l_{g,\sigma} - M)_+ + (-l_{h,\sigma} - M)_+\big) d\lambda_\sigma,$$

$$C_i = \sum_{\sigma,I,J} |m_\sigma| \int_\sigma |b_{\sigma,I,J}| d\lambda_\sigma, \qquad H_{i,a} = \max_{\sigma, w\in\sigma} (-l_{a,\sigma}(w))_+ \quad (a = g, h).$$

Empty sums have $C_i = H_{i,g} = H_{i,h} = 0$. Every integrand in these definitions is continuous on a compact cell. Thus these are legitimate frozen real integrals; no measure extension or cancellation of total variations is needed. Taking absolute values term by term in (I.1.10) proves (I.1.8). If $M > H_i$ the bound is zero. If $M \le H_i$, then

$$A_i(M) e^{aM} \le C_i (H_{i,g} + H_{i,h}) e^{aH_i} < w_i.$$

Proposition 8.15.13 with $\varepsilon(M) = e^{-aM}$ gives (I.1.9). The constants use actual multiplicities rather than an unweighted support or a claimed uniform comparison of charts. □

Projected fibres, sectors and Gauss lifts.

Let K be complete for its specified real-valued non-Archimedean absolute value, possibly trivial. All affinoid algebras and domains are actual generalized affinoid objects with their given Banach structures. A finite map is required to have the canonical finite-module topology. Fibre algebras retain their nilpotents. Purity refers to analytic dimension.

Proposition I.1.8 (One whole degree is not one cone weight)**.** *For every $d \geq 1$ there is an interior analytic point with a pure d-dimensional pointed fan and an entire moment-fibre algebra finite with its canonical norm for two projections injective on every top-cone lattice, for which the whole-fibre Gauss degree divided by the index on a specified cone has different values. The intrinsic cone weights do exist in this example; the two whole degrees measure projected sums, not individual cone weights.*

Proof. Take a trivially valued field K, for example $\mathbb{Q}$ with the trivial norm; it is complete. On

$$Z = \operatorname{Spec} K[t, t^{-1}, (1-t)^{-1}, z_2^{\pm 1}, \dots, z_d^{\pm 1}]$$

use $f = (t, 1-t, z_2, \dots, z_d)$. Let x have the trivial norm on $K(t, z_2, \dots, z_d)$, and let X be the affinoid domain where the coordinates of t_f lie in $[-\epsilon, \epsilon]$, with $\epsilon > 0$. These bounds are strict at x. It is a rational domain in a sufficiently large closed d-polydisc, with the inverses of t, $1-t$, and the z_j imposed by Laurent inequalities. Thus 5.35.3 gives purity of dimension d. The polydisc coordinates and these inequalities are strict at x, giving absolute interior. Its moment initials generate $K(t, z_2, \dots, z_d)$, of transcendence degree d.

The pointed fan is

$$C = (\mathbb{R}_{\geq 0}(1,0) \cup \mathbb{R}_{\geq 0}(0,1) \cup \mathbb{R}_{\geq 0}(-1,-1)) \times \mathbb{R}^{d-1}.$$

The ultrametric inequality for $t + (1-t) = 1$ allows exactly these possibilities for the first two norms. Weighted Gauss norms in t, $1-t$, or t^{-1}, together with the z_j, realize every one. This is also the graded-relation fan at x, so 5.55.8 gives this pointed germ for every sufficiently small ordinary neighbourhood. Write $\sigma_1, \sigma_2, \sigma_3$ for its maximal cones.

The entire moment fibre at zero has algebra

$$D = K\langle T, T^{-1}, U, U^{-1}, Z_2^{\pm 1}, \dots, Z_d^{\pm 1} \rangle / (T + U - 1).$$

For a trivial norm restricted series are finite sums; this is the coordinate ring of Z with its trivial Banach norm. No analytic point or component of the fibre is omitted.

For positive integers a, b set

$$Q_{a,b}(u, v, \lambda) = (au + bv, \lambda), \qquad S = T^a(1 - T)^b.$$

The three saturated cone lattices have indices $a, b, a + b$; each restriction of $Q_{a,b}$ is injective. The exact target is $R = K\langle S^{\pm 1}, Z_2^{\pm 1}, \dots, Z_d^{\pm 1}\rangle$. There is an actual algebra identification

$$D = R[T]/(T^a(1 - T)^b - S).$$

Indeed the relation makes both T and $1 - T$ invertible, with

$$T^{-1} = S^{-1}T^{a-1}(1 - T)^b, \qquad (1 - T)^{-1} = S^{-1}T^a(1 - T)^{b-1}.$$

The polynomial is monic up to a unit and has degree $a + b$. Polynomial division gives the basis $1, T, \dots, T^{a+b-1}$. The given norm and the canonical finite-module norm are both trivial, so this is also a bounded analytic identification. The entire Gauss fibre consequently has degree

$$\delta_{a,b} = a + b.$$

There are genuine full finite collars as well. Use the same monic presentation over a target polyannulus in (S, Z); it is norm-admissible finite by 2.33.18. If $|t| < 1$, then $|S| = |t|^a$; if $|1 - t| < 1$, then $|S| = |1 - t|^b$; and if $|t| > 1$, then $|S| = |t|^{a+b}$. The remaining case has both norms one. Hence for a sufficiently small target logarithmic box its entire inverse image lies in X, with strict defining bounds. The finite analytification theorem 2.33.26, followed by actual domain base change, identifies this full inverse image with the constructed finite analytic algebra. The obstruction is not a failure of norm-admissible finiteness.

On σ_1, both $Q_{1,1}$ and $Q_{1,2}$ have index one; their whole-fibre degrees are 2 and 3. Thus the proposed quotients differ. The actual generic weight of each cone is one: on σ_1 its entire fibre is the exact polytorus in (t, z), because $|t| < 1$ forces $|1 - t| = 1$. Projection to (t, z) has degree and index one, and 5.37.1 gives weight one. Use $(1 - t, z)$ on σ_2 and (t, z) on σ_3.

For a small positive target first weight s, the full projected level has two original moment weights

$$(s/a, 0, \lambda), \quad (0, s/b, \lambda),$$

with contributions a and b. At a negative first weight only σ_3 contributes, with index $a+b$. These explain the whole degree $a+b$. Thickening by $\epsilon'^h = 0$ multiplies all degrees and all cone weights by h with unchanged support; its generic nilpotent length has not disappeared. □

Throughout, K is complete for its specified real-valued non-Archimedean absolute value, possibly trivial. All affinoids, domains and completed tensors are the actual generalized analytic objects with their given Banach structures. Finite maps must carry the canonical finite-module topology. All fibre algebras keep their nilpotents.

Definition I.1.9 (Two saturated finite collars with common Gauss lifts)**.** Let $X = \mathcal{M}(A)$ be nonempty and pure of analytic dimension $d \geq 1$, let $f = (f_1, \dots, f_n) \in (A^\times)^n$, and put $t = t_f = -\log|f|$. Let M be a finite A-module. Fix $w_0 \in \mathbb{R}^n$ and distinct integral maps $Q_i : \mathbb{Z}^n \to \mathbb{Z}^d$, $i = 1, 2$. For each i, put $u_i^0 = Q_i w_0$ and choose a full-dimensional closed rectangular box P_i with u_i^0 in its interior. Assume that

$$C_i = (Q_i t)^{-1}(P_i) \subset X, \qquad \psi_i : C_i \longrightarrow \mathbb{T}_{P_i}$$

is norm-admissible finite, where ψ_i is given by the actual units $f^{q_{i1}}, \dots, f^{q_{id}}$. The equality defining C_i is for the entire inverse image in X; it is the *saturation hypothesis*.

Let η_i be the target Gauss point at u_i^0. Assume the equality of actual point sets

$$\psi_1^{-1}(\eta_1) = \psi_2^{-1}(\eta_2) = S = \{x_1, \dots, x_r\} \subset t^{-1}(w_0), \qquad 1 \leq r < \infty.$$

These are analytic Gauss lifts, not selected lifts after scalar extension. The fibre algebras may have arbitrary finite lengths and residue-field degrees. No isomorphism of the two central fibre algebras is assumed. Require $x_j \in \mathrm{Int}(X/K)$ and graded moment rank d at every x_j.

Let C_{x_j} be the pure d-dimensional pointed fan supplied by 5.55.8, and choose a common rational fan subdivision Σ of their union so that each C_{x_j} is a subfan. Assume that both Q_i are injective on the real span of every d-cone of Σ. For a top cone σ, write

$$N_\sigma = \mathbb{Z}^n \cap \mathrm{span}_{\mathbb{R}}(\sigma), \qquad e_{i,\sigma} = [\mathbb{Z}^d : Q_i N_\sigma].$$

These saturated-lattice indices are finite.

These are hypotheses for a local class, not an existence theorem for such pairs of collars at arbitrary moment points. In particular, separate finite presentations and equal numbers of Gauss lifts do not supply the displayed equality of point sets inside the same X. The functions and the coefficient module must also be the same original-field data.

Choose pairwise disjoint ordinary open sets O_j about x_j. After shrinking, choose ordinary affinoid neighbourhoods $V_j \subset O_j \cap C_1 \cap C_2$ such that

$$t(V_j) \subset w_0 + C_{x_j}, \tag{I.1.11}$$

and the pointed-image equality holds for every smaller ordinary neighbourhood of x_j. Here the collar inequalities are strict at x_j, so $C_1 \cap C_2$ is an ordinary neighbourhood of S. The stated choice follows from the full-stabilization theorem, continuity of t, and the ordinary affinoid-neighbourhood basis recorded in 5.52.3: first restrict to a real ball where the upper fan containment holds, then take a smaller ordinary affinoid neighbourhood inside its inverse image. No new pointed-support theorem is being proved.

Lemma I.1.10 (Whole projected levels in a common union of neighbourhoods)**.** *For each j, let $U_{1j}, U_{2j} \subset V_j$ be ordinary affinoid neighbourhoods of x_j. There are ordinary affinoid neighbourhoods $W_j \subset U_{1j} \cap U_{2j}$ of x_j, open real neighbourhoods $B_i \subset \operatorname{int}(P_i)$ of u_i^0, and finite unions H_i of proper integral-normal affine hyperplanes in $\mathbb{R}^d$ such that*

$$\{y \in X : Q_i t(y) = u\} \subset \bigcup_{j=1}^{r} \operatorname{Int}_{\mathrm{top}}(W_j, X) \qquad (u \in B_i \setminus H_i). \tag{I.1.12}$$

This includes every analytic point of each projected tropical level. Its intersections with the W_j form a disjoint finite affinoid cover and hence give a bounded product decomposition of its actual algebra and its finite coefficient modules.

Proof. Choose the W_j using the ordinary affinoid-neighbourhood basis, and set $G = \bigcup_j \operatorname{Int}_{\mathrm{top}}(W_j, X)$. For each i, the set $C_i \setminus G$ is compact. Its image under ψ_i is closed in the Hausdorff target and misses η_i, because the *entire* analytic fibre there is $S \subset G$. Compactness and the evaluation topology are 2.24.1. Thus

$$O_i' = \mathbb{T}_{P_i} \setminus \psi_i(C_i \setminus G)$$

is an ordinary open neighbourhood of η_i with full inverse image inside G. Apply the exact reviewed lemma C.1.43 to O_i'. It puts the entire target polytorus $\mathbb{T}_u$ inside O_i' for $u \in B_i \setminus H_i$. Saturation of C_i then gives (I.1.12).

The level is an actual affinoid, with algebra

$$B_i(u) = \mathcal{O}(C_i)\widehat{\otimes}_{\mathcal{O}(\mathbb{T}_{P_i})} R_i(u),$$

where $R_i(u) = \mathcal{O}(\mathbb{T}_u)$. It is a canonical finite $R_i(u)$-module by 2.33.19. Intersections with the W_j are actual affinoid domains by 2.36.9 and 2.36.10. They cover by (I.1.12) and are disjoint because $W_j \subset O_j$. Apply 2.38.1 to this finite cover. All pairwise intersections have zero algebra, so its norm-strict degree-zero equalizer is a bounded isomorphism from $B_i(u)$ to the product of the restriction algebras. For a finite module the same theorem gives the corresponding module product. The characteristic idempotents are actual elements of $B_i(u)$, and each factor has the quotient finite-module topology. No reduction or selection of a maximal ideal has occurred. □

Theorem I.1.11 (Sectorwise full-fibre overlap and projection comparison)**.** *Use Definition I.1.9, the V_j, and the neighbourhoods U_{ij}, W_j of Lemma I.1.10. After shrinking the real neighbourhoods, the following hold.*

For each top cone σ there is a finite union E_σ of proper affine hyperplanes in the affine plane $w_0 + \operatorname{span}_{\mathbb{R}} \sigma$ such that, whenever $v \in w_0 + \operatorname{relint} \sigma$ is sufficiently close to w_0 and $v \notin E_\sigma$, the whole original moment fibre $F_v = t^{-1}(v)$ satisfies

$$F_v = \coprod_j F_{j,v}, \qquad F_{j,v} = F_v \cap W_j = F_v \cap U_{1j} = F_v \cap U_{2j}.$$

Every nonempty $F_{j,v}$ lies in the absolute interior of all three domains in the displayed equality. The equalities are equalities of actual analytic domains, so their full algebras are canonically the same algebra $D_{j,v}$.

For $u = Q_i v$, let $\Lambda_i(u)$ be the finite set of original moment weights on the entire projected level $\{y \in X : Q_i t(y) = u\}$. For every such regular u, restriction gives a bounded isomorphism with bounded inverse

$$B_i(u) \;\simeq\; \prod_{v' \in \Lambda_i(u)} \prod_{j=1}^{r} D_{j,v'}. \tag{I.1.13}$$

Zero factors are omitted. The corresponding idempotent $e_{i,j,v'}$ is uniquely determined by the actual labelled domain $F_{j,v'}$, not by a numerical match of

lengths. All original moment weights and all Gauss-lift neighbourhoods are included.

Let $H_i(v)$ be the Gauss field of $R_i(Q_i v)$ and put

$$E_{i,j}(v) = D_{j,v} \widehat{\otimes}_{R_i(Q_i v)} H_i(v), \qquad L_{i,j}(v) = M \otimes_A E_{i,j}(v).$$

Then $D_{j,v}$ is norm-admissible finite over both indicated target algebras, and

$$\frac{\dim_{H_1(v)} L_{1,j}(v)}{e_{1,\sigma}} = \frac{\dim_{H_2(v)} L_{2,j}(v)}{e_{2,\sigma}} = m_{M|W_j,f}(v) \in \mathbb{Z}_{\geq 0}. \tag{I.1.14}$$

The same value is obtained using U_{1j} or U_{2j}. An empty factor has value zero.

For either projection the numerator retains the full arithmetic:

$$\dim_{H_i(v)} L_{i,j}(v) = \sum_{\mathfrak{m} \in \operatorname{Max} E_{i,j}(v)} \operatorname{length}_{E_{i,j}(v)_{\mathfrak{m}}} L_{i,j}(v)_{\mathfrak{m}} \, [\kappa(\mathfrak{m}) : H_i(v)]. \tag{I.1.15}$$

This includes all local factors, full inseparable degrees and nilpotent lengths. Generic lengths of the restricted module enter through the inherited module-weight formula.

Proof. We give the choices uniformly; there is no choice of an analytic sheet for an individual projection.

Control of all inverse weights. Since Q_i is injective on the span of each cone of the finite fan Σ, compactness of its intersection with a unit sphere gives $c_i > 0$ such that

$$\|Q_i a\| \geq c_i \|a\| \qquad (a \in |\Sigma|).$$

Use (I.1.11) for every W_j and U_{ij}. The full-stabilization theorem gives one $\rho > 0$ on which all their moment images agree with their respective $w_0 + C_{x_j}$. Shrink B_i to have $\|u - u_i^0\| < c_i \rho$. By (I.1.12), every point of a projected level is in some W_j, and its original moment weight is consequently in $w_0 + |\Sigma|$ and within distance ρ of w_0. Thus no distant inverse weight remains in that projected level.

Let J_i contain, for every cone τ of Σ of dimension less than d, an affine hyperplane containing $u_i^0 + Q_i \tau$. These hyperplanes are proper. Replace H_i by $H_i \cup J_i$. For $u \in B_i \setminus H_i$, every inverse weight belongs to the relative interior of a top cone. There is at most one inverse weight on each top cone, by injectivity there. Hence $\Lambda_i(u)$ is finite. For a fixed σ, pull back

both exceptional sets along $Q_i : w_0 + \operatorname{span}\sigma \to \mathbb{R}^d$. This map is an affine isomorphism, so the pullbacks are proper hyperplanes. They give E_σ.

Common whole factors. Take v as in the statement. Saturation implies that the entire F_v belongs to both C_i. The retention lemma puts it inside the union of the ordinary interiors of the W_j. Because $U_{ij} \subset O_j$ and the O_j are disjoint, intersecting with U_{ij} gives exactly $F_v \cap W_j$. These are actual domain identities, not identifications of reduced spectra. The domain universal property and 2.36.9 identify their actual algebras and their restrictions of M.

For the entire projected level at u, first split its finite set of moment values $\Lambda_i(u)$, then intersect with the W_j. Each exact moment fibre is an affinoid domain obtained by imposing all the equal-radius conditions for the f_k. The intersections are affinoid by the actual domain theorems. This is a finite disjoint affinoid cover of the entire projected level. For any $v' \in \Lambda_i(u)$, retention from this one projection already proves equality of its factors in W_j, U_{1j} and U_{2j}. The flat-germ argument below therefore compares both projections on that factor, even if $Q_k v'$ lies in the exceptional set for the other projection k. Apply 2.38.1, exactly as in Lemma I.1.10. It gives (I.1.13) including the module product and the bounded inverse. The characteristic idempotents are unique because the restriction isomorphism fixes every factor. Since $B_i(u)$ is a canonical finite $R_i(u)$-module, its idempotent factors have the canonical finite $R_i(u)$-module topology. The finite-module comparisons are 1.18.3 and 1.18.7.

Interior and the two normalized degrees. All points of the projected level have target weights strictly inside P_i. They are absolute interior in C_i: the target polyannulus bounds are strict, the finite map is relatively interior by 2.33.18, and interior composes by 2.33.21. By the source-factor inclusion and ordinary local testing they are absolute interior in X. Each point labelled by j lies in the ordinary interiors of W_j, U_{1j} and U_{2j}. The domain interior theorem 2.44.3 and composition then make them absolute interior in these domains as well.

Every nonempty W_j and U_{ij} is pure of dimension d by 5.35.3. At v in the relative interior of σ, their local moment images are either empty or contained in the affine plane $v + (N_\sigma)_{\mathbb{R}}$, by the chosen fan subdivision and the uniform stabilization radius. Apply 5.40.2 to each nonempty whole fibre in W_j and to its restrictions from the two U_{ij}. All of these computations use the same $D_{j,v}$

and the same module, so that theorem gives (I.1.14). We have not compared two sums with their original-weight labels erased.

Lengths and field normalization. The algebra $E_{i,j}(v)$ is finite dimensional over $H_i(v)$ and hence Artinian. Decompose it into its local factors and use a composition series of the finite module in each factor. Every simple quotient is its residue field; taking dimensions proves (I.1.15). For $A_j = \mathcal{O}(W_j)$ and $M_j = M \otimes_A A_j$, the generic version is exactly the inherited formula

$$m_{M_j,f}(v) = \sum_{\mathfrak{p} \in \operatorname{Min} A_j} \operatorname{length}_{(A_j)_{\mathfrak{p}}}(M_j)_{\mathfrak{p}}\, m_{A_j/\mathfrak{p},f}(v).$$

Finite tensors are already complete by 1.18.7.

If radii are normalized after a common complete isometric extension and $|a_k| = e^{-v_k}$, use $\prod_k a_k^{q_{i\ell k}}$ for the projected unit $f^{q_{i\ell}}$. The idempotents in (I.1.13) base change as actual idempotents; retain every factor into which they split. The finite Gauss-field comparison 5.36.2 and model normalization 5.36.3 preserve the total dimensions and their full length-degree formulas. This is a finite-fibre calculation, with no selected geometric lift and no assertion about scalar extension of an integral. □

Proposition I.1.12 (Point labels and sector labels are both necessary)**.** *The hypotheses of Definition I.1.9 occur in every dimension with $r = 2$, a nonflat three-cone fan, and different nilpotent lengths on the two Gauss lifts. For this example $Q_{1,1}$ and $Q_{1,2}$ have whole degrees 6 and 9, and even after separation by Gauss lift their degrees are respectively $(2, 4)$ and $(3, 6)$. After separation by original moment weight, the normalized coefficients on each cone are $(1, 2)$ for both projections.*

Moreover, on either individual lift there is no analytic idempotent on a full projected neighbourhood of the central Gauss fibre that selects the first positive sector and excludes the second on every sufficiently close positive Gauss fibre. Thus the sector idempotents need not extend across the vertex.

Proof. Use the exact reviewed example I.1.8 over trivially valued $K = \mathbb{Q}$:

$$Z = \operatorname{Spec} K[t, t^{-1}, (1-t)^{-1}, z_2^{\pm 1}, \dots, z_d^{\pm 1}], \qquad f = (t, 1-t, z_2, \dots, z_d).$$

Take its bounded moment-box affinoid Y about zero and form the disjoint union of the two actual finite thickenings

$$X = Y \coprod \mathcal{M}\big(\mathcal{O}(Y)[\epsilon]/(\epsilon^2)\big).$$

Use the same moment functions on both components and $M = A$. The two points x_1, x_2 are the trivial generic norms on the two reductions; their thicknesses are $h_1 = 1, h_2 = 2$. The reviewed example proves the pure dimension, interior, full pointed fan and norm-admissible saturated finite collars. Finite products and these canonical thickenings preserve them. The fan on each component is

$$\big(\mathbb{R}_{\geq 0}(1,0) \cup \mathbb{R}_{\geq 0}(0,1) \cup \mathbb{R}_{\geq 0}(-1,-1)\big) \times \mathbb{R}^{d-1}.$$

For $Q_{a,b}(u, v, \lambda) = (au + bv, \lambda)$, $a, b > 0$, the whole finite algebra in the reviewed example has degree $a + b$. Its central analytic Gauss algebra on the jth component is

$$K(t, z_2, \ldots, z_d)[\epsilon]/(\epsilon^{h_j}) \quad \text{over} \quad K(t^a(1-t)^b, z_2, \ldots, z_d).$$

For $h_j = 1$ this means the field itself. These fields have their trivial complete norms; the full degree is $a + b$. Each algebra is local, so the central analytic Gauss fibre consists of precisely x_j. Thus both projections have the same full two-point set S, although their central algebras have different dimensions.

The cone indices are $a, b, a + b$. At a small positive first projected weight s, the two original moment weights are

$$(s/a, 0, \lambda), \qquad (0, s/b, \lambda).$$

Their Gauss dimensions on component j are $h_j a$ and $h_j b$, by the reviewed cone-weight calculation and finite thickening. At a negative projected weight only the third cone contributes, with dimension $h_j(a + b)$. Consequently the full degrees are $(h_1 + h_2)(a + b)$, giving 6 and 9, and the point-labelled degrees are as stated. Dividing each *sector* factor by its own index gives h_j, hence $(1, 2)$ for both projections. Dividing a mixed point-labelled degree by the first cone index still gives 2 versus 3 on the first component. Matching the two point labels by an arbitrary permutation would likewise compare 1 with 2. The same points and the same original weights, rather than counts or degree multisets, fix the correct matching.

Finally fix a component j and one $Q_{a,b}$. Its central analytic Gauss fibre is the singleton x_j. Suppose an analytic idempotent on the full inverse image of an ordinary target neighbourhood of the central Gauss point made the proposed separation for all small $s > 0$. Its value at x_j is 0 or 1, and continuity makes it constant on an ordinary neighbourhood of x_j. Shrink to an affinoid

target neighbourhood to use compactness. The image of the compact complement of that source neighbourhood misses the central Gauss point. The target Gauss points of weights $(s, 0, \dots, 0)$ converge to the central Gauss point, so their *entire analytic fibres* eventually lie in that one constant-idempotent locus. Both positive-sector factors are nonzero: their Gauss dimensions are $h_j a > 0$ and $h_j b > 0$. The idempotent therefore cannot be 1 on one and 0 on the other. This contradiction proves the nonextension assertion. It does not prevent the actual sector idempotents at each nonzero regular projected level. □

The ground field K is complete for its specified real-valued non-Archimedean absolute value, which may be trivial. Every finite analytic map below is required to carry the canonical finite-module norm, up to uniform equivalence. All fibres are actual analytic fibres over K, with their full algebras and nilpotents. No scalar extension is used in the construction.

Theorem I.1.13 (Simultaneous collars after one fixed finite cover)**.** *Use Definition C.1.46. Suppose that*

$$\pi : X = \mathcal{M}(B) \longrightarrow Y_\varepsilon$$

is norm-admissible finite, that X is nonempty and pure of dimension d, and that $S = \pi^{-1}(\eta)$ is nonempty. Let $f = \pi^* g$ and let M be any finite B-module.

For any two distinct positive arrays a, a'*, choose boxes satisfying (2), separately for the two arrays. Then*

$$C_a = (Q_a t_f)^{-1}(P_a), \qquad C_{a'} = (Q_{a'} t_f)^{-1}(P_{a'})$$

are saturated norm-admissible finite collars in the same X. Their entire central analytic Gauss fibres are the same finite point set $S \subset t_f^{-1}(0)$. Every $x \in S$ is absolutely interior and has graded moment rank d.

The full pointed fan at every $x \in S$ is

$$F = F_1 \times \cdots \times F_p \times \mathbb{R}^k, \tag{7}$$

where F_ℓ is (5). The same rational subdivision of $\mathbb{R}^k$ may be used for both projections. On each top cone σ the projections are injective on its span, and their saturated-lattice indices are

$$e_{a,\sigma} = [\mathbb{Z}^d : Q_a N_\sigma] = \prod_{\ell=1}^{p} \begin{cases} a_{\ell j}, & \sigma \text{ uses the puncture ray } j, \\ A_\ell, & \sigma \text{ uses the last ray.} \end{cases} \qquad N_\sigma = \mathbb{Z}^n \cap \operatorname{span}_{\mathbb{R}} \sigma. \tag{8}$$

Thus these data satisfy all hypotheses of the independently reviewed definition I.1.9 and theorem I.1.11, including its common entire Gauss set and saturation requirements. If some $m_\ell \geq 2$, F is not a d-plane.

Proof. Write $Y_a = q_a^{-1}(\mathbb{T}_{P_a})$. Lemma C.1.47 gives $Y_a \subset Y_\varepsilon$ as the full inverse image, with its actual finite algebra. Domain base change and finite base change, 2.36.9 and 2.33.19, identify

$$C_a = \pi^{-1}(Y_a), \qquad \mathcal{O}(C_a) = B \otimes_{\mathcal{O}(Y_\varepsilon)} \mathcal{O}(Y_a).$$

The tensor is already complete with its canonical finite norm. The map $C_a \to Y_a$ is finite, as is $Y_a \to \mathbb{T}_{P_a}$. Composing finite free quotient presentations proves finiteness with the canonical norm for the composite. This construction also proves the displayed saturation equality for all of X. The same argument applies to a'.

By (3), a point of C_a maps to the central target Gauss point if and only if its image under π is η. The entire fibre is therefore exactly S, independently of a. Its finiteness follows from the actual finite-dimensional algebra over $\mathcal{H}(\eta)$; all local factors are kept. The map π is everywhere relatively interior by 2.33.18. Absolute interiority of η and the composition inclusion 2.33.21 give absolute interiority of every $x \in S$.

We identify the fan before transferring it to X. The norm calculation in the preceding lemma gives global containment $t_g(Z^{\mathrm{an}}) \subset F$. Every vector of F sufficiently near 0 is realized as follows. For a puncture ray of size $s \geq 0$, use the Gauss norm in $t_\ell - c_{\ell j}$ of radius e^{-s}. For the last ray use the Gauss norm in t_ℓ of radius e^{s}. Give each z_b its prescribed Gauss radius. Take the simultaneous Gauss norm in these d independent variables. These points have precisely the stated moments. As all parameters tend to zero, every such family tends to η. Indeed at radius 1 translation by an element of K° preserves the unit Gauss norm, and polynomial Gauss evaluations are continuous in the radii. The same is true for the inverses of the puncture coordinates, hence, by uniform approximation, for the affinoid functions on a fixed surrounding domain. There are only finitely many choices of rays. Every ordinary neighbourhood of η therefore realizes every sufficiently small vector in F. The frozen full-stabilization theorem identifies its pointed fan with F.

For $x \in S$, the isometric field embedding $\mathcal{H}(\eta) \hookrightarrow \mathcal{H}(x)$ induces an injective map of graded residue fields. The graded relations of the initial forms of $f(x)$ over $\widetilde{K}^{\mathrm{gr}}$ are consequently *exactly* the relations of $g(\eta)$, not a larger

ideal. The initial forms of $t_\ell - c_{\ell 1}$ and z_b are algebraically independent, and all other initial forms are obtained from them by the displayed translations. Thus the graded moment rank is d. In 5.55.5 the fan is defined from precisely this homogeneous relation ideal. Together with 5.55.8, this proves that every C_x equals F, even when X is nonreduced.

For a top cone, its saturated tangent lattice is the direct sum of the primitive ray lattice of each block and the full $\mathbb{Z}^k$. Each primitive block vector maps to $a_{\ell j}$ or $-A_\ell$ times the corresponding target basis vector. The matrix is diagonal, with the identity on the last k directions. This proves injectivity and (8). If $m_\ell \geq 2$, the span of F_ℓ has dimension $m_\ell > 1$, while that fan has dimension one. Thus the span of F has dimension greater than d, and F is not a d-plane.

We have verified, individually, purity, actual units and module, both saturated finite collars, the same full finite Gauss set, absolute interiority, graded rank, and simultaneous genericity on every top cone. These are exactly the hypotheses of the reviewed sector comparison. □

Fix a complete non-Archimedean field K with its specified real-valued absolute value, possibly trivial. All affinoids are generalized affinoids, with arbitrary positive real presentation radii. Finite maps are norm-admissible finite: their given Banach structures are equivalent to the canonical finite-module structures. All domains, fibres and modules below have their actual analytic structures; nilpotents are retained. Write $t_g = -\log|g|$ for a tuple of analytic units. For a closed rectangular box $P \subset \mathbb{R}^m$, $\mathbb{T}_P$ is the entire inverse image of P in the analytic m-torus. The point η_s is its weighted Gauss point at $s \in P$.

For a point x and an actual unit tuple f, write

$$r_f(x) = \operatorname{trdeg}_{\widetilde{K}^{\mathrm{gr}}} \widetilde{K}^{\mathrm{gr}}\big(\widetilde{f_1(x)}, \dots, \widetilde{f_n(x)}\big).$$

The full pointed fan C_x is the one supplied by 5.55.8. It is pure of dimension $r_f(x)$.

Lemma I.1.14 (Interior Gauss recognition under a finite fan projection)**.** *Let Z be a generalized affinoid, let $x \in \operatorname{Int}(Z/K)$, and let f be an actual unit tuple with $t_f(x) = w$. Suppose that C_x is contained in the support of a finite pure d-dimensional rational fan $\Sigma \subset \mathbb{R}^n$, where $d \geq 1$. Let $Q : \mathbb{Z}^n \to \mathbb{Z}^d$ be*

integral and injective on the real span of every top cone of Σ*. For the actual monomial tuple* $g = f^Q$*,*

$$g(x) = \eta_{Qw} \quad \Longleftrightarrow \quad r_f(x) = d. \tag{7}$$

This is an equality criterion for analytic points of the target torus. It does not identify the different projected fibre algebras with one another.

Proof. First, for any d-tuple g, the target point $g(x)$ is the weighted Gauss point at $t_g(x)$ if and only if its d initial forms are algebraically independent over $\widetilde{K}^{\mathrm{gr}}$. Here is the original-field argument. For a Laurent polynomial $\sum_\nu a_\nu T^\nu$, put

$$R = \max_\nu |a_\nu| \prod_j |g_j(x)|^{\nu_j}.$$

The terms attaining R define a nonzero homogeneous polynomial of degree R in the graded variables. Independent initial forms make its value nonzero; consequently the evaluated polynomial has norm exactly R. These equalities identify the seminorm with the weighted Gauss seminorm. Conversely, lift the finitely many homogeneous coefficients of a proposed graded relation to K. A nonzero homogeneous component of that relation has one common weighted degree. Its lifted Laurent polynomial has that Gauss norm, whereas the relation would force a strictly smaller evaluated norm. This is impossible at a Gauss point. This argument uses neither realizability of the radii in $|K^\times|$ nor a change of the given absolute value.

The monomial initial forms of g belong to the graded field generated by those of f. Hence $r_g(x) \le r_f(x)$. The containment $C_x \subset |\Sigma|$ and the full pointed-fan theorem give $r_f(x) = \dim C_x \le d$. If $g(x)$ is Gauss, the preceding criterion gives $r_g(x) = d$, and therefore $r_f(x) = d$.

Now suppose $r_f(x) = d$. Choose a d-cone τ of the pointed fan. Its intersections with the finitely many cones of Σ cover it. At least one such intersection has dimension d: a finite union of proper linear subspaces cannot contain the relative interior of a d-cone. Thus some d-dimensional subcone $\tau' \subset \tau$ lies in a top cone of Σ. The map Q is injective on its span, so $Q\tau'$ has dimension d.

For every sufficiently small ordinary neighbourhood W of x, pointed stabilization supplies all sufficiently small vectors of $w + \tau'$ in $t_f(W)$. Their images occur in $t_g(W) = Qt_f(W)$. Applying full pointed stabilization also to g, and choosing W small enough for both tuples, shows that its pointed image fan contains a d-dimensional conical germ. Its dimension is $r_g(x)$; hence

$r_g(x) \geq d$. There are only d generators, so $r_g(x) = d$. The Gauss criterion proved in the first paragraph completes the proof. This uses a dimension lower bound from the actual neighbourhood images, not a claim that arbitrary projection commutes with an uncontrolled image germ. □

Proposition I.1.15 (A nonflat pointed germ with no finite saturated box)**.** *Let $K = \mathbb{Q}$ with its trivial absolute value, $d \geq 1$, and use one puncture block $0, 1$, with $k = d-1$. Fix $\varepsilon > 0$ and $0 < r < 1$, and define the affinoid domain*

$$X_r = Y_\varepsilon \cap \{|t-2| \geq r\}, \qquad f = (t, t-1, z_1, \ldots, z_{d-1}).$$

Let $x = \eta$. Then X_r is pure of dimension d, $x \in \mathrm{Int}(X_r/K)$, and the pointed moment fan at x is the nonflat three-ray fan times $\mathbb{R}^{d-1}$, with graded rank d.

For every $a, b > 0$, the map

$$\psi_{a,b} = (t^a(t-1)^b, z_1, \ldots, z_{d-1})$$

is finite at x in the ordinary-neighbourhood sense. Its full fibre over the target unit Gauss point is $\{x\}$. Nevertheless, for no *full-dimensional closed rectangular box P with $0 \in \mathrm{int}(P)$ is the saturated map*

$$(Q_{a,b}t_f)^{-1}(P) \longrightarrow \mathbb{T}_P \tag{11}$$

norm-admissible finite. This failure already occurs separately for $Q_{1,1}$ and $Q_{1,2}$; hence the same fan, common analytic Gauss set, interior moment point, and ordinary local finiteness do not imply the two finite-collar hypotheses.

Proof. The lower bound on $t-2$ is a Laurent-domain condition. Domain purity gives the asserted dimension. At x its inequality is strict, since $|t-2|(x) = 1 > r$; all original moment bounds are also strict. Adjoining the inverse of $t-2$ with radius $r^{-1} > 1$ to the presentation in Lemma C.1.47 witnesses absolute interiority of x. As X_r is an ordinary neighbourhood of x in Y_ε, full pointed stabilization and Theorem I.1.13 with the identity cover give the same rank and fan. The fibre assertion follows from (3), since x remains in the domain.

For completeness, ordinary local finiteness can be exhibited using only the frozen local ingredients. Choose a small box P_0 satisfying (2), and let $Y_0 = q_{a,b}^{-1}(\mathbb{T}_{P_0}) \subset Y_\varepsilon$. It is compact and finite over the full polyannulus. Inside Y_0, the open set $G = \{|t-2| > r\}$ contains its *entire* central analytic Gauss fibre $\{x\}$. The image of $Y_0 \backslash G$ is compact, hence closed in the Hausdorff

target, and misses the target Gauss point. Choose an ordinary affinoid target neighbourhood V of that point, inside the complementary open set and the ordinary interior of $\mathbb{T}_{P_0}$. The ordinary affinoid-neighbourhood basis is the one used in 5.52.3. Finite base change gives $q_{a,b}^{-1}(V) \to V$ finite, and its full inverse image lies in $G \subset X_r$. It is an ordinary neighbourhood of x. The domain-interior and composition formulae (with ordinary openness for this finite free map) identify the ordinary interior of $q_{a,b}^{-1}(V)$ in Y_0 with the inverse image of the ordinary interior of V in $\mathbb{T}_{P_0}$: compute relative interior over $\mathbb{T}_{P_0}$ using the two finite factorizations. Since V lies in the ordinary interior of that polyannulus, these are also ordinary open neighbourhoods in the ambient source and target. Restricting gives a finite map between them, as required by finiteness at x. Only this ordinary target neighbourhood, not a tropical box, has been constructed.

Suppose (11) were norm-admissible finite. Restrict its target to a sufficiently small closed box about zero. Finite base change preserves the supposed property. We may therefore assume that P satisfies (2). Set

$$Y_P = q_{a,b}^{-1}(\mathbb{T}_P), \qquad C = X_r \cap Y_P.$$

Then C is an affinoid domain of Y_P, and is the entire inverse image in (11).

For $0 < \rho < 1$, let y_ρ be the simultaneous Gauss point in the coordinates $(t-2, z_1, \dots, z_{d-1})$, of radii $(\rho, 1, \dots, 1)$. The trivial ground norm gives

$$|t(y_\rho)| = |t(y_\rho) - 1| = |z_b(y_\rho)| = 1, \qquad |t(y_\rho) - 2| = \rho.$$

Every y_ρ lies in Y_P and has original and projected weight zero. The map $\rho \mapsto y_\rho$ is continuous: polynomial Gauss norms are continuous maxima, the puncture inverses have norm 1, and uniform approximation in an ambient affinoid presentation handles every analytic function. But $y_\rho \in C$ exactly when $\rho \geq r$. Thus $y_r \in C$ is not in the ordinary interior of C inside Y_P.

The supposed norm-admissible finiteness of $C \to \mathbb{T}_P$ makes every point relatively interior, by 2.33.18. Apply the frozen composition identity (using the source-factor implication) to $C \hookrightarrow Y_P \to \mathbb{T}_P$:

$$\operatorname{Int}(C/\mathbb{T}_P) = \operatorname{Int}(C/Y_P) \cap (C \hookrightarrow Y_P)^{-1} \operatorname{Int}(Y_P/\mathbb{T}_P).$$

It forces $y_r \in \operatorname{Int}(C/Y_P)$. The domain-interior theorem 2.44.3 says this is exactly ordinary interior, contradicting the preceding path. This proves the obstruction. □

The end cycle of a finite balanced graph

Use the finite graph datum of definition C.1.22, the cylinder description of lemma C.1.23, and the interleaved convention of lattice normalization. The smooth real profile is the one used in the compact-cutoff proof. Write $N = \mathbb{Z}^r$, $E = N_{\mathbb{R}} \times \mathbb{R}$, with coordinates (y, t), projection $\pi : E \to N_{\mathbb{R}}$, and ambient lattice $N \oplus \mathbb{Z}$. A polyhedron below is closed and given by finitely many affine linear inequalities, with rational directions and arbitrary real constants. For its tangent space L_σ, its lattice is the saturated lattice $N_\sigma = L_\sigma \cap (N \oplus \mathbb{Z})$.

After a common subdivision of the polytopes Q_σ, define the weighted end chain

$$D_\infty(C) = \sum_{\sigma \text{ unbounded},\, \dim \sigma = n} m_\sigma [Q_\sigma]. \tag{2.2}$$

Coincident projected pieces are added with all their weights. Equation (2.1) fixes the vertical index at one; degrees already present in m_σ must still be retained.

Let $W \subset N_{\mathbb{R}}$ be open. Assume that the restriction of C to $\pi^{-1}W$ is a balanced local n-cycle, with the indicated integer weights, exactly as in NAG-002384. This means that every relevant codimension-one normal sum is tangent to its facet; it includes all finite lower and side faces meeting this open set.

Theorem I.1.16 (Weak end-cycle identity; F8LA-P3R)**.** *For every $\eta \in \mathcal{A}_c^{n-1,n-1}(W)$, extended by zero outside W,*

$$I_C\big((-t)d'd''\pi^*\eta\big) = I_{D_\infty(C)}(\eta). \tag{3.1}$$

The left side is absolutely convergent in the cell sense of definition C.1.22.

Choose $\rho \in C_c^\infty((0,1))$, $\rho \geq 0$, $\int \rho = 1$, and define

$$h_R(t) = -t + \int_{\mathbb{R}} (t - R - s)_+ \rho(s)\, ds. \tag{3.2}$$

Then $h_R = -t$ for $t \leq R$, $h_R = -R - \mu$ for $t \geq R + 1$, where $\mu = \int s\rho(s)\, ds$, and $h_R'' = \rho(t - R)$. For $R \geq H$,

$$I_C\big(d'd''h_R \wedge \pi^*\eta\big) = I_{D_\infty(C)}(\eta). \tag{3.3}$$

Thus these pairings stabilize exactly, on this prescribed class of tests.

Proof. For completeness, the smooth-profile construction in the proof of NAG-002427 gives $E(t) = e^{-1/t}$ for $t > 0$ and $E(t) = 0$ otherwise. One may take $\theta(t) = 1 - E(t)/(E(t) + E(1-t))$. To obtain a density with support strictly inside $(0,1)$, normalize $E(t-\frac{1}{4})E(\frac{3}{4}-t)$ by its positive continuous integral. These formulas supply the θ and ρ used here. The integral in (3.2) has a continuous, compactly supported coefficient; the established one-dimensional integral and fundamental theorem give the stated derivatives.

Put $\beta = \pi^*\eta$. Since $d'd''\beta = \pi^*(d'd''\eta)$ has bidegree (n,n), theorem C.1.24 proves absolute convergence in (3.1).

Choose $\theta \in C^\infty(\mathbb{R})$ equal to one on $(-\infty, 0]$ and zero on $[1, \infty)$, and put $w_R(t) = -t\theta(t-R)$. The forms $w_R d''\beta$ and $d'w_R \wedge \beta$ have compact support on the local cycle over W: horizontally their supports lie in the fixed compact support of η, and vertically they lie in $[a, R+1]$. Two applications of `v037:integration:balancedcurrent` give

$$0 = I_C\big(d'(w_R d''\beta)\big) = I_C(d'w_R \wedge d''\beta) + I_C(w_R d'd''\beta),$$
$$0 = I_C\big(d''(d'w_R \wedge \beta)\big) = -I_C(d'd''w_R \wedge \beta) - I_C(d'w_R \wedge d''\beta).$$

Consequently

$$I_C(w_R d'd''\beta) = I_C(d'd''w_R \wedge \beta). \tag{3.4}$$

For $R \geq H$, the left side is the left side of (3.1). The right side is supported in the cylindrical region $R \leq t \leq R+1$. On a cylinder choose an integral basis of N_{Q_σ} followed by e_t. The product lattice has covolume one. Moving the pair $d't \wedge d''t$ past the even-degree horizontal top form gives sign $+1$. Iterated real integration therefore yields

$$I_C(d'd''w_R \wedge \beta) = \left(\int_R^{R+1} w_R''(t)\,dt\right) I_{D_\infty(C)}(\eta) = I_{D_\infty(C)}(\eta),$$

because $w_R'(R) = -1$ and $w_R'(R+1) = 0$. This proves (3.1). Replacing w_R'' by $h_R'' = \rho(t-R)$, whose integral is also one, proves (3.3). □

The ordinary tube and its absolute-boundary image

The ordinary image-tube scope also applies over each actual Gauss residue field used below. The dimension calculation uses the valued-field tower formula and the equality of completed residue fields in the actual boundary cover.

Lemma I.1.17 (Uniform tube and boundary defect; F8RC-T)**.** *Let $V = \mathcal{M}(A)$ be affinoid, $f \in A$, and let the nonempty actual zero scheme $D = \mathcal{M}(A/(f))$ have dimension at most d. For any unit tuple g, put $P_0 = t_g(D)$. There are $\rho > 0$ and a finite integral affine polyhedral set $\Delta \subset P_0$, with $\dim \Delta \leq d-1$, such that*

$$t_g(\{|f| < \rho\}) \subset P_0, \tag{I.1.16}$$

$$t_g(\partial_K V \cap \{|f| < \rho\}) \subset \Delta. \tag{I.1.17}$$

Here $\Delta = \varnothing$ if $d = 0$. If D is empty, a sufficiently small tube is empty. The same assertions hold over any specified complete base field and with arbitrary radii.

Proof. By NAG-002358, P_0 is a compact finite integral affine polyhedral set of dimension at most d. The inverse image of each compact cell is an actual affinoid Laurent domain: integral affine inequalities become bounds on monomials in the units g_i, with positive real radii. Their finite union $W_0 = t_g^{-1}(P_0)$ is an analytic domain, obtained by gluing its affinoid pieces along their actual intersections. It contains the closed subspace D. Lemma H.0.3 gives an ordinary neighbourhood O of D contained in W_0. On the compact complement $V \setminus O$, $|f|$ has a positive minimum, if the complement is nonempty. This proves (I.1.16) for a sufficiently small positive ρ.

Use NAG-002356 to write the entire absolute boundary as a finite union of actual compact analytic fibres V_j over fields H_j, where $d(H_j/K) = 1$ and the maps $V_j \to V$ preserve completed residue fields. Let D_j be the actual zero scheme of $f|_{V_j}$. Its points are exactly $D \cap V_j$. For such a point z, the tower formula and the maximum dimension bound give

$$d_{H_j}(z) = d_K(z) - 1 \leq d - 1.$$

Consequently $\dim_{H_j} D_j \leq d-1$, by NAG-001591. If $d = 0$, no such point exists. Each nonempty D_j has a finite polyhedral image $\Delta_j = t_g(D_j)$ of dimension at most $d-1$, by NAG-002358 over H_j.

Apply the first paragraph over H_j, with V_j, D_j, to get $t_g(V_j \cap \{|f| < \rho_j\}) \subset \Delta_j$. If D_j is empty, compactness gives a positive minimum of $|f|$ on V_j, so its small tube is empty. Shrink ρ to work for all finitely many j, and take $\Delta = \bigcup_j \Delta_j$. The maps preserve the absolute values of the original units, so this is a subset of P_0. It gives (I.1.17) for the actual absolute boundary, not merely for a polyhedral boundary of a chosen chart. □

Example I.1.18 (A higher-dimensional local application)**.** Let A be a generalized K-affinoid algebra and let

$$X = \mathcal{M}\big(A\{r_1^{-1}T_1, \dots, r_m^{-1}T_m\}\big), \qquad r_j > 0,$$

be good and pure of analytic dimension n, and assume that each coordinate hyperplane $Y_j = \{T_j = 0\}$ used below has analytic dimension at most $n - 1$. Evaluation at $T_j = 0$ and the inclusion of series independent of T_j are bounded algebra maps whose composition is the identity. The actual quotient by (T_j) is the corresponding algebra in the other variables, by its power-series coefficients and `fnd:generalizedaffinoidquotients`. The induced spectral maps give the closed immersion $Y_j \hookrightarrow X$ and retraction $X \to Y_j$. For an analytic unit u and integers a_j, choose

$$g = u \prod_{a_j>0} T_j^{a_j}, \qquad h = \prod_{a_j<0} T_j^{-a_j}.$$

Assume these chosen g, h satisfy the local non-zero-divisor hypotheses of Theorem G.0.15. Their zero and pole set is contained in the union of the coordinate hyperplanes. At every point of that set, choose one coordinate hyperplane containing it. Its coordinate retraction supplies (R_{n-1}). Thus the theorem gives the logarithmic current and the uniform stationarity on each top-degree presentation. The original absolute value and arbitrary positive radii are retained.

Fix a complete field K with its specified real-valued non-Archimedean absolute value. Trivial valuation and generalized affinoid radii are allowed. Spaces in this supplement are good and Hausdorff. Coherent modules live on the analytic G-site. A line bundle means a coherent module which is free of rank one on ordinary open neighbourhoods. The symbol q^* on coherent modules denotes ordinary tensor pullback; it is not a derived functor.

Proposition I.1.19 (Coherent tensor projection)**.** *Let $q : Y \to X$ be norm-admissible and finite. For $\mathcal{F} \in \mathrm{Coh}(Y_G)$ and $\mathcal{E} \in \mathrm{Coh}(X_G)$ there is a canonical isomorphism*

$$q_*(\mathcal{F} \otimes_{\mathcal{O}_Y} q^*\mathcal{E}) \simeq q_*\mathcal{F} \otimes_{\mathcal{O}_X} \mathcal{E}. \tag{I.1.18}$$

It commutes with affinoid-domain restriction and analytic base change. Neither $\mathcal{F}$ nor $\mathcal{E}$ is required to be locally free. If X, Y are pure of the same analytic dimension d and $\alpha \in \mathcal{A}^{d,d}_{X,c}(X)$ is an ordinary smooth moment form, then

$$\int_{Y/K,\,\mathcal{F}\otimes q^*\mathcal{E}} q^*\alpha = \int_{X/K,\,q_*\mathcal{F}\otimes\mathcal{E}} \alpha. \tag{I.1.19}$$

Both integrals use the fixed ground field K.

Proof. On $V = \mathcal{M}(A)$ and its full inverse image $\mathcal{M}(B)$, let M and N represent $\mathcal{E}$ and $\mathcal{F}$. The map

$$N \otimes_B (B \otimes_A M) \longrightarrow N \otimes_A M, \qquad n \otimes (b \otimes m) \longmapsto bn \otimes m$$

has inverse $n \otimes m \mapsto n \otimes (1 \otimes m)$. These are maps of finite A-modules, so they are bounded, with bounded inverses, for the canonical norms. The finite-tensor theorem identifies the modules with the analytic completed constructions.

For a bounded affinoid base change $A \to C$, put $D = B \otimes_A C$. The same formulas identify both base changes with $N \otimes_A M \otimes_A C$. In particular they respect domain restrictions. The finite coherent direct-image theorem and affinoid coherent equivalence therefore glue them to (I.1.18). This argument concerns an isomorphism of tensors, and asserts no exactness for tensoring with an arbitrary $\mathcal{E}$. Finally apply the fixed-field finite projection theorem to the coherent module $\mathcal{F} \otimes q^*\mathcal{E}$. It supplies compact support of $q^*\alpha$ and the integral equality with coefficient $q_*(\mathcal{F} \otimes q^*\mathcal{E})$. Substitute (I.1.18). □

Fix a complete field K with its specified real-valued non-Archimedean absolute value. Trivial valuation and arbitrary positive affinoid radii are allowed. All analytic spaces below are good and Hausdorff. A finite morphism is norm-admissible finite: full affinoid inverse images have finite algebras with their canonical finite-module topology. No algebra is replaced by its reduction. Line bundles are coherent modules with frames on ordinary open neighbourhoods.

Let $q : Y \to X$ be finite, and assume that $E = q_*\mathcal{O}_Y$ is locally free of constant rank $n \geq 1$ on ordinary opens. Fix an analytic line bundle $\mathcal{M}$ on X with a continuous metric. The working class upstairs consists of the *specified* pullback $\mathcal{L} = q^*\mathcal{M}$ with its pulled-back metric. For a frame e of $\mathcal{M}$, put $\phi_e = -\log\|e\|$. Call the metric ordinary moment-smooth when these weights belong to $\mathcal{A}_X^{0,0}$ in the frozen ordinary smooth moment sheaf. This condition is independent of the frame: $\phi_{ue} = \phi_e - \log|u|$, and the logarithm of an analytic unit is a smooth moment function.

The reviewed determinant projection isomorphism is

$$\iota_q : \mathrm{Nm}_q(q^*\mathcal{M}) := \det(q_*q^*\mathcal{M}) \otimes \det(E)^\vee \xrightarrow{\sim} \mathcal{M}^{\otimes n}. \tag{I.1.20}$$

Transport the tensor-power metric through ι_q. This defines what this note calls the *projection-compatible norm metric* on this class. It is specified by the downstairs metrized line and its pullback presentation. No construction for an arbitrary metrized line upstairs is presumed.

For a section s of $q^*\mathcal{M}$ on a full inverse image $q^{-1}U$, the map $a \mapsto as$ from $E|_U$ to $(q_*q^*\mathcal{M})|_U$ gives a determinant section $\mathrm{Nm}_q(s)$. If e is a frame on U and $s = b\,q^*e$, its coefficient under (I.1.20) is

$$\iota_q(\mathrm{Nm}_q(s)) = N(b)e^{\otimes n}, \qquad N(b) = \det(m_b : E|_U \to E|_U). \tag{I.1.21}$$

The useful link is between the vanishing order of this coefficient and the ordinary local intersection lengths of s.

Theorem I.1.20 (Compatibility on the pulled-back metric class)**.** *Use the finite locally free analytic map and the metrized line $\mathcal{M}$ of Section 1.*

1. *The projection-compatible metric on $\mathrm{Nm}_q(q^*\mathcal{M})$ is continuous. If the metric on $\mathcal{M}$ is ordinary moment-smooth, so is this metric. In the norm frame corresponding to $e^{\otimes n}$, its weight is exactly $n\phi_e$.*

2. *For $s = b\,q^{*}e$, the determinant section satisfies (I.1.21). Wherever $N(b)$ is an analytic unit,*

$$-\log\|\operatorname{Nm}_q(s)\| = -\log|N(b)| + n\phi_e. \tag{I.1.22}$$

In the smooth case this is an ordinary smooth moment function on that locus. The line, section, metric and this formula commute with analytic base change between good Hausdorff spaces, with the full finite inverse image and its actual norm retained.

3. *Fix $x \in U$ such that the ordinary local ring $A = \mathcal{O}_{X,x}$ is a DVR. Write $k = \kappa(x)$ for its ordinary residue field. Suppose the coefficient germ $b_y \in \mathcal{O}_{Y,y}$ is a non-zero-divisor for every $y \in q^{-1}(x)$. Then the local Cartier multiplicity of the determinant section is*

$$\operatorname{ord}_x \operatorname{Nm}_q(s) = \sum_{y \in q^{-1}(x)} [\kappa(y) : \kappa(x)]\, \operatorname{length}_{\mathcal{O}_{Y,y}}(\mathcal{O}_{Y,y}/b_y\mathcal{O}_{Y,y}). \tag{I.1.23}$$

The field degrees here are those of the ordinary local residue fields, not a count of analytic points or embeddings. The lengths include every nilpotent layer. This local multiplicity is independent of the chosen metric and frame.

The section s need not be the pullback of a downstairs section. The DVR and non-zero-divisor hypotheses in part (3) are additional; they are not assertions about all analytic points or arbitrary base changes.

Proof. The isomorphism (I.0.11) sends the norm of the pulled-back frame to $e^{\otimes n}$. The tensor-power metric therefore gives weight $n\phi_e$. If $e' = ue$ for an analytic unit u, then

$$\phi_{e'} = \phi_e - \log|u|, \qquad (e')^{\otimes n} = u^n e^{\otimes n}.$$

These are exactly the metric transition rules. They prove the construction glues and is continuous. Scalar multiplication preserves the ordinary smooth moment sheaf, so it also preserves the asserted regularity. A new frame of the norm line multiplies this frame by an analytic unit v; subtracting $\log|v|$ keeps the weight smooth. This verifies regularity for every frame, not just the displayed one.

Locally trivialize E. The map $a \mapsto as$ is then the matrix m_b tensored with e, so exterior multiplication gives (I.1.21). Under $e' = ue$, the coefficient becomes $b' = (q^{*}u)^{-1}b$. Multiplication by $q^{*}u$ on E is uI_n; hence

$N(b') = u^{-n}N(b)$. The displayed determinant section and (I.1.22) are therefore independent of e. For example, the two changes in the right side are $+n\log|u|$ and $-n\log|u|$, which cancel. Where $N(b)$ is a unit, its negative logarithm is the one-coordinate linear moment representative $t \mapsto t$ for that unit. The frozen sheaf theorem consequently proves the last regularity claim.

Finite coherent direct image commutes with analytic base change by `NAG-001752`. On an affinoid base change, the new finite algebra is the full ordinary tensor with its canonical complete finite-module norm, not its reduction. The matrix of multiplication and its determinant are the base changes of the old matrix and determinant. The reviewed projection isomorphism has the same compatibility. Pullback of metric weights is composition on points, and ordinary smooth pullback is provided by `NAG-002424`. Thus both constructions have weight n times the pulled-back ϕ_e, proving the claimed isometry and section compatibility. No claim that DVR orders are unchanged by base change is made.

For the local identity, frozen `NAG-001735` gives the actual ordinary-stalk decomposition

$$B = (q_*\mathcal{O}_Y)_x \simeq \prod_{y\in q^{-1}(x)} \mathcal{O}_{Y,y}.$$

The module B is free of rank n over A by hypothesis. Each factor is finite over A, and the decomposition includes the whole fibre. The assumptions on b_y say precisely that multiplication by b is injective on this product. Lemma C.1.95 therefore applies. The germ of $N(b)$ is its determinant, and $\operatorname{length}_A A/(N(b)) = \operatorname{ord}_A N(b)$ is the local Cartier multiplicity at the DVR. The Artinian factors in the lemma are exactly the nonzero quotients of the displayed local-ring factors. This proves (I.1.23) with the stated residue fields. Changing the frame multiplies $N(b)$ by a unit, whose order is zero. The metric enters only the regular term $n\phi_e$ in (I.1.22), not the determinant or any quotient ring. □

Fix a complete field K with its specified real-valued non-Archimedean absolute value. In the new propositions the value may be trivial. All finite algebras and maps retain their canonical finite-module topology, their full fibres, and their nilpotents. A finite analytic map means a norm-admissible finite map. Analytic spaces are good and Hausdorff. All analytic integrals are taken over this *same* K.

For an ordinary locally framed analytic line bundle and a metric h, write

$$\phi_{e,h} = -\log \|e\|_h, \qquad h' = e^{-u}h \quad \Longleftrightarrow \quad \|v\|_{h'} = e^{-u}\|v\|_h.$$

Thus $\phi_{e,h'} - \phi_{e,h} = u$. We use $v(a) = -\log|a|$, without a factor 2, 2π, $[L : K]^{-1}$, or a rescaling of $|\,|$. For an ordinary moment-smooth metric, put $\Theta_h = d'd''\phi_{e,h}$. This form is independent of the frame: if $e' = ae$, then $\phi_{e',h} = \phi_{e,h} - \log|a|$; the unit a can be adjoined as a moment coordinate, on which $-\log|a|$ is affine and has $d'd''$ equal to zero. The frozen germ sheaf makes restriction, wedge product, and pullback compatible with this calculation.

For bounded variation in positive dimension we use a compact space X pure of dimension d, ordinary moment-smooth metrics $h_1, \dots, h_d$, and

$$\theta = \Theta_{h_1} \wedge \cdots \wedge \Theta_{h_d}.$$

When an estimate or a uniform extension is asserted, we explicitly assume that θ is positive in the frozen top-form sense. We do not identify this hypothesis with a model-theoretic nef condition. The initial variation metric h_0 may be any continuous metric; the ratio u must be smooth or belong to the uniform closure specified below. No assertion that every model metric satisfies these conditions is made.

For a finite projection $q : Y \to X$ we additionally require $E = q_*\mathcal{O}_Y$ to be locally free of constant rank $n \geq 1$ on ordinary opens when a determinant norm or a scalar degree formula is used. This is the precise finite locally free hypothesis here. It is not inferred from a proper-finite collar. Both spaces have the same pure dimension in the analytic integral statements. The metrics upstairs are the specified pullbacks of the downstairs metrics.

Proposition I.1.21 (Coherent bounded projection)**.** *Let $q : Y \to X$ be finite between good Hausdorff spaces pure of the same dimension d, with X compact. Let $\mathcal{G}$ be coherent on Y_G, let $u \in \mathcal{A}_X^{0,0}(X)$, and let $\theta \in \mathcal{A}_X^{d,d}(X)$. Put*

$$V_{X,\mathcal{F}}(u;\theta) = \int_{X,\mathcal{F}} u\theta.$$

Then Y is compact and

$$V_{Y,\mathcal{G}}(q^*u; q^*\theta) = V_{X,q_*\mathcal{G}}(u;\theta). \tag{I.1.24}$$

If $q_*\mathcal{G}$ is locally free of constant rank ρ on the analytic G-site, this is $\rho V_{X,\mathcal{O}_X}(u;\theta)$.

If θ is positive, then, for every coherent $\mathcal{F}$,

$$|V_{X,\mathcal{F}}(u;\theta)| \le \|u\|_\infty\, m_{X,\mathcal{F}}(\theta), \qquad m_{X,\mathcal{F}}(\theta) = \int_{X,\mathcal{F}} \theta \ge 0. \tag{I.1.25}$$

This functional extends uniquely and continuously to $u \in \mathcal{B}(X)$, retaining (I.1.25). For positive θ, pullback sends $\mathcal{B}(X)$ into $\mathcal{B}(Y)$ and (I.1.24), including the rank case, holds for these extensions.

Proof. A finite affinoid cover of compact X has full inverse images that are affinoid; their finite union is Y, so Y is compact. Multiplication and pullback in NAG-002424 give $q^*(u\theta) = q^*u\, q^*\theta$. Apply NAG-002430 to the compactly supported form $u\theta$. Its rank clause gives the second assertion.

Let $C = \|u\|_\infty$. The two forms $(C+u)\theta$ and $(C-u)\theta$ are positive. Linearity and positivity in NAG-002425 therefore give $-Cm_{X,\mathcal{F}}(\theta) \le V_{X,\mathcal{F}}(u;\theta) \le Cm_{X,\mathcal{F}}(\theta)$. Applying this inequality to differences shows that the integral values of a uniformly Cauchy smooth sequence are Cauchy. Their limits depend only on the uniform limit, by the same bound. This constructs the unique continuous extension to the specified closure, including the zero-mass case.

Pullback is continuous for the uniform norm since $\|q^*u\|_\infty \le \|u\|_\infty$. The pullback of a positive top form is positive: on a common moment presentation the coefficient on a source tangent d-plane is the corresponding target coefficient multiplied by the square of the real determinant of the induced tangent map; a rank drop gives zero. This is a pointwise superform calculation. Thus the same bounds apply to $q^*\theta$ on Y. Taking limits in the proved smooth identity gives the asserted identity for $\mathcal{B}(X)$ and its rank specialization. □

Proposition I.1.22 (Norm and bounded metric variation)**.** *Assume X is compact, $\dim X = \dim Y = d$ purely, and $q_*\mathcal{O}_Y$ is ordinary-locally free of constant rank n. Let h_0, h_0' be continuous metrics on the same line L_0, with $h_0' = e^{-u}h_0$ and $u \in \mathcal{B}(X)$. Let θ be a positive ordinary smooth top form on X, in particular the positive wedge of smooth curvature forms specified in Section 1. Then*

$$(h_0')^N = e^{-nu}h_0^N$$

and

$$V_{Y,\mathcal{O}_Y}(q^*u; q^*\theta) = V_{X,\mathcal{O}_X}(nu; \theta) = nV_{X,\mathcal{O}_X}(u; \theta). \tag{I.1.26}$$

The absolute value of each expression is at most $n\|u\|_\infty m_{X,\mathcal{O}_X}(\theta)$. For smooth u, the equalities hold without the positivity hypothesis; the stated bound and uniform extension use positivity.

Proof. In a frame e of L_0, the two norm-frame weights are $n\phi_{e,h_0}$ and $n\phi_{e,h_0'}$. Their difference is nu. It is independent of e, so it gives the displayed global metric ratio. Proposition I.1.21 with $\mathcal{G} = \mathcal{O}_Y$ gives the first and third expressions in (I.1.26); linearity gives the middle one. Its bound is (I.1.25) multiplied by n. □

I.2 A common class and the two comparison objects

Let K be an algebraically closed, complete, nontrivially valued non-Archimedean field. Set $v(a) = -\log|a|$, without rescaling it. Fix $d \geq 1$ and integers $m_i \geq 1$, and put

$$X = (\mathbf{P}^1_K)^d, \qquad T = (\mathbf{G}_{m,K})^d, \qquad L_i = \mathrm{pr}_i^*\, \mathcal{O}_{\mathbf{P}^1}(m_i \infty).$$

Use the usual analytification of this explicit smooth projective variety, with its good Hausdorff structure and pure dimension d. Write $t_i = -\log|T_i|$ on T^{an}. The continuous extension

$$\bar{t} : X^{\mathrm{an}} \longrightarrow \overline{\mathbf{R}}^d, \qquad \overline{\mathbf{R}} = [-\infty, +\infty],$$

sends $T_i = 0$ to $+\infty$ and $T_i = \infty$ to $-\infty$. The lattice is $N = \mathbf{Z}^d$, dual to the character lattice $M = \mathbf{Z}^d$. Lebesgue measure dt gives N covolume one.

Choose convex functions $\phi_i \in C^\infty(\mathbf{R})$ and numbers $A_i < B_i$ with

$$\phi_i(t) = -m_i t + c_i^- \quad (t \leq A_i), \qquad \phi_i(t) = c_i^+ \quad (t \geq B_i). \tag{I.2.1}$$

In the frame $e_{i,0} = 1$ on the finite coordinate chart, give L_i the metric h_i with weight $-\log\|e_{i,0}\| = \phi_i(t_i)$. In the frame $e_{i,\infty} = T_i^{m_i} e_{i,0}$ its weight is $\phi_i(t_i) + m_i t_i$. The latter is constant near ∞; the former is constant near zero. Thus these formulas define an actual global metric. They give ordinary smooth moment functions and smooth functions on algebraic tropical charts in the primary theory. At a boundary point, the weight is constant in that coordinate, so a very affine coordinate chart avoiding two other points of $\mathbf{P}^1$ suffices. There is no logarithm of a vanishing coordinate in that local representative.

This class is nonempty. If $\rho_i \in C_c^\infty((A_i, B_i))$ is nonnegative and has integral one, then

$$\phi_i(t) = m_i \int_t^\infty (s - t)\rho_i(s)\, ds \tag{I.2.2}$$

satisfies (I.2.1) and $\phi_i'' = m_i \rho_i$. Put

$$\theta_i = d'd''\phi_i(t_i), \qquad \theta = \theta_1 \wedge \cdots \wedge \theta_d, \qquad W(t) = \prod_{i=1}^d \phi_i''(t_i), \qquad D = \prod_{i=1}^d m_i. \tag{I.2.3}$$

The curvature expressions glue because frame changes add affine functions of logarithmic absolute values. In the primary smooth δ-metric convention, the same smooth representative has zero residual corner term. This is a comparison of the explicit local representatives, not a claim identifying the two general sheaves of forms.

We use the positive generator

$$\omega_d = d't_1 \wedge d''t_1 \wedge \cdots \wedge d't_d \wedge d''t_d, \qquad \int a\,\omega_d = \int a(t)\,dt.$$

With grouped primed and double-primed factors the coefficient changes by $(-1)^{d(d-1)/2}$. This is the convention of the frozen polyhedral integral. In particular $\theta = t^*(W\omega_d)$ on T^{an}, with no factorial in this mixed wedge.

Let $\mathcal{S}$ denote the smooth functions F on $\mathbf{R}^d$ which are eventually independent of each coordinate at both ends, uniformly in all the other coordinates. Explicitly, for each i there exist $a_i < b_i$ such that F is independent of t_i on each region $t_i < a_i$ and $t_i > b_i$. They extend continuously to $\overline{\mathbf{R}}^{,d}$. This class contains 1 and all compactly supported smooth functions. The function $u_F = F \circ \bar{t}$ is globally smooth in both stated chart conventions: near a boundary point ignore the coordinates in which F is constant, and use the remaining units. Define also the larger, explicitly limited test space

$$\mathcal{C}_{\mathrm{rad}} = \{u_F = F \circ \bar{t} : F \in C(\overline{\mathbf{R}}^{,d})\}.$$

No assertion that these are all continuous functions on X^{an} is made.

Let $S_i = \mathrm{supp}(\phi_i'')$ and $S = \prod_i S_i$. Choose a finite box $B = \prod_i [a_i', b_i']$ whose interior contains S. Then

$$Q = t^{-1}(B) = \{e^{-b_i'} \le |T_i| \le e^{-a_i'} \text{ for all } i\} \tag{I.2.4}$$

is a compact affinoid polyannulus. Its ordinary interior in X^{an} contains $\mathrm{supp}(\theta)$, and θ is zero off Q. Every fibre used below is the whole fibre in this polyannulus. In particular Q is not replaced by a set of Gauss points.

Write $I_K(u\theta) = \int_{X/K,\mathcal{O}_X} u\theta$ for the frozen compact smooth integral. The primary comparison object is the smooth Gubler–Künnemann pairing $J_{\mathrm{GK}}(u\theta)$: on a very affine chart of integration its value is the integral of the representing top form on the weighted tropicalization. In our case the single chart T already contains the support. If μ_{GK} denotes the signed Radon measure for these smooth metrics, its defining action is

$$\int u\, d\mu_{\mathrm{GK}} = J_{\mathrm{GK}}(u\theta) \quad \text{for smooth } u.$$

Lemma I.2.1 (The full torus chart has weight one)**.** *For an interior weight w of the box B in (I.2.4), the frozen structure-module weight of Q with moment coordinates $T_1, \dots, T_d$ is one. Its saturated tangent lattice is $\mathbf{Z}^d$. The primary algebraic tropicalization of T has the same lattice and coefficient one. Consequently both chart integrals of $a\omega_d$, for every $a \in C_c^\infty(\operatorname{Int} B)$, equal $\int_B a(t)\,dt$.*

Proof. Write $r_i = e^{-w_i}$. The entire weight fibre has the actual algebra

$$T_w = K\{r^{-1}Z, rZ^{-1}\} = \left\{ \sum_{\nu \in \mathbf{Z}^d} a_\nu Z^\nu : |a_\nu| r^\nu \longrightarrow 0 \right\}, \qquad \|a\|_w = \max_\nu |a_\nu| r^\nu.$$

This is the relation quotient, with its exact quotient norm, of NAG-001553; the fibre identification is NAG-002081. The Laurent bounds of Q impose no further relation at this weight. All points of the fibre satisfy the strict upper bounds for both Z_i and Z_i^{-1} in the presentation of Q, hence lie in $\operatorname{Int}(Q/K)$. The image germ is open in $\mathbf{R}^d$, whose saturated lattice is $\mathbf{Z}^d$. Use the identity lattice projection in NAG-002362. The source fibre algebra and target polytorus algebra are both T_w. If H_w is its Gauss field, multiplicativity of the Gauss norm and the actual tensor identification give

$$T_w \widehat{\otimes}_{T_w} H_w = H_w, \qquad [\mathbf{Z}^d : \mathbf{Z}^d] = 1.$$

Thus the full Gauss-module dimension divided by the lattice index is one. No reduction, radical quotient, separated quotient losing a module, or count of analytic points has entered this calculation.

For the primary torus chart the defining ideal in its own Laurent coordinate ring is zero. Its initial ideal is again zero at every weight. Over a valued extension realizing that weight, its initial scheme is a Laurent torus, with one reduced generic component and length one. Its tangent lattice is exactly $\mathbf{Z}^d$. This verifies its tropical coefficient directly, without a general multiplicity or pushforward theorem. Finally NAG-002405 computes the frozen integral with these weights, NAG-002389 gives the covolume-one real integral, and the defining primary chart integral uses the same coefficient and the same positive generator. This proves the claim. □

Theorem I.2.2 (Identity (M) on every continuous radial test)**.** *For the class in Section I.2, Identity* (M_{tor}) *holds for every* $F \in \mathcal{S}$*:*

$$I_K(u_F\theta) = J_{\mathrm{GK}}(u_F\theta) = \int_{X^{\mathrm{an}}} u_F \, d\mu_{\mathrm{GK}} = \int_{\mathbf{R}^d} F(t)W(t)\,dt. \tag{I.2.5}$$

Both restricted functionals have a unique continuous extension from $\mathcal{S}$ *to all* $F \in C(\overline{\mathbf{R}}^{,d})$ *in the uniform norm, and* (I.2.5) *holds for every such* F*, with* I_K *understood as this extension. These tests belong to the uniform closure of the ordinary smooth moment functions on* X^{an}*. The common functional is positive, vanishes if* $F|_S = 0$*, and satisfies*

$$|I_K(u_F\theta)| \le D\|F\|_\infty, \qquad I_K(\theta) = D. \tag{I.2.6}$$

Here D *is the algebraic mixed degree of* $L_1, \dots, L_d$ *on* X*, including the local intersection lengths. If* $L = L_1 \otimes \cdots \otimes L_d$ *has the product metric, then* $c_1(L)^d = d!\theta$*, so its mass and algebraic self-degree are* $d!D$*.*

Proof. The local weights and their affine frame transitions give the same curvature representative $d'd''\phi_i$ in each of the two smooth chart conventions. Multiplication and wedge product therefore represent $u_F\theta$ on T by $FW\omega_d$. This representative has support in $S \subset \operatorname{Int} B$ even when F is not compactly supported. On X^{an} the whole form has support inside the ordinary interior of Q. NAG-002425 consequently permits its frozen integral to be computed on this one affinoid neighbourhood. Lemma I.2.1 computes it as $\int FW\,dt$. In the primary definition, T is already a very affine chart of integration for the very same compact representative; the same lemma computes its defining pairing. The equality with the smooth action of μ_{GK} is its specified definition.

Since each ϕ_i'' is nonnegative and compactly supported, ordinary one-variable calculus and (I.2.1) give

$$\int_{\mathbf{R}} \phi_i''(t)\,dt = \phi_i'(+\infty) - \phi_i'(-\infty) = m_i.$$

Iterated integration gives $\int W\,dt = D$. This proves positivity, the support assertion for radial tests, and (I.2.6).

For completeness, the density required for the declared continuous tests is explicit. Identify $\overline{\mathbf{R}}$ with $[-1,1]$ by $t \mapsto \tanh t$. For any $F \in C(\overline{\mathbf{R}}^{,d})$, its restriction to $\mathbf{R}^d$ is bounded and uniformly continuous. Convolution with a compactly supported smooth approximate identity gives smooth bounded F_ϵ with $\|F_\epsilon - F\|_{\infty,\mathbf{R}^d} \to 0$. Choose a smooth clamp $c_R : \mathbf{R} \to \mathbf{R}$ equal to the

identity on $[-R,R]$ and constant on both ends outside $[-R-1,R+1]$, with $c_R(t)\ge R$ for $t\ge R$ and $c_R(t)\le -R$ for $t\le -R$. Such a clamp is obtained by integrating a smooth cutoff of the derivative from one to zero on each end. Let C_R be its coordinatewise product. The function $F_\epsilon\circ C_R$ belongs to $\mathcal{S}$. Moreover

$$\|F_\epsilon\circ C_R-F\|_\infty\le\|F_\epsilon-F\|_\infty+\|F\circ C_R-F\|_\infty.$$

The last term tends to zero as $R\to\infty$, because each of $\tanh(c_R(t))$ and $\tanh t$ lies in the same end interval of length $1-\tanh R$ whenever $|t|>R$. This estimate holds at the endpoints as well. Uniform continuity on $[-1,1]^d$ proves the assertion. Composing with $\bar t$ now gives uniform approximation on X^{an} by the specified globally smooth functions.

The bound (I.2.6) gives unique extensions of the two restricted functionals. The right real integral has the same bound, so their extensions still equal it. The action of the given finite signed primary measure is also continuous in the uniform norm, hence it has the same values on these limits. If the previously reviewed bounded extension is subsequently adopted, uniqueness identifies it with this extension on $\mathcal{C}_{\mathrm{rad}}$; no further density theorem is being assumed.

Finally choose $a_i\in K^\times$ and the effective divisor $m_i\{T_i=a_i\}$ representing L_i. These divisors meet properly at one point. Writing $z_i=T_i-a_i$, their local intersection quotient is

$$K[z_1,\dots,z_d]_{(z_1,\dots,z_d)}/(z_1^{m_1},\dots,z_d^{m_d}).$$

The equations are a regular sequence, since successively the next variable is a polynomial variable over the previous quotient. The residue monomials $z_1^{e_1}\cdots z_d^{e_d}$ with $0\le e_i<m_i$ form a K-basis. The quotient has length D and residue degree one; this computes the mixed degree in this explicit complete intersection. It retains all the nilpotent layers. Since $\theta_i\wedge\theta_i=0$ and $(1,1)$-forms commute with one another, expansion gives $(\sum_i\theta_i)^d=d!\theta$. Independently, the Hilbert polynomial of L is $\prod_i(m_ik+1)$, whose leading coefficient is D; the algebraic self-degree is $d!D$. This verifies both normalizations. □

Proposition I.2.3 (Full degree in the common class)**.** *Let $q : X' = (\mathbf{P}^1_K)^d \to X$ be given by $T_i = S_i^{n_i}$, where $n_i \geq 1$, and put $N = \prod_i n_i$. The map is finite locally free of rank N. Its analytic map, with full inverse images and their canonical finite norms, has the same rank. The pulled-back profiles are $\phi_i(n_i s_i)$, where $s_i = -\log|S_i|$; they belong to the class of Section I.2 with degrees $n_i m_i$. For every $F \in C(\overline{\mathbf{R}}^{,d})$,*

$$\begin{aligned} I_K(q^*u_F\, q^*\theta) &= \int_{X'^{\mathrm{an}}} q^*u_F \, d\mu_{\mathrm{GK},q^*h_1,\dots,q^*h_d} \\ &= N \int_{\mathbf{R}^d} F(t)W(t)\,dt. \end{aligned} \tag{I.2.7}$$

The common absolute value is at most $ND\|F\|_\infty$. Here N includes inseparable degree, without a division by it.

For a line bundle M on X^{an} with continuous metric h_0, give $\mathrm{Nm}_q(q^*M)$ the projection-compatible metric from its canonical isomorphism with $M^{\otimes N}$. If $h_0' = e^{-u_F}h_0$, the logarithmic ratio of the two norm metrics is Nu_F. Its bounded pairing against θ is precisely the value in (I.2.7). This assertion uses the specified pulled-back metric class only.

Proof. On any product of the finite and infinite standard coordinate charts, the algebraic map is a tensor product of maps $K[T_i] \to K[S_i]$, $T_i \mapsto S_i^{n_i}$ (using inverse coordinates at infinity). Division of exponents gives the free basis $\prod_i S_i^{e_i}$, $0 \leq e_i < n_i$. These charts cover the target and their whole inverse images, proving finite local freeness of rank N in every characteristic.

The same assertion is analytic, including its norm. On a closed polydisc, or on a closed polyannulus in these coordinates, expand a convergent series upstairs and group its exponent vectors modulo $(n_1, \dots, n_d)$. This gives a unique sum $\sum_{0 \leq e_i < n_i} S^e a_e(T)$ of N convergent downstairs series. Convergence follows by grouping the weighted coefficient families; shifting by one of the finitely many exponents e changes the coefficient norms by fixed positive factors only. Thus both this map and its inverse are bounded. It is the canonical finite-module topology of NAG-001701. Its spectra use the whole inverse domains; for (I.2.4) the inverse box is $\prod_i [a_i'/n_i, b_i'/n_i]$. No point or branch is dropped.

For the pulled-back metrics, direct differentiation gives

$$q^*\theta_i = n_i^2 \phi_i''(n_i s_i)\, d's_i \wedge d''s_i.$$

Their affine-tail degrees are $n_i m_i$. Theorem I.2.2 applied upstairs gives, for smooth tests first,

$$\int_{\mathbf{R}^d} F(n_1 s_1, \dots, n_d s_d) \prod_i n_i^2 \phi_i''(n_i s_i)\, ds.$$

Substitute $t_i = n_i s_i$. The ordinary Jacobian removes one factor $\prod_i n_i$ from $\prod_i n_i^2$, leaving exactly N. The continuous-test assertion follows either from the same integral or from the already proved uniform approximation and bound. If some n_i is divisible by the characteristic, this algebraic rank and real substitution are unchanged. In particular $T = S^p$ has factor p, although it is purely inseparable and has only one geometric point over each point. Nilpotents in inseparable fibres are retained by the free algebra calculation.

NAG-002539 identifies $\mathrm{Nm}_q(q^*M)$ with $M^{\otimes N}$. In a local frame the chosen metric is the tensor-power metric, so changing its downstairs weight by u_F changes the norm weight by Nu_F, exactly as in NAG-002554. Applying the bounded functional of Theorem I.2.2 gives $NI_K(u_F\theta)$, equal to (I.2.7). This uses no determinant section with a zero or pole, and does not construct a norm metric for an arbitrary upstairs metrized line. □

Let K be algebraically closed, complete and nontrivially valued, with its fixed absolute value and $v = -\log|\cdot|$. Throughout,

$$d \geq 2, \qquad X = (\mathbf{P}^1_K)^d, \qquad T = (\mathbf{G}_{m,K})^d, \qquad L_i = \mathrm{pr}_i^*\,\mathcal{O}(m_i\infty), \quad m_i \geq 1.$$

We use the usual good Hausdorff analytification, pure of dimension d. Put $t_i = -\log|T_i|$ on T^{an}, and let $\bar{t} : X^{\mathrm{an}} \to \overline{\mathbf{R}}^{,d}$ be its continuous extension, where $\overline{\mathbf{R}} = [-\infty, +\infty]$; zero maps to $+\infty$ and infinity to $-\infty$. The lattices are $N = M = \mathbf{Z}^d$ in the coordinate dual bases, and dt has covolume one.

Choose $\phi_i \in C^\infty(\mathbf{R})$ convex, with exact tails

$$\phi_i(t) = -m_i t + c_i^- \quad (t \leq A_i), \qquad \phi_i(t) = c_i^+ \quad (t \geq B_i), \qquad A_i < B_i. \tag{I.2.8}$$

The frame $e_{i,0} = 1$ of L_i has weight $\phi_i(t_i)$, and $e_{i,\infty} = T_i^{m_i} e_{i,0}$ has weight $\phi_i(t_i) + m_i t_i$. Both are constant near their respective boundary points. These define global metrics h_i in both the ordinary moment-smooth convention and the primary algebraic tropical smooth convention. Explicit examples are $\phi_i(t) = m_i \int_t^\infty (s-t)\rho_i(s)\,ds$, with $\rho_i \in C_c^\infty((A_i, B_i))$, $\rho_i \geq 0$, $\int \rho_i = 1$.

Set

$$\theta_i = d'd''\phi_i(t_i), \quad \theta = \bigwedge_{i=1}^d \theta_i, \quad W(t) = \prod_i \phi_i''(t_i), \quad D = \prod_i m_i, \quad S = \prod_i \mathrm{supp}(\phi_i''). \tag{I.2.9}$$

Use the positive generator $\omega_d = \bigwedge_i (d't_i \wedge d''t_i)$, so that $\theta = t^*(W\omega_d)$ and $\int a\omega_d = \int a(t)dt$. There is no $d!$ in this mixed wedge and no rescaling of the valuation. The curvature is zero near $X^{\mathrm{an}} \backslash T^{\mathrm{an}}$. If a finite box B contains S in its interior, then the whole compact polyannulus $Q = t^{-1}(B)$ is an ordinary neighbourhood of its support. All frozen chart weights use full fibres and actual canonical Banach algebras. For $w \in \mathbf{R}^d$, let $\rho(w)$ be the Gauss point

$$\left| \sum_{m \in \mathbf{Z}^d} a_m T^m \right|_{\rho(w)} = \max_m |a_m| e^{-\langle m, w\rangle} \quad \text{on finite Laurent polynomials.} \tag{I.2.10}$$

Write $\Gamma = \rho(\mathbf{R}^d)$. Let $\mathcal{A}$ be the real algebra of global ordinary smooth moment functions on X^{an}. Let $\mathcal{A}_{\mathrm{com}}$ be its subalgebra of functions also smooth on primary algebraic tropical charts. Write

$$L_K(u) = \int_{X/K, \mathcal{O}_X} u\theta \quad (u \in \mathcal{A}), \qquad \nu = W(t)dt, \qquad \mu_\Gamma = \rho_*\nu.$$

The last expression is an explicit positive Radon measure: W has compact support S, and $\rho|_S$ is continuous into the Hausdorff space X^{an}. Its Radon regularity also follows directly by transporting regularity from the compact set S through this homeomorphism onto its image.

For the specified primary smooth measure, take as given its defining action: on a common algebraic tropical chart, it integrates the representing smooth curvature form with its chart weights. No formal-measure comparison enters.

Theorem I.2.4 (Identity (M) on all continuous analytic tests)**.** *Under the standing hypotheses, for every $u \in \mathcal{A}$,*

$$L_K(u) = \int_{\mathbf{R}^d} u(\rho(t))W(t)\,dt, \qquad |L_K(u)| \le D \sup_{\rho(S)} |u|. \tag{I.2.11}$$

It has a unique continuous extension to all $u \in C(X^{\mathrm{an}})$ in the uniform norm. For every such test, including nonradial tests, this extension and the primary smooth Gubler–Künnemann measure satisfy

$$\overline{L}_K(u) = \int_{X^{\mathrm{an}}} u\,d\mu_{\mathrm{GK}} = \int_{X^{\mathrm{an}}} u\,d\mu_\Gamma = \int_{\mathbf{R}^d} u(\rho(t))W(t)\,dt. \tag{I.2.12}$$

The measures have support exactly $\rho(S)$ and mass $D = \prod_i m_i$, the explicit algebraic mixed degree. The product line $L_1 \otimes \cdots \otimes L_d$ has self-measure $d!\mu_\Gamma$ and self-degree $d!D$. No logarithmic test with a zero or pole is asserted to be integrable by this theorem.

Proof. First recover the needed radial calculation directly. On a whole interior fibre of the polyannulus Q, the actual Laurent algebra is $T_w = K\{e^w T, e^{-w}T^{-1}\}$, with its quotient norm (NAG-001553 and NAG-002081). For the identity projection of the saturated lattice $\mathbf{Z}^d$, its actual Gauss algebra is $T_w \widehat{\otimes}_{T_w} H_w = H_w$. Thus the full module dimension and lattice index in NAG-002362 are both one. The frozen chain integral NAG-002405, with NAG-002389's positive generator, gives

$$L_K(F \circ \bar{t}) = \int F(t)W(t)dt \qquad (F \in C_c^\infty(\mathbf{R}^d)). \tag{I.2.13}$$

The same calculation gives $L_K(1) = D$, since $\int \phi_i'' = \phi_i'(+\infty) - \phi_i'(-\infty) = m_i$. The primary torus chart has defining ideal zero, hence initial Laurent torus of generic length one, with the same saturated lattice and positive normalization. Its defining smooth pairing gives the identical formulas. There is no factorial in these mixed calculations.

Let $u \in \mathcal{A}$. The trace $u \circ \rho$ is continuous on $\mathbf{R}^d$. On a compact neighbourhood of S, convolution and a smooth compact cutoff give $F_\epsilon \in C_c^\infty(\mathbf{R}^d)$ with

$$\sup_{t \in S} |u(\rho(t)) - F_\epsilon(t)| < \epsilon.$$

For example, first multiply the trace by a cutoff equal to one near S, convolve with a sufficiently small smooth approximate identity, and multiply by a second cutoff equal to one on that neighbourhood. The function $v = u - F_\epsilon \circ \bar{t}$ is globally ordinary smooth. It satisfies $|v| < \epsilon$ on $\rho(S)$ and hence on an open neighbourhood of this compact set. By Lemma G.0.22, θ has zero germ outside $\rho(S)$. Therefore both $(\epsilon + v)\theta$ and $(\epsilon - v)\theta$ are globally positive sections: on that neighbourhood their scalar coefficients are positive, and on its complement they are zero germs. Positivity of NAG-002425 and $L_K(1) = D$ imply

$$|L_K(u) - L_K(F_\epsilon \circ \bar{t})| \le \epsilon D.$$

Using (I.2.13) and the same error bound for the real integral proves (I.2.11). This proof uses the trace only in the approximation, without pretending that $u \circ \rho \circ \bar{t}$ is itself smooth.

The ordinary smooth algebra is uniformly dense by Lemma G.0.23; the bound in (I.2.11) is at most $D\|u\|_\infty$. Thus L_K has a unique continuous extension. The explicit functional $u \mapsto \int u \, d\mu_\Gamma$ already extends it, so the first and last expressions in (I.2.12) agree for every continuous u. This constructs the full measure in the frozen class without invoking a general Riesz existence result for all smooth forms.

For a common smooth function $u \in \mathcal{A}_{\mathrm{com}}$, apply exactly the same approximation to the primary smooth pairing. The primary zero-germ statement was proved separately in Lemma G.0.22. Its smooth chart integral is nonnegative on a nonnegative smooth top form: after restriction to faces its coefficients are integrated against the nonnegative tropical multiplicities, with the fixed positive normalization. This is the chart definition, and is all the positivity required here. Its radial value and mass were computed above. Hence its value at $u\theta$ is $\int u \circ \rho \, W \, dt$. The defining smooth action of the given finite signed measure μ_{GK} has these values. The common algebra is uniformly dense, and integration against either finite signed Radon measure is continuous in that norm. Thus the equality extends to every continuous u, proving (I.2.12) and, in particular, positivity and support of μ_{GK} in this class. The nonnegative continuous density W has support exactly S: every product neighbourhood of a point of $\prod_i \operatorname{supp}(\phi_i'')$ contains a product of points where all factors are

positive. Thus its measure has support S, and the section homeomorphism gives measure support exactly $\rho(S)$.

For the degree normalization choose $a_i \in K^\times$ and the divisors $m_i\{T_i = a_i\}$. They meet at one point with regular sequence $z_1^{m_1}, \dots, z_d^{m_d}$ in the local polynomial ring, where $z_i = T_i - a_i$. The quotient basis is $\prod_i z_i^{e_i}$ with $0 \le e_i < m_i$, so its full length is D, including nilpotent layers; its residue degree is one. This computes the mixed degree. Finally $\theta_i \wedge \theta_i = 0$ and the $(1,1)$-factors commute, so $(\sum_i \theta_i)^d = d!\theta$. The Hilbert polynomial of the product line is $\prod_i (m_i k + 1)$, confirming self-degree $d!D$. □

Proposition I.2.5 (Power projection and the specified norm metric)**.** *Let $q : X' = (\mathbf{P}^1_K)^d \to X$ be $T_i = S_i^{n_i}$, with $n_i \ge 1$ and $N = \prod_i n_i$. Give q^*L_i the pulled-back metrics and denote their full mixed measure from Theorem I.2.4 by μ'. For every $u \in C(X^{\mathrm{an}})$,*

$$\int_{X'^{\mathrm{an}}} q^*u \, d\mu' = N \int_{X^{\mathrm{an}}} u \, d\mu_\Gamma, \qquad \left| \int q^*u \, d\mu' \right| \le ND\|u\|_\infty. \tag{I.2.14}$$

This is the same identity for the extended frozen integrals and the primary smooth measures. The rank N includes inseparable degree. For a continuously metrized analytic line (M, h_0) on X^{an}, use only the projection-compatible metric on $\mathrm{Nm}_q(q^*M) \simeq M^{\otimes N}$. Replacing h_0 by $e^{-u}h_0$ changes its norm-metric weight by Nu; its bounded curvature pairing is the value in (I.2.14).

Proof. On the finite and infinite coordinate charts, q is finite free with basis $\prod_i S_i^{e_i}$, $0 \le e_i < n_i$. On analytic polydiscs and polyannuli, grouping the convergent coefficient families by these exponent classes gives the same basis with bounded inverse coefficient maps. Finite shifts change the weighted norms only by fixed positive factors; thus this is the actual canonical finite topology of NAG-001701. All inverse domains are retained. This proves rank N in every characteristic, including nilpotents in inseparable fibres.

For $s_i = -\log|S_i|$, the upstairs profiles are $\phi_i(n_i s_i)$. Their mixed density and Gauss map satisfy

$$W'(s) = \prod_i n_i^2 \phi_i''(n_i s_i),$$
$$q(\rho'(s)) = \rho(n_1 s_1, \dots, n_d s_d).$$

The second equality follows by evaluating Laurent polynomials in the Gauss norm: multiplying distinct exponents by (n_i) does not identify them. Hence the full-measure formula yields

$$\int q^{*}u\, d\mu' = \int u(\rho(n_1 s_1, \dots, n_d s_d)) \prod_i n_i^2 \phi_i''(n_i s_i)\, ds.$$

The real substitution $t_i = n_i s_i$ removes one product of the n_i and leaves N. This proves (I.2.14) for every continuous u. The computation still gives p for $T = S^p$ in characteristic p; a point count or separable degree would be wrong. Finally the frozen norm isomorphism NAG-002539 and the specified metric of NAG-002554 identify the norm frame weight with N times the downstairs weight. Its change is Nu, giving the stated bounded pairing. □

Let K be complete and nontrivially discretely valued, with valuation ring R, residue field k, uniformizer π, and the fixed number $\lambda = -\log|\pi| > 0$. Let X be an integral proper K-variety of dimension $d \geq 2$. A model in this note is proper, flat, integral and normal over R, of finite type, with generic fibre identified with X. Retain explicitly the ordinary DVR local rings at all height-one points used below. Its special components have dimension d. For a special component V put

$$A_V = \mathcal{O}_{\mathcal{X},\eta_V}, \qquad b_V = \operatorname{ord}_V(\pi) > 0, \qquad |f(\xi_V)| = |\pi|^{\operatorname{ord}_V(f)/b_V} \quad (f \in K(X)^\times).$$

The valuation norm defines an analytic point by NAG-001707. Its kernel is zero, and its centre on the model is η_V. Distinct components have distinct points. No assertion that an ordinary analytic stalk at ξ_V is a DVR is made.

For lines $\mathcal{L}_i$ extending $L_i^{\otimes e_i}$, $1 \leq i \leq d$, write

$$E = \prod_{i=1}^{d} e_i, \qquad \delta_V = \deg_{\mathcal{L}_1|_V,\dots,\mathcal{L}_d|_V,k}(V), \qquad \mu_{\mathcal{X}} = \sum_V \frac{b_V \delta_V}{E} \delta_{\xi_V}. \quad \text{(I.2.15)}$$

This is the specified finite model measure, with the ordinary mixed component degree over k. All root exponents, nilpotent lengths and full residue-field degrees are retained. It can be signed. The root model metric has $\|s\| = |a|^{1/e}$ when $s^{\otimes e} = a e_{\mathcal{M}}$ in a model frame of $\mathcal{M}$. The finite measure is the object compared here; its general independence is not assumed in its definition.

A *displayed modification* is a proper morphism $p : \mathcal{Y} \to \mathcal{X}$ inducing the identity on X, together with an open $U \subseteq \mathcal{X}$ containing X and every height-one point of $\mathcal{X}$, such that $p^{-1}(U) \to U$ is an isomorphism. This open is part of the hypotheses. We do not infer it merely from the equality of generic fibres. The complement has codimension at least two. A component W of $\mathcal{Y}_k$ is called exceptional here if it does not dominate a component of $\mathcal{X}_k$.

Lemma I.2.6 (Codimension-one coefficients under a modification)**.** *Let p be a displayed modification. For each prime divisor V of $\mathcal{X}$ there is exactly one prime divisor $\widetilde{V}$ of $\mathcal{Y}$ dominating it, and their ordinary local DVRs are identified inside $K(X)$. For a Cartier divisor D with rational section presentation,*

$$p_* \operatorname{cyc}(p^* D) = \operatorname{cyc}(D). \quad \text{(I.2.16)}$$

The pushforward uses full residue-field degrees on equal-dimensional images and zero on dimension-decreasing images. In particular, for special components, $b_{\widetilde{V}} = b_V$ and $\xi_{\widetilde{V}} = \xi_V$. Every exceptional special component has image of dimension at most $d - 1$.

The codimension-one isomorphism hypothesis is checkable for a blowup of a finite-type ideal I with $I|_X = \mathcal{O}_X$: it holds wherever I is locally principal and nonzero, hence on an open containing every height-one point of the normal model. This assertion concerns the blowup itself; any additional normalization or domination needs its own compatibility check.

Proof. Over the generic point of a prime divisor V, the morphism is an isomorphism. Taking the closure of its inverse-image point gives $\widetilde{V}$ and identifies its local ring and residue field with those of V. No second divisor can dominate V, since it would also meet this isomorphic inverse image. Any other prime divisor lies over the complement of U, so its image has smaller dimension. Properness makes that image closed. The coefficient of p^*D at $\widetilde{V}$ is the coefficient of D at V, because the same rational function is measured in the same DVR. Its pushforward degree is one, and the other coefficients push forward to zero. This proves (I.2.16). Apply it locally to π and to arbitrary rational functions to obtain the assertions about b and ξ.

At a height-one point v, I_v is a nonzero finitely generated ideal in a DVR and thus is principal, say (a). After shrinking a neighbourhood, a is a section of I and every chosen finite generator of I is a multiple of a; clearing the finitely many localization denominators proves this assertion on an open. On that open, the Rees algebra is $\bigoplus_{n\geq 0}(a^n)T^n \simeq A[t]$, since a is a non-zero-divisor. Its Proj is $\operatorname{Spec} A$. The union of these opens and the generic fibre gives the required U for the blowup. □

Theorem I.2.7 (Exact component-degree criterion for model measures)**.** *Use $p : \mathcal{Y} \to \mathcal{X}$ as above and the pulled-back model lines $p^*\mathcal{L}_i$ with the same root exponents. Then the following are equivalent:*

1. *The two finite measures on the common X^{an} are equal.*
2. *Their component degrees satisfy*

$$\delta_{\widetilde{V}} = \delta_V \quad \text{for every } V, \qquad \delta_W = 0 \quad \text{for every exceptional } W. \tag{I.2.17}$$

Under this criterion all continuous tests, and all Borel tests finite on the common finite support, have equal integrals. In particular, if M has a model $\mathcal{M}$ extending $M^{\otimes e_0}$, the pullback model metric is the same metric on M. Every nonzero rational section s satisfies

$$\int -\log\|s\|\, d\mu_{\mathcal{Y}} = \int -\log\|s\|\, d\mu_{\mathcal{X}}. \tag{I.2.18}$$

The logarithm is used off its zero/pole support and may be extended arbitrarily across that null set for these atomic measures. Both are finite total-variation integrals. If $a_V = \operatorname{ord}_V(s^{\otimes e_0})$ *in a model frame, the common downstairs expression is*

$$\frac{\lambda}{e_0 E}\sum_V a_V \delta_V, \qquad -\log\|s(\xi_V)\| = \frac{\lambda a_V}{e_0 b_V}. \tag{I.2.19}$$

Replacing s *by* πs *changes it by* $+\lambda\mu_{\mathcal{X}}(X^{\mathrm{an}})$.

Proof. The strict-transform atoms and their b's agree by Lemma I.2.6. An exceptional atom cannot equal one of these: its centre on $\mathcal{X}$ is in $\mathcal{X}\setminus U$, whereas the strict-transform atom has centre $\eta_V \in U$. Distinct components of $\mathcal{Y}$ also give distinct atoms. Comparing the coefficients of each Dirac mass in (I.2.15), and using $b_W > 0$, proves precisely the equivalence with (I.2.17). This argument allows signed degrees; no cancellation between distinct atoms is possible. Equality of the finite measures proves equality for every stated test.

A frame of $\mathcal{M}$ pulls back to a frame of $p^*\mathcal{M}$ at every point reducing over that frame. The coefficient of a generic section is the same rational function, evaluated at the same analytic point. The root metric formula therefore proves equality of these metrics on all of X^{an}. The reduction maps commute with p, as follows directly by pulling back the inequalities $|f| \le 1$ and $|f| < 1$ defining a centre. Every atom has generic underlying scheme point, so a nonzero rational section is regular and nonvanishing there. The root norm gives the second formula in (I.2.19); multiplication by its mass $b_V\delta_V/E$ gives the first. This proves finiteness without any singular limiting argument. Finally a_V becomes $a_V + e_0 b_V$ for πs, giving the positive change $\lambda\sum_V b_V\delta_V/E$. □

Proposition I.2.8 (Two semipositive systems on the point blowup)**.** *The special fibre is* $V' + F$ *with both multiplicities one. Its two component DVR norms are*

$$|f(\xi_{V'})| = |f(\xi_0)|, \qquad \left|\sum_m a_m z^m\right|(\xi_F) = \max_m |a_m|\,|\pi|^{|m|},$$

where $z_i = Z_i/Z_0$ *and* ξ_0 *is the standard unit-radius Gauss point. Put* $A = H \otimes \mathcal{O}(-F)$*. Both* H *and* A *are generated by global sections and have*

semipositive model metrics. For positive integers $m_1, \dots, m_d$ and $D = \prod_i m_i$, their mixed degrees are

	V'	F
$H^{m_1}, \dots, H^{m_d}$	D	0
$A^{m_1}, \dots, A^{m_d}$	0	D

(I.2.20)

Consequently the pullbacks of the standard model lines give $\mu_H = D\delta_{\xi_0}$ on both models, verifying (I.2.17). The other semipositive system gives $\mu_A = D\delta_{\xi_F}$. Although H and A have the same generic line bundle, A is not being treated as the pullback of that standard metrized line.

Proof. Near P, the ideal is $(\pi, z_1, \dots, z_d)$. The π-chart is $R[u_1, \dots, u_d]$ with $z_i = \pi u_i$. Its exceptional generic DVR has uniformizer π and residue field $k(u_1, \dots, u_d)$. The z_j-chart has equation

$$R[z_j, u_0, (u_i)_{i\neq j}]/(\pi - z_j u_0), \qquad z_i = z_j u_i \ (i \neq j).$$

These are the usual regular charts of the blowup of the coordinate regular closed point: at a crossing over a codimension-c point of $k[(u_i)_{i\neq j}]$, the local ring has dimension $c+2$ and its maximal ideal is generated by z_j, u_0 and lifts of c regular parameters. Away from the crossing one of z_j, u_0 is a unit, giving a localization of a polynomial chart over R. Thus the total space is regular, in particular normal. The blowup is projective over the proper model. These charts also show explicitly that the special fibre consists of $z_j = 0$ and $u_0 = 0$, each with multiplicity one. The component V' is $\mathrm{Bl}_P \mathbf{P}^d_k$, while $F = \mathbf{P}^d_k$. The generic DVR of V' is unchanged from $\mathcal{X}_k$. In the π-chart, the reduction of a polynomial in the independent u_i cannot cancel its distinct monomials at the generic point. Its order is therefore $\min_m(\mathrm{ord}_R\, a_m + |m|)$, which gives the stated Gauss norm at F.

The sections $Z_0, \dots, Z_d$ generate H. The sections $\pi Z_0, Z_1, \dots, Z_d$ generate A: their ideal is the pullback of the centre ideal times H, hence becomes the invertible ideal $\mathcal{O}(-F)$ times H on the blowup. On F the line H is trivial, and the restrictions of those divided generators identify $A|_F$ with $\mathcal{O}_{\mathbf{P}^d_k}(1)$. On V' the first divided generator πZ_0 restricts to zero and the remaining d generators have no common zero. These descriptions can also be read from the two displayed charts. Global generation gives nonnegative degree on every special-fibre curve: a nonzero generating section on an integral curve has an effective zero divisor. Thus the two metrics are semipositive.

For H on V', use $Z_0 + Z_i$, $1 \le i \le d$. Each avoids P, and their common zero is the single rational point $Q = [1 : -1 : \cdots : -1] \neq P$, where p is an isomorphism. Raising the ith section to m_i gives the local algebra $k[t_1, \ldots, t_d]/(t_1^{m_1}, \ldots, t_d^{m_d})$, of length D by its monomial basis. On F, choose nonzero constant sections of the trivial restrictions of H; there is no intersection. This proves the first row of (I.2.20).

For A on $F = \mathbf{P}_k^d$, d coordinate hyperplanes meet at a rational point and the same powers give length D. On V', the remaining divided coordinate generators define the resolution of projection from P to $\mathbf{P}_k^{d-1}$. In the z_j-chart this is $[z_1 : \cdots : z_d] = [u_1 : \cdots : 1 : \cdots : u_d]$; its fibre direction is the line through P. The d coordinate hyperplanes of $\mathbf{P}^{d-1}$ have empty total intersection. Their pullbacks intersect properly through each nonempty stage (the chart fibres are one-dimensional), and the final intersection is empty. Taking powers preserves that support and gives degree zero. This proves the second row. Substituting the degrees and the two multiplicities into (I.2.15) proves all measure assertions. □

Proposition I.2.9 (Two ways that forgetting support loses information)**.** *In every dimension $d \ge 2$ the following hold.*

1. *On $\mathbf{P}_R^d$, a closed rational special-fibre point has class zero in the ordinary Chow group $CH_0(\mathbf{P}_R^d)$, but has vertical degree one. Thus a degree homomorphism on that ordinary Chow group cannot recover the required vertical intersection degree. The support must be retained.*

2. *On the blowup of Section 3, $p_*[F] = 0$ as a d-cycle, but*

$$\deg_{A|_F, \ldots, A|_F, k}(F) = 1.$$

The two semipositive model metrics h_H, h_A on the same generic $\mathcal{O}(1)$ agree outside the tube of P. On the standard unit polydisc around P their difference of weights is

$$u = \log(h_A/h_H) = -\log \max\{|\pi|, |z_1|, \ldots, |z_d|\}. \tag{I.2.21}$$

It satisfies $u(\xi_0) = 0$ and $u(\xi_F) = \lambda$. With the semipositive model measure $\mu_A = \delta_{\xi_F}$ one therefore has $\int u \, d\mu_A = \lambda > 0$. Agreement outside that tube and equality of generic line-bundle classes do not imply zero metric correction. If the supported model values of the preceding proposition are available, changing the first model line from A to $H = A(F)$, with the other d lines equal to A, changes that value by $+\lambda$.

Proof. For (1), choose the horizontal closed section $C = \{Z_1 = \cdots = Z_d = 0\} \simeq \operatorname{Spec} R$. The divisor of π on this integral one-dimensional scheme is its closed point with coefficient $\operatorname{length}_R(R/\pi R) = 1$. Its pushforward is a principal-divisor relation in $CH_0(\mathbf{P}^d_R)$, so that point has ordinary class zero. Its degree as a zero-cycle on the special fibre is $[k : k] = 1$. Rational equivalence inside the vertical support cannot use the horizontal curve C; this is exactly the information lost by forgetting support.

For (2), the image of F is the point P, so cycle pushforward in dimension d is zero. But $A|_F = \mathcal{O}_{\mathbf{P}^d_k}(1)$ by Proposition I.2.8, whose top mixed degree is one. This does not contradict projection: the factors A are not the pulled-back line H. On the unit polydisc, a generator of the pulled-back centre ideal has absolute value $\max\{|\pi|, |z_1|, \ldots, |z_d|\}$. The canonical generic section of $\mathcal{O}(F)$ has that norm. Since $H = A \otimes \mathcal{O}(F)$, the ratio of the metrics gives (I.2.21). Away from the tube $\{\operatorname{red}_{\mathcal{X}}(x) = P\}$ the centre ideal is generated by a unit of norm one, so the metrics agree there. At ξ_0 one of the displayed coordinate norms is one; at ξ_F they all equal $|\pi|$. This proves the two values and the integral. Finally, compatible generic sections of H and A have model divisors differing by F. Additivity of the stated supported interface gives $\lambda \deg(c_1(A|_F)^d[F]) = \lambda$, with the asserted positive sign. □

Let R be a DVR, $S = \operatorname{Spec} R$, η its generic point, and k its residue field. For analytic assertions assume that R is the valuation ring of a complete nontrivially discretely valued field K with its fixed absolute value. Use the dimension function $\delta(\eta) = 1$, $\delta(s) = 0$ at the closed point. On a finite-type S-scheme, dimensions below are δ-dimensions. In particular, a horizontal integral model of relative dimension d has dimension $d + 1$, and a vertical integral k-scheme has its usual dimension. For a closed subset T of a finite-type S-scheme $\mathcal{X}$ set

$$C_r(\mathcal{X}; T) = \mathrm{CH}_r(T_{\mathrm{red}}).$$

Rational equivalences use integral subschemes *inside* T. This group is not defined as the image in $\mathrm{CH}_r(\mathcal{X})$. Reduction identifies Chow groups: integral subschemes, their rational functions, and their divisor relations are unchanged. This observation does not replace the fundamental cycle of a nonreduced scheme by that of its reduction; its generic lengths remain coefficients of the cycle. We freely use a scheme-theoretic intersection to construct a cycle and the canonical reduction identification to place its class in the group on its closed support.

Use the existing supported Gysin operation $G_{(\mathcal{L},s),T} : C_r(\mathcal{X}; T) \to C_{r-1}(\mathcal{X}; T \cap |Z(s)|)$ for an invertible sheaf $\mathcal{L}$ and any global section s, including the zero section or a zero-divisor. Use the selected signed presentations, with their signed operation defined by (C.1.50). For proper integral W/k, the mixed degree $\delta(W; M_1, \dots, M_d)$ is the degree of $c_1(M_1) \cdots c_1(M_d) \cap [W]$ as in the selected algebraic component-degree formula. Now let K be complete and nontrivially discretely valued with ring R, and put $\lambda = -\log|\pi| > 0$. Let $\mathcal{X}$ be an integral normal proper flat model of relative dimension $d \geq 2$. For $0 \leq i \leq d$, let $\mathcal{L}_i$ extend $L_i^{\otimes e_i}$, $e_i \geq 1$, and let $\sigma_i = s_i^{\otimes e_i}$ be a nonzero rational model section. Specify signed presentations on closed supports Z_i satisfying

$$\bigcap_{i=0}^{d} Z_i \cap X = \varnothing, \qquad X = \mathcal{X}_K. \tag{I.2.22}$$

Write I_i for the supported operations, $E = \prod_{i=0}^{d} e_i$, and $T = \bigcap_i Z_i$. Define

$$J_{\mathcal{X}} = \frac{\lambda}{E} \deg_k\big(I_0 \cdots I_d[\mathcal{X}]\big), \qquad I_0 \cdots I_d[\mathcal{X}] \in \mathrm{CH}_0(T_{\mathrm{red}}). \tag{I.2.23}$$

The value is defined on this model data. This construction also applies to the horizontal integral cycles occurring below, using the remaining pulled-back factor presentations, even when a factor vanishes identically.

Theorem I.2.10 (Refined operations on every prescribed support)**.** *The maps $G_{(\mathcal{L},s),T}$ are well-defined on Chow groups and satisfy all the following assertions.*

1. *For an integral $W \subset T$, if $s|_W$ is nonzero, the result is the divisor cycle of $s|_W$, with its actual local lengths. If $s|_W = 0$, it is the image of $c_1(\mathcal{L}|_W) \cap [W]$ in the stated target, not an instruction to discard W.*
2. *Let $p : \mathcal{Y} \to \mathcal{X}$ be proper, let $T' \subset \mathcal{Y}$ and $T \subset \mathcal{X}$ be closed with $p(T') \subset T$, and pull back the actual line and section. Then*

$$p_* G_{(p^*\mathcal{L},p^*s),T'}(\alpha) = G_{(\mathcal{L},s),T}(p_*\alpha) \quad \text{in } C_{r-1}(\mathcal{X}; T \cap |D|). \tag{I.2.24}$$

   This includes naturality under enlargement of the prescribed support.
3. *Two such operations commute in the group on $T \cap |Z(s)| \cap |Z(t)|$. No proper-intersection hypothesis is needed.*
4. *For $(\mathcal{M}, t)$ a second pair, set $B = |Z(s)| \cup |Z(t)|$. After pushing the three targets into $T \cap B$,*

$$G_{(\mathcal{L}\otimes\mathcal{M},s\otimes t),T} = G_{(\mathcal{L},s),T} + G_{(\mathcal{M},t),T}. \tag{I.2.25}$$

   After pushing into T, the operation is $c_1(\mathcal{L}|_T) \cap -$. If a coherent $\mathcal{F}$ on $\mathcal{X}$ is supported in T, has $\dim_\delta \operatorname{Supp}(\mathcal{F}) \le r$, and $s : \mathcal{F} \otimes \mathcal{L}^{-1} \to \mathcal{F}$ is injective, then

$$G_{(\mathcal{L},s),T}[\mathcal{F}]_r = [\mathcal{F}/s(\mathcal{F} \otimes \mathcal{L}^{-1})]_{r-1} \quad \text{in } C_{r-1}(\mathcal{X}; T \cap |D|).$$

   All generic and quotient lengths are retained.

Proof. The definition gives (1), and Stacks, Tag 02TO proves descent through rational equivalence. Apply Stacks, Tag 02TA to the proper map $T'_{\mathrm{red}} \to T_{\mathrm{red}}$ and the restricted line and section. Its target is the zero scheme of the restricted section on T, so its pushforward identity is exactly (I.2.24) after reduction. Applying this also to closed immersions proves the support-enlargement statement. It does not pass through the image of $\mathrm{CH}(T)$ in the ambient Chow group.

For clarity, the proper-pushforward calculation retains the factor $[K(W') : K(p(W'))]$ when dimensions agree. If an integral W' is contracted, choose a rational section of the relevant line on its integral image W. Its pullback divisor is supported over a proper closed subset of W. Every component then

has image dimension less than $\dim_\delta W' - 1$, and its cycle pushforward is zero. This also handles the contained-component Chern term by its divisor representative. Thus dimension-decreasing images do not create an unrecorded coefficient.

Apply Stacks, Tag 0B73 on T_{red}. The rational equivalence in its proof lies on the intersection of both zero schemes; in particular its target is precisely the support in (3). Reduction and the naturality just proved identify the successive targets used here with those of that lemma.

To prove (4), work on an integral cycle $[W]$. If neither restricted section is zero, divisors of their tensor product add as cycles. Locally this is $\operatorname{ord}(fg) = \operatorname{ord}(f) + \operatorname{ord}(g)$; at a one-dimensional local domain one can see the length equality from $0 \to A/(f) \xrightarrow{g} A/(fg) \to A/(g) \to 0$. If one or both sections vanish identically on W, then $W \subset B$. The product contributes $c_1((\mathcal{L} \otimes \mathcal{M})|_W)[W]$; each nonzero restricted section represents its own first Chern class on W. Additivity of that class, Stacks, Tag 02SP, proves equality already in $\mathrm{CH}(W)$, and hence in the required target. Linearity proves (I.2.25). Finally Stacks, Tag 02T9 identifies the push into T with the first Chern operation, and the coherent assertion uses the actual annihilator scheme $Z = V(\operatorname{Ann} \mathcal{F})$, with $|Z| \subset T$. Keep the full coherent module on Z. Tensor the asserted injection with the invertible line so that Stacks, Tag 02TB(2), with $k = r - 1$, applies to the actual module and its restriction to the zero scheme. This restriction is exactly $\mathcal{F}/s(\mathcal{F} \otimes \mathcal{L}^{-1})$. The closed inclusion $Z_{\mathrm{red}} \to Z$ and its base-changed zero scheme give the canonical identifications of the Chow groups: the cycle and rational-function generators are unchanged. Apply Stacks, Tag 02TA to these inclusions and then apply Stacks, Tag 02TA to the proper closed map $Z_{\mathrm{red}} \to T_{\mathrm{red}}$ with its actual zero support. The coherent cycles are computed on the full modules before these reduction identifications, so all lengths are retained. Injectivity remains essential. □

Theorem I.2.11 (The missing component-degree projection identity)**.** *Let $q : W \to V$ be a proper morphism of proper integral k-schemes, with $\dim W = d$ and $\dim V \le d$, and let $M_1, \dots, M_d$ be invertible sheaves on V. If $\dim q(W) < d$, then*

$$\delta(W; q^*M_1, \dots, q^*M_d) = 0.$$

If q is dominant and $\dim V = d$, then

$$\delta(W; q^*M_1, \dots, q^*M_d) = [k(W) : k(V)]\delta(V; M_1, \dots, M_d). \tag{I.2.26}$$

In particular, let $p : \mathcal{Y} \to \mathcal{X}$ be a supplied proper map of integral normal proper flat DVR models, inducing the identity on the generic fibre, and an isomorphism over an open containing every height-one point of $\mathcal{X}$. For arbitrary model lines $\mathcal{L}_i$, each strict-transform special component retains its mixed degree and each exceptional special component has mixed degree zero. The finite model measures with masses $b_V \delta_V / \prod_i e_i$, where $b_V = \mathrm{ord}_V(\pi)$, are consequently equal on every continuous test and every Borel test finite on their finite support. The conclusion concerns these supplied pullback models.

Proof. Use the global pairs $(M_i, 0)$ on V. Their Gysin operations are exactly $c_1(M_i)$, since their zero schemes are all of V. Iterating (C.1.48) gives

$$q_*\big(c_1(q^*M_1)\cdots c_1(q^*M_d)\cap[W]\big) = c_1(M_1)\cdots c_1(M_d)\cap q_*[W].$$

In the contracted case $q_*[W] = 0$. In the dominant equal-dimensional case it is $[k(W) : k(V)][V]$, with the full field degree. Proper pushforward preserves degree over k, proving both formulas.

For the models, the supplied open identifies the ordinary DVRs at a special component and its unique strict transform. The proper map between these integral special components has degree one. An exceptional component has image dimension less than d, so the two formulas give respectively the old mixed degree and zero. The identified DVRs have the same b_V and the same valuation point on the common generic analytic fibre. The additional exceptional terms have zero weight. Substitution in the specified finite atomic measure proves equality, and hence equality for all the stated tests. Neither existence of the map nor an analytic integral comparison enters this argument. □

Theorem I.2.12 (Supported projection and horizontal–vertical induction)**.** *The value* (I.2.23) *is independent of the permitted signed presentations and symmetric in all $d+1$ inputs. Let $p : \mathcal{Y} \to \mathcal{X}$ be a supplied proper dominant map of integral proper flat models of the same relative dimension, and put $N = [K(\mathcal{Y}) : K(\mathcal{X})]$. With the actual pulled-back factor data and supports on $\mathcal{Y}$, one has*

$$J_{\mathcal{Y}} = N J_{\mathcal{X}}. \tag{I.2.27}$$

Normality of $\mathcal{Y}$ is not needed for this supported equality.

At the ordinary height-one DVRs of $\mathcal{X}$, write

$$\mathrm{div}_{\mathcal{L}_0}(\sigma_0) = \sum_{H \text{ horizontal}} a_H[H] + \sum_{V \text{ vertical}} a_V[V].$$

Let J_H be the construction (I.2.23) on H using the remaining d pulled-back presentations and denominator $\prod_{i=1}^{d} e_i$. Put $\delta_V = \delta(V; \mathcal{L}_1|_V, \dots, \mathcal{L}_d|_V)$. Then

$$J_{\mathcal{X}} = \frac{1}{e_0} \sum_H a_H J_H + \frac{\lambda}{e_0 \prod_{i=1}^{d} e_i} \sum_V a_V \delta_V. \tag{I.2.28}$$

Thus the horizontal coefficients are exactly those of $\operatorname{div}(s_0)$ on the generic fibre. For the root model metric and the specified finite model measure, the second summand is

$$\int -\log \|s_0\| \, d\mu, \qquad -\log \|s_0(\xi_V)\| = \frac{\lambda a_V}{e_0 b_V}, \qquad \mu = \sum_V \frac{b_V \delta_V}{\prod_{i=1}^{d} e_i} \delta_{\xi_V}. \tag{I.2.29}$$

It is a finite total-variation integral, regardless of signs of the mixed degrees. At fixed metrics, replacing any s_i by πs_i changes J by $+\lambda$ times the corresponding model-measure mass. Only (I.2.22) is required; no pairwise proper intersection or generic nonvanishing on every intermediate cycle is imposed.

Proof. The operations produce a zero-class on T after $d+1$ steps. Condition (I.2.22) makes T_{red} a proper k-scheme, so its degree is defined even if T has positive dimension. Presentation independence and commutation prove the first assertions. For the supplied proper map, repeated supported projection gives

$$p_*(I_{p^*0} \cdots I_{p^*d}[\mathcal{Y}]) = I_0 \cdots I_d p_*[\mathcal{Y}] = N I_0 \cdots I_d[\mathcal{X}].$$

The supports remain the displayed inverse images; degree compatibility proves (I.2.27). This proves a statement about a supplied map and compatible data, not existence of a common model.

Apply I_0 first. Each factor section in its signed presentation is nonzero on $\mathcal{X}$. Its Gysin image of $[\mathcal{X}]$ is therefore its divisor cycle, and subtraction gives the displayed cycle of σ_0 on Z_0. A positive coefficient at a height-one point is the length of the quotient by a local equation in the ordinary DVR; differences give the signed coefficient. Apply the remaining operators to each component, using proper compatibility for its closed immersion. On a horizontal H, the remaining generic supports have empty total intersection: $H \subset Z_0$ and (I.2.22) applies. This contribution is $(a_H/e_0)J_H$. The value J_H uses the restricted factor presentations, not a purported restriction of a rational section that vanishes identically on H.

On a vertical V, push the remaining supported intersection class into $\mathrm{CH}_0(V)$. The last assertion of Theorem C.1.101, its signed extension, and

proper compatibility show that the result is $c_1(\mathcal{L}_1|_V)\cdots c_1(\mathcal{L}_d|_V)[V]$. This push stays inside the proper vertical scheme V, so it preserves the relevant degree. It gives $a_V\delta_V$ and proves (I.2.28). Localization at π identifies the horizontal DVR with its generic-fibre DVR. Since $\sigma_0 = s_0^{e_0}$, its horizontal coefficient is e_0 times the coefficient of $\operatorname{div}(s_0)$.

For (I.2.29), the point ξ_V has norm $|f(\xi_V)| = |\pi|^{\operatorname{ord}_V(f)/b_V}$ and generic scheme support. A model frame gives the stated root norm. Multiplying its negative logarithm by the mass cancels b_V, giving exactly the vertical summand of (I.2.28). All these finitely many values are finite; the zero/pole locus is null for the finite atomic measure. This proves the integral assertion by a finite sum, without a limit.

Finally $s_i \mapsto \pi s_i$ changes the model divisor by $e_i \operatorname{div}(\pi)$ and may enlarge its support by the special fibre. Its first supported operation on $[\mathcal{X}]$ gives $e_i \sum_V b_V[V]$. Commutation and the same vertical calculation give

$$\Delta J = \frac{\lambda}{\prod_{j\neq i} e_j} \sum_V b_V \delta(V; (\mathcal{L}_j|_V)_{j\neq i}),$$

with positive sign. This is the stated model mass; identifying it with a generic-fibre degree would require the separate specialization result. □
